Organized by

Technology Collaboration Programme on Heat Pumping Technologies by International Energy Agency

Co-organized by

The Society of Air-conditioning & Refrigerating Engineers of Korea

Korea National Committee of IIR

Sponsored by

LG Electronics, SAMSUNG, KRAAC, G·ENONE Energy, Carrier 캐리어에어컨, H&C SYSTEM, INTERTECH, KHPA 히트펌프얼라이언스 Korea Heat Pump Alliance, PEB, SWEP, 3S, BOOSTER CO., LTD., KOREA TOURISM ORGANIZATION, Jeju CVB Jeju Convention & Visitors Bureau 제주컨벤션뷰로, KOFST Korean Federation of Science & Technology Societies

MULTI V 5

LG Business Solutions

DESIGNED FOR THE ULTIMATE

CONTINUOUS HEATING

ENHANCED CONTINUOUS HEATING

with Delayed Defrost, Partial Defrost and Smart Oil Management

Delayed Defrost via Dual Sensing Control

By controlling the evaporation temperature considering the humidity, heating operation time is improved.

Partial Defrost

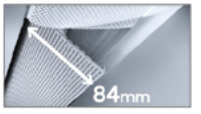
It partially defrosts lower, upper and lower parts of the heat exchanger in order to provide consistent heating for increased heating capacity.

Smart Oil Management

Oil sensor of the Ultimate Inverter Compressor offers enhanced heating operation without periodic oil recovery operation.

SAMSUNG

Free of Wind, Full of Cool



15,700 micro holes keep your space cool without direct wind

Wind-Free™ Cooling

15,700 micro holes allow comfortable cooling without cold drafts.

Big Blades, Long Wind

84mm big blades at wide angles spread cool air farther and evenly.

Motion Detection Sensor

Auto adjusts to optimal modes by detecting movement for energy efficiency.

Carrier 캐리어에어컨

AUTECH GROUP

'2018 아시아-태평양 지역
고성장 1000대 기업'
(영국 파이낸셜 타임즈 선정)

전 세계의 선택!
시스템 에어컨도 캐리어입니다

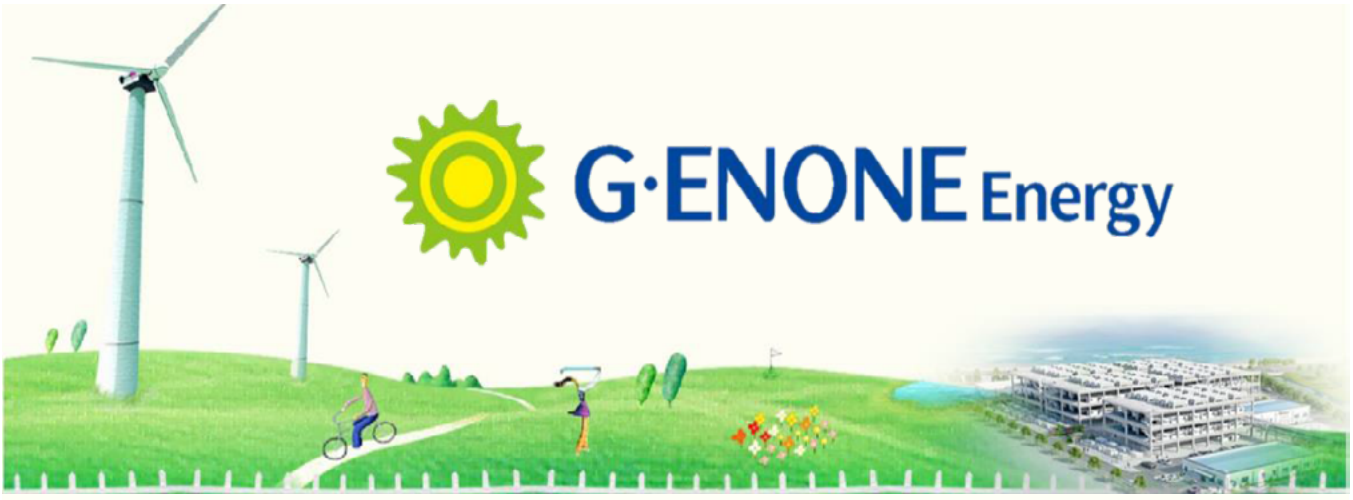
세계최고 빌딩 공조 시스템 전문 기업

다양한 실내기 연결 / 에너지 비용 절감 / 강력 냉난방
책임 A/S 시스템 / 호텔, 사무실, 쇼핑몰, 병원에 최적화

인버터 히트펌프 냉동기
USX Edge 칠러

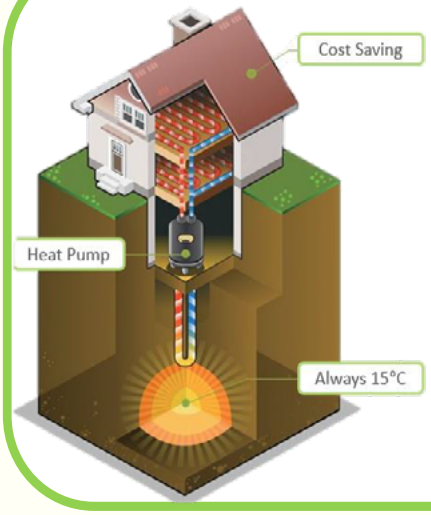
- 한냉지형 실외온도 -15℃에서도 온수 50℃ 출수 가능
- 인버터 펌프 내장 가능

최고의 상업용 멀티에어컨
SMMS-e 시리즈



- 강화된 한냉지 난방 (-25℃ 난방 가능)
- 새로운 DC 트윈 로터리 압축기
- 다양한 실내기 연결 (최대 64대)
- 최대 조합 50HP

빌딩 최적 냉난방 멀티에어컨
V6 시리즈



- 32HP의 단일 모델 최대 용량
- 고효율 EVI 인버터 스크롤 압축기
- 강화된 한냉지 난방 (-25℃ 난방 가능)
- 호텔, 사무실, 쇼핑몰, 병원에 최적화

에어컨 전문점 개설문의 전국 주요 지역 / 에어컨, 냉난방 공조기기 분야 종사자 및 판매 유 경험자 / 02-3441-8902, 2572 **본사판매원 모집 문의** 02-3416-4801

Geothermal Heating & Cooling System

01 Outstanding Economics
- Minimize energy cost → cost reduction
- Semi-permanent life of major parts (geo-heat exchanger 50 years, heat pump at least 20 years)

02 Geothermal Heating and Cooling System Using Heat Pump
- Next-generation air conditioning system in combination of boiler + air conditioner
- Minimize the area of the machine room to use efficiently

03 Stable Energy Source
- The temperature 200 m underground is consistently at an annual average of 15°C.
- Eco-friendly energy that can be used continuously

04 Safety and Eco-Friendly
- No risk of explosion or fire
- No problems of exhaust gas, pollutant emission or groundwater pollution

WELCOME MESSAGE

Welcome,

The IEA Technology Collaboration Programme on Heat Pumping Technologies (HPT TCP) operates under the International Energy Agency, as a non-profit organization where member-country participants cooperate in projects in the field of heat pumps and related heat pumping technologies such as air conditioning and refrigeration. Under the management of an Executive Committee representing the member countries, the program carries out a strategy to accelerate heat pump use in all applications where they can reduce energy consumption for the benefit of the environment.

This event is the world's premier event where industry and research experts go to discuss the latest advancements in the field of heat pumps. Focused primarily on technical applications, the event provides a side opportunity for dialogue and the establishment of business and research partnerships.

The Heat Pump Conference is also a key event for policymakers, executives and representatives from industry, utilities and the public sector, R&D managers and technology supporters, energy managers, planners, consultants, etc. This is the place to be for all those who wish to learn about the market trends and the future applications of heat pumps.

The 13th IEA Heat Pump Conference will take place on April 26-29, 2021, a year later than originally scheduled. Due to the corona virus outbreak, the conference is held as online-offline hybrid. The offline conference is held at Ramada Plaza Hotel Jeju in Korea, and the online conference is held along with offline for those who cannot attend the conference physically.

This conference is the perfect forum to learn from and communicate with industry and research experts from all over the world. In spite of the COVID-19, more than 200 high quality papers are ready to be presented. As Chairman of the National Organizing Committee (NOC), it is my pleasure to extend an invitation to showcase your technologies and products as a sponsor.

The Jeju conference will be the 13th in a series of triennial conferences. Previous conferences were held in, Graz, Austria (1984), Orlando, Florida, USA (1987), Tokyo, Japan (1990), Maastricht, the Netherlands (1993), Toronto, Canada (1996), Berlin, Germany (1999), Beijing, China (2002), Las Vegas, USA (2005), Zurich, Switzerland (2008), Tokyo, Japan (2011), Montreal, Canada (2014) and Rotterdam, Netherland (2017).

Although the conference has changed several times, we appreciate your patience, understanding and strong support of the HPC 2020. We hope you stay safe and healthy, and we are looking forward to seeing you at the conference!

Min Soo Kim

Chair
National Organizing Committee of HPC 2020

IEA HPT TCP

Technology Collaboration Programme on Heat Pumping Technologies by International Energy Agency

Every three years the IEA Technology Collaboration Programme on Heat Pumping Technologies, (IEA HPT TCP) stages the IEA Heat Pump Conference. We are members of IEA International Energy Agency (IEA) and the programme was founded in 1978. We have been active in more than 40 years, which is a strength since a lot of knowledge and experiences has been generated during the years.

Only a country's government can participate in a TCP (Technology Collaboration Programme), not separate organisations. This means that all people living in a member country are participants of the programme. We have 16 members in HPT TCP. The current member countries are Austria, Belgium, Canada, Denmark, Finland, France, Italy, Germany, Japan, the Netherlands, Norway, South Korea, Sweden, Switzerland, United Kingdom and the United States.

The HPT TCP is a non-profit organization working in the field of heat pumping technologies, i.e. all technologies where heat is pumped from a lower temperature level to a higher one, such as heat pumps, air conditioning and refrigeration. Under the management of an Executive Committee representing the member countries, the programme carries out a strategy to accelerate the use of heat pumping technologies in all applications where they can reduce energy consumption and increase the use of renewal energy sources for the benefit of the environment.

Chair for HPT TCP is **Mr. Stephan Renz (Switzerland).**

▶ Read more about IEA HPT TCP at our website (http://www.heatpumpingtechnologies.org)

DISCLAIMER

The HPT TCP is part of a network of autonomous collaborative partnerships focused on a wide range of energy technologies known as Technology Collaboration Programmes or TCPs. The TCPs are organized under the auspices of the International Energy Agency (IEA), but the TCPs are functionally and legally autonomous. Views, findings and publications of the HPT TCP do not necessarily represent the views or policies of the IEA Secretariat or its individual member countries.

INTRODUCTION

About the Conference

Energy and the environment – two topics that are always of great concern to human beings. Heating and cooling play a great role in our daily life, we use a tremendous amount of fossil fuels for heating and cooling. When changing temperature levels using substantial energy input, a heat pump is always recommended as promising technologies against climate change.

With this in mind, the 13th IEA Heat Pump Conference will be held in Jeju Island from Monday, April 26st through Thursday, April 29th in 2021. With the theme 'Heat Pumps – Mission for the Green World', we aim to address global climate change and discuss necessary actions.

Considering the varied applications of heat pump systems in the residential, building and industrial fields, this major conference with hundreds of participants will definitely broaden the horizons of our heat pump community. The theme, "Heat Pumps – Mission for the Green World", will make all the researchers proud that we really are creating a Green World together through research and development for a better future.

Conference Goal

Heat pumps, as a reliable and confirmed technology, is the key equipment for energy savings and greenhouse gas reductions with its wide range of application to various energy sources. The upcoming conference will serve as a forum to discuss the latest technologies in heat pumps, and exchange valuable knowledge in market, policy, and standards information on related technologies.

Conference Structure

- Keynote and Plenary lectures by renowned researchers
- Oral and poster presentations on innovative heat pump technology, applications and markets
- Workshops on collaborative projects, connected to annexes in the HPT TCP
- Global Student Video Competition

Previous Conferences

The upcoming conference will be 13th of the series of conferences held by Technology Collaboration Programme on Heat Pumping Technologies by International Energy Agency, (IEA HPT TCP). Preceding conferences were held in Austria (1984), USA (1987, 2005), Japan (1990, 2011), The Netherlands (1993, 2017), Canada (1996, 2014), Germany (1999), China (2002), and Switzerland (2008). After successful histories in Japan and China, it is the fourth Heat Pump Conference to be held in Asia, and the first to be held in the Republic of Korea.

ORGANIZATION

The conference is organized by the International Organizing Committee (IOC) and the National Organizing Committee (NOC) on behalf of the Executive Committee of the IEA HPT TCP.

International Organizing Committee (IOC)

Chair

- Per Jonasson: Swedish Refrigeration & Heat Pump Association, Sweden

Vice-chair

- Sophie Hosatte: CanmetENERGY, Canada
- Hideaki Maeyama: HPTCJ (Heat Pump and Thermal Storage Technology Centre of Japan)

National Organizing Committee (NOC)

Chair

- Min Soo Kim: Seoul National University, South Korea

Vice-chair

- Yong Tae Kang: Korea University, South Korea

Members

- Jae Dong Chung: Sejong University, South Korea
- Young Soo Chang: Kookmin University, South Korea
- Taesung Kim: Sungkyunkwan University, South Korea
- Seong Hyuk Lee: Chung-Ang University, South Korea
- Jun Young Choi: Korea Testing Laboratory, South Korea
- Ji Hwan Jeong: Pusan National University, South Korea
- Jeongsik Seo: Korean Refrigeration and Air Conditioning Assessment Center, South Korea
- Dong Kyu Kim: Chung-Ang University, South Korea
- Youn Cheol Park: Jeju National University, South Korea

Secretary General

- Minsung Kim: Chung-Ang University, South Korea

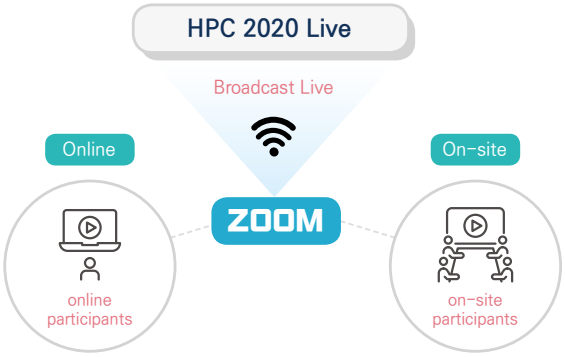
HOW IT WORKS

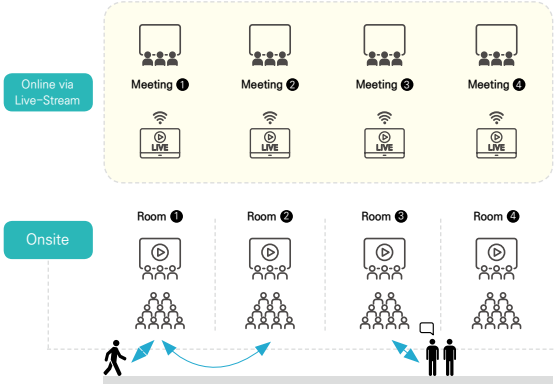
For the online participants, online conference platform will be provided. The conference program will be a generous online platform, which will give attendees the possibility to take part of the presentations over an extended amount of time. Register now and you will have the opportunity to take part of all the highlights of the 13th IEA Heat Pump Conference between the 18th of April until the 1st of May – on-demand when it suites you.

The Conference will be organized to offer as much value as possible to "offline" (physical) as well as online attendees. The presentations will be pre-recorded, broadcasted online and shown at the conference venue in accordance with the conference program. However, in order to make it possible for the conference attendees to select and take part in as many presentations as possible, it is recommended to watch the pre-recorded presentations on-demand before the conference start. The whole online conference plan in accordance with the scheme is shown in below.



When it comes to questions & answers, there will be two separate schemes for the attendees as well as for the authors. It will be possible for the conference attendees to pose their questions online during the whole pre-conference as well during the conference period. The author is responsible for answering the questions until 1st of May at the latest. During the offline program slot for the presentation, the authors will be encouraged to attend online via Zoom, or physically at the venue, to be able to answer questions from the audience live.

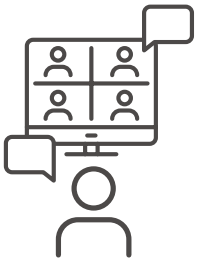
HYBRID OPERATIONS OVERVIEW



The HPC 2020 Hybrid Model

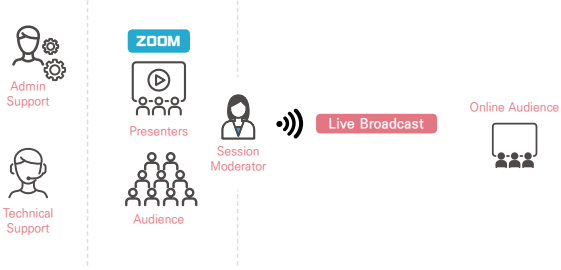
Onsite-online hybrid model ensures effective interaction between online participants (participants that are not at the venue) and onsite participants (participants that can attend the venue).

Onsite & Online Operations



Each room in the conference venue will be equipped with a screen and a microphone, so that participants can join a zoom meeting together and connect with other participants. Whether onsite or online, attendees can freely change room, depending on what presentations are of the most interest. All sessions will be broadcast (live-streamed) to the website on HPC 2020.

Onsite & Online Communication



Onsite and Online participants will be able to engage with each other via the Zoom chat interface, leaving questions and comments during pre-conference period on the HPC 2020 website, which the session moderator can navigate through.

Also, The presenters are responsible for answering the questions at the website until 1st of May at the latest.

Room Overview and Roles Involved

Each presentation session will involve the following support roles: Session Chair– moderates the panel; Admin support – hosts the zoom meeting; Technical support – prevents onsite technical issues. (Admin staff and Session Chair do not have to be onsite.)

DETAILED FORMATS FOR ALL PRESENTATIONS

Category		Operation	
		Offline	Online
Plenary	Presentation Video	Pre-recorded presentation must be submitted via website in advance.	
	Q&A	Speakers will participate in real time online or communicate with the participants via chat window of virtual conference platform.	
	Participation	Considering being broadcast on ZOOM, arrive at session room 15 minutes prior to session.	
Keynote /Oral	Presentation Video	Pre-recorded presentation must be submitted via website by Mar. 5, 2021.	
	Q&A	Speakers must participate in real time in the session room.	Speakers must decide whether to participate in live Q&A while submitting their video on website. (Please consider the time difference.)
		All speakers even if who participated in live Q&A is responsible for answering the questions at the website until 1st of May at the latest.	
	Participation	Considering being broadcast on ZOOM, arrive at session room 15 minutes prior to session.	
Poster	Presentation Video	Pre-recorded presentation must be submitted via website by Mar. 5, 2021.	
	Poster File	Submit the poster file via website in advance for online availability by Mar. 5, 2021.	
	Poster Size	A0 (Width 84cm × Height 118cm)	
	Posting	Presenters should put up the poster on your own at the designated place.	The secretariat will print it out and attach it to the assigned spot.
	Q&A	All speakers are responsible for answering the questions at the website until 1st of May at the latest.	
	Participation	Under the social distance policy, direct face-to-face presentation of posters will be omitted.	-
Participants		All participants are able to watch presentation videos or leave questions and comments on the website during Pre-conference (April 18, 2021) to Post-conference (May 1, 2021.) period.	
		Participate in the session room. - If access to the session hall is difficult due to restricted number of people, participate through ZOOM.	Participate in real time through ZOOM.

Time allocation

- **Plenary Lectures** : 25min. (20 min. speech + 5 min. Q&A)
- **Keynote lectures** : 20 min. (15 min. speech + 5 min. Q&A)
- **Oral presentations** : 15 min. (12 min. speech + 3 min. Q&A)
- **Poster presentations** : 5 min. (5 min. speech)

GENERAL INFORMATION

Time Zone

The live stream schedule is based on Korea Standard Time (KST / UTC +9).

Program at a Glance also included Eastern Daylight Time (EDT / UTC-4) and Central European Summer Time (CEST / UTC+2) for international participants.

Participants Precautions

Offline Participants

- All participants are required to have their temperature checked.
- Entry is restricted in case of fever (37.5 °C or higher) and respiratory symptoms (cough, sore throat, etc.).
- Keep a 1-meter distance from each other in the session room. (Photo will be taken in order to keep the room setting.)
- Masks must be worn in all spaces.
- Wash hands often and use hand sanitizer provided.
- Due to social distance policy, it could be difficult to enter the session room if the session room is crowded.

Online Participants

- We recommend you check the network before the session.
- If your security system settings prevent you from accessing through PC, watch it on your mobile device.
- Viewing will be restricted when two or more people enter with the same ID.
- Only one device (PC or mobile) can enter.
- Avoid simultaneous access.
- Use of Chrome/ Safari/ Edge/ Firefox browser is recommended.
- Using Internet Explorer may restrict viewing or access.

Hybrid Conference Platform

- https://www.hpc2020.org
- ID/PW are the same as the HPC 2020 Website.
- It is highly recommended you use only Chrome, Safari, or Firefox to access the platform.
- The platform will be open from April 19, 2021 to May 1, 2021.

Full Papers

- After logging into the Hybrid Conference Platform, you can view the full papers of HPC 2020 by clicking the 'Proceedings' button at the top of the main page or clicking the 'Paper' button next to each presentation video.

GENERAL INFORMATION

Opening Ceremony

Date/Venue	Tuesday, April 27, 2021, 09:00~09:20 (KST/UTC+9) | Room A (Tamna Hall, 8F)
Host	Taesung Kim (Sungkyunkwan University, South Korea)

- **Welcome Address** — Stephan Renz (IEA HPT TCP Chair, Switzerland)
- **Opening Remarks** — Min Soo Kim (President of Society of Air-conditioning and Refrigerating Engineers of Korea, NOC Chair)
- **Congratulatory Remarks** — Won Hee-ryong (Governor of Jeju Province, South Korea)

Closing Ceremony

Date/Venue	Thursday, April 29, 2021, 16:00~17:00 (KST) | Room A(Tamna Hall, 8F)
Host	Minsung Kim (Chung-Ang University, South Korea)

- **Opening Speech** — Per Jonasson (IOC Chair)
- **Award Ceremony** — Per Jonasson (IOC Chair)
  - Ritter von Rittinger Award
  - Global Student Video Competition
- **Conference Report & Closing Speech** — Minsung Kim (Secretary General)
- **The 14th IEA Heat Pump Conference (HPC 2023)** — Brian A. Fricke (Chair of U.S. National Organizing Committee)
- **Closing Remarks** — Minsung Kim (Secretary General)

Session Chair

- **Guideline**

※ **Important Notice**

· We recommend the session chairs to check the **network condition** before the session.
· Use a **high-speed network** for a stable connection to the meeting.
· Use a **headset** to minimize any noise issues.
· Please try to find a **quiet environment** and maintain the environment during a session.
· Please note that **photo taking and video recording are strictly prohibited.**
· Please visit the zoom help center to get more information : https://support.zoom.us/hc/en-us
· **For detailed instructions as follows, please refer to our website.**
- Initial Setup / Before Session / During Session / During Q&A/ After Session

- **List of Session Chairs and Schedule**

  * Time: The live stream schedule is based on Korea Standard Time (KST / UTC +9)

CONFERENCE INFORMATION

- **Registration**
- **For Offline Participants**
  - Conference Venue
  - Floor Plan
  - Wireless Internet
  - Lunch / Banquet / Coffee Break
- **Peter Ritter von Rittinger International Heat Pump Award**
- **Global Student Video Competition**

REGISTRATION

※ Offline registration is not accepted for the safety of participants in accordance with the COVID-19 quarantine policy.

※ Participants who have registered in advance should come to the 8th floor, Ramada Plaza Jeju Hotel to receive a name tag, Certificate of participation, program book, and a small gift from HPC 2020 NOC.

Registration Fee

- Considering the current COVID-19 pandemic situation, HPC 2020 will be held as a hybrid event; a combination of "live" face to face event and a "virtual" online component.
- HPC 2020 has decided to reduce registration fees to make the virtual conference widely accessible.

Category		Early Bird (~Jan. 31, 2021)	Regular (~Mar. 15, 2021)	Late (~Mar. 31, 2021)	Last Time (~April 29, 2021)
Offline	Regular	$700	$800	~~$900~~ $800	N/A
	Student	$350	$400	~~$450~~ $400	N/A
Online	Regular	$350	$400	~~$600~~ $400	~~$600~~ $400
	Student	$175	$200	~~$300~~ $200	~~$300~~ $200

※ If you would like to change from offline to online participation, please contact secretariat at secretariat@hpc2020.org no later than April 1, 2021.

Offline Conference Registration

Domestic attendees are recommended to registration for the offline conference. Full registration includes access to all sessions, lunches, banquet, and break refreshments.

Online Conference Registration

International attendees who are not able to come to the conference will give their presentation by the video clip. The registrants can access all the sessions through the online portal.

Requirement of Paper Presentation

- In principle, at least one of the authors must register by January 30, 2021 in order for their papers to be included in the program of HPC 2020
- For authors presenting multiple papers, one registration is valid for rest presentations.

Cancellation and Refund Policy

Before applying for cancellation, please refer to the following policy

Date of Cancellation	Amount to be Refunded
Cancellation before February 28, 2021	Refundable but 75%
Cancellation between March 1 and March 30, 2021	Refundable but 50%
Cancellation after April 1, 2021	Non-refundable

- Note that for administrative reasons, refund will be made after the conference.
- All bank service charges will be deducted from the refunded amount.
- Any phone application will not be accepted, a request letter by email(secretariat@hpc2020.org) is required.

FOR OFFLINE PARTICIPANTS

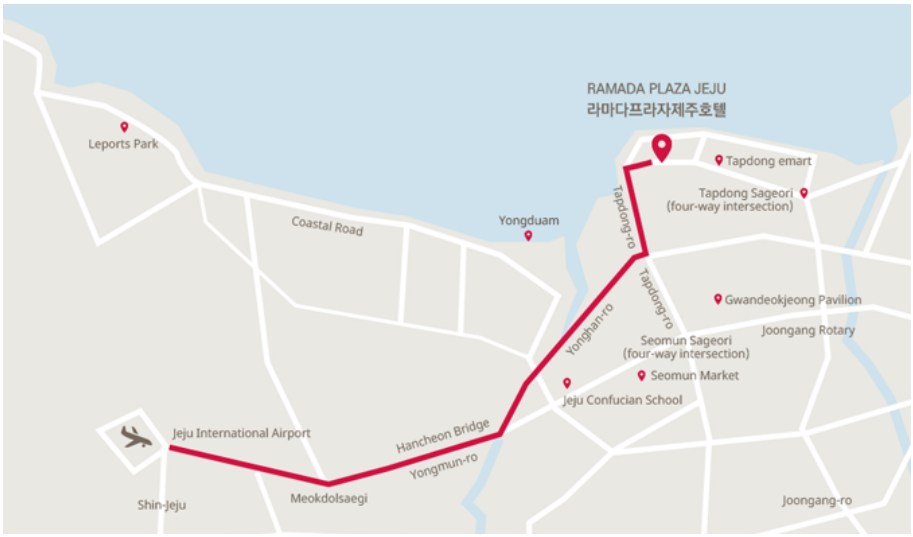
Conference Venue

About Jeju

Jeju Island is the largest volcanic island in Korea and it has a mild oceanic climate throughout the year with the smallest annual temperature range in South Korea. Officially called Jeju Special Self-Governing Province, this best tourist destination boasts mild weather, as well as scenic beauties of beaches, waterfalls, cliffs and caves. The island is 73km wide and 31km long with a total area of 1,848.85km2. Jeju is the largest island in South Korea.

Mt. Halla rises in the center of Jeju to 1950m above sea level. The rest of the island slopes down from its summit and is covered with dark gray volcanic rocks and volcanic ash soil. Seongsan Ilchulbong Peak with breathtaking views is also one of the most scenic areas, and Manjanggul Cave, the world's longest lava tube has been registered as a UNESCO World Natural Heritage. Meanwhile, Jeju has recently won the Global Geopark certificate, and also has been selected as the New 7 Wonders of Nature.

Ramada Plaza Hotel Jeju

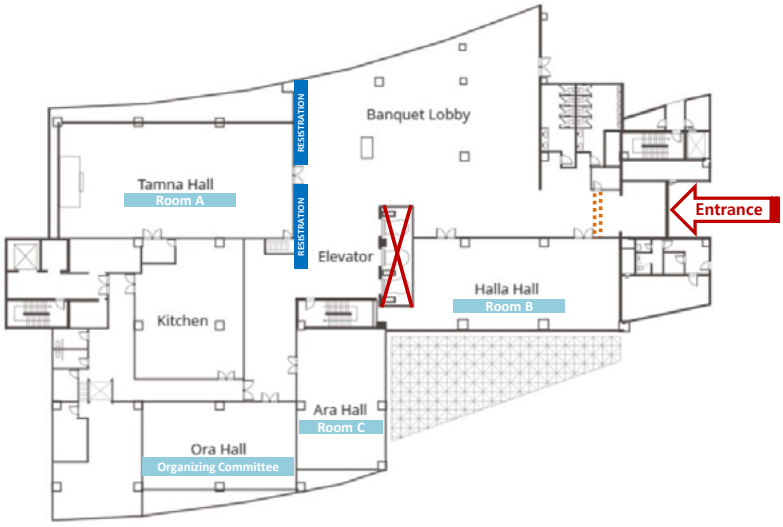


Located near the beautiful ocean at the center of Jeju city

The conference venue is 5 star hotel with 400 guest rooms and suites and a convention room with a meeting capacity of 1200 people. This country's first costal hotel built right on the ocean is located just five minutes away from Jeju International Airport and Jeju Port.

Transportation

The Hotel is located in 3.8 km away from Jeju International Airport. You can reach the hotel in ten minutes by taxi. No shuttle is provided. See the map below:



Duration	15 minutes
Fare	About 7,000 KRW(USD 6~7)

Ramada Plaza Jeju Hotel

- Address: 66 Topdong Ro, Jeju, 63165, Korea
- Tel: +82-64-729-8100

FLOOR PLAN

8th Floor,
Ramada Plaza Hotel Jeju

Lobby	• Body Temperature Measurement • Registration/Conference Kit • Poster Session	**Tamna Hall**	• Opening Ceremony • Plenary Sessions • Oral Presentation • Closing Ceremony
Halla Hall	• Oral Presentation	**Ora Hall**	• Organizing Committee (until noon on April 29,2021)
Ara Hall	• Oral Presentation		

Wireless Internet

Wireless internet is available for the participants at the conference venue. ID/PW will be informed on-site.

Lunch / Banquet / Coffee Break

Depending on the COVID-19 situation, Lunches, Banquet, and Coffee Breaks will be provided by applying the local Social Distancing Policy in Jeju at the time of the conference. The NOC is committed to the convenience of offline participants, and the secretariat will inform the details before the conference. We hope for your kind understanding on this matter.

HPC 2020 will do our best to ensure safety of our attendees

1. All participants' body temperature will be checked at the entrance.
2. Hand sanitizer will be provided.
3. All participants must wear a mask.
4. Keep a 1-meter distance from each other in the session room.
5. An attendee list will be made.

RITTER VON RITTINGER AWARD

Peter Ritter von Rittinger International Heat Pump Award

Trittingerhe Peter Ritter von Rittinger International Heat Pump Award is the highest international award in the air conditioning, heat pump and refrigeration field and was introduced at the Las Vegas Conference (8th IEA HP Conference). This award highlights outstanding contributions to the advancement of international collaboration in research, policy development and applications for energy-efficient heat pumping technologies. It is awarded every three years in conjunction with the International Heat Pump Conference.

The Rittinger award is named for Peter Ritter von Rittinger who is credited with the design and installation of the first energy-conserving heat pump system at a salt works in Upper Austria in 1855.

The winners of the Ritter von Rittinger Award 2020 will be announced at the online homepage and closing ceremony.

Previous Awardees

2017	Prof. Eckhard A Groll, Prof. Alberto Cavallini, ORNL Building Equipment Team, Prof. Per Lundqvist
2014	Mr. Frédy Burkhalter, Mr. Daniel Ellis, Dr. Andrew Pearson, Dr. Koichi Watanabe, Dr. Michel Bernier.
2011	Prof. Per-Erling Frivik, Prof. Hermann Halozan, Mr. John D. Ryan.
2008	Prof. Eric Granryd, Prof. Predrag S. Hrnjak, Mr Gerald C. Groff.
2005	Dr Bernard Spinner, Dr Katsuhiko Narita, Mr Nance C. Lovvorn, Research Team GEMINI, Mr. Wayne R. Reedy.

WORKSHOP - ONLINE ONLY

Monday, April 26, 2021

1. Workshop A1 (20:00~22:00 KST/13:00~15:00 CEST/07:00~09:00 EDT)

Title	Annex 42 (HPs in smart grids) and Annex 45 (Hybrid HPs)
Organizer	Peter Wagener (Business Development Holland, wagener@bdho.nl) Maarten Hommelberg (Business Development Holland, hommelberg@bdho.nl)
Theme	What role can hybrid HPs play in the energy transition and how can they contribute to smart grid success? • Introduction into hybrid HPs • The hybrid HP success story in the Netherlands • First results from a hybrid HP monitoring campaign • Hybrid HPs in a smart grid: great results from the Freedom Project (Wales, UK)
Speakers	Peter Wagener (BDH, Netherlands) Oliver Lancaster (Wales & West Utilities, Wales, UK)

2. Workshop A2 (22:00~24:00 KST/15:00~17:00 CEST/09:00~11:00 EDT)

Title	Heat Pumps for Low GWP Refrigerants (Annex 54)
Organizer	Yunho Hwang (University of Maryland, USA)
Theme	Annex 54 aims at promoting the low GWP refrigerant application to accelerate phase down of high GWP HFCs via 1) a comprehensive review of recent R&D progress on component optimization using low-GWP refrigerants, 2) in-depth case studies of component optimization, which can provide design guidelines and real-world experiences.
Program	• *"Introduction of IEA HPT's Annex 54 for Heat Pumps for Low-GWP refrigerants"* by Yunho Hwang (University of Maryland, USA) • *"Experimental evaluation of R410A, R407C and R134a alternative refrigerants in residential heat pumps"* by Pierre Pardo (CETIAT, France) • *"Modular and scalable heat pump models for the design process of heat pump systems"* by Christian Vering (RWTH Aachen University, Germany) • *"Commercialization of R32 in a Window Type Air Conditioner for US Market and Split Air Conditioners for European Market"* by Younghwan Ko (LGE Korea) • *"Comparitive analysis of propane heat pumps - a try to harmonize technical boundary conditions in world-wide projects"* by Thore Oltersdorf, Peter Schossig, Lena Schnabel (ISE Fraunhofer, Germany) • *"Lower GWP Refrigerants for Heap Pump Application"* by Samuel Yana Motta (Honeywell, USA)

3. Workshop B2 (22:00~24:00 KST/15:00~17:00 CEST/09:00~11:00 EDT)

Title	Annex 55 (combined with ECES Annex 34) on Heat Pumps and Storage
Organizer	Peter Wagener (Business Development Holland, wagener@bdho.nl) Maarten Hommelberg (Business Development Holland, hommelberg@bdho.nl)
Theme	Heat pumps and energy storage in smart grids - how can we achieve better results by better integration of HP and storage components? • Introduction to the goal and contents of the annex. • Present status and latest annex results • Recommendations for policy action
Speakers	Peter Wagener (BDH, Netherlands) Caroline Haglund-Stignor (RISE, Sweden) Liu Xiaobing (Oakridge National Laboratories, USA)

4. Workshop C1 (20:00~22:00 KST/13:00~15:00 CEST/07:00~09:00 EDT)

Title	Heat Pumps in Multi-Family Buildings for space heating and DHW (Annex 50)
Organizer	Marek Miara (Fraunhofer ISE, Germany)

Program

Time CEST	Speaker	Topic
13:00-13:20	Odile Cauret EDF – Research & Development	Presentation of the Multi-Family Buildings status in participating countries (results from the Task 1)
13:20-13:40	**Marek Miara** Fraunhofer ISE	Presentation of the "solution matrix" as the main outcome of the Annex 50. From general categorization of solutions to the case studies.
13:40-14:10	**Charles Geelen** Infinitus Energy Solutions Group, **Andreas Zottl** AIT Austrian Institute of Technology GmbH	Presentation of the "solution matrix" as the main outcome of the Annex 50. From general categorization of solutions to the case studies.
14:10-14:30	Nicole Calame CSD INGÉNIEURS SA	Presentation of the case studies, different types of building and dedicated solutions
14:30-14:50	**Marco Simonetti** Politecnico di Torino	New simulation approach – as simple as possible, as precise as required

5. Workshop C2 (22:00~24:00 KST/15:00~17:00 CEST/09:00~11:00 EDT)

Title	Design and integration of heat pumps for nZEB (Annex 49)
Organizer	Prof. Carsten Wemhöner (Professor for Building system technologies Institute partner IET –Institute of Energy Technology, OST – Eastern Switzerland Univ. of Appl. Sciences)
Theme	The workshop presents result of IEA HPT Annex 49 on heat pump application in nearly Zero energy buildings nZEB. Starting from the state of the art of nZEB results of heat pump monitoring in nZEB and simulation-based studies on design and control of heat pumps are presented. The workshop is concluded with developed multifunctional HP prototypes and lessons learned.
Program	**nZEB definition and ambition level** 15:00 – 15:10 Introduction and overview of IEA HPT Annex 49 (C. Wemhoener) 15:10 – 15:20 Swedish nZEB implementation and comparison of heating systems (O. Gustafsson) 15:20 – 15:35 Methodology to compare nZEB ambition level in different countries (F. Ochs) **Case studies and optimisation of heat pumps in nZEB by monitoring/simulation** 15:35 – 15:50 Group of eight buildings with low temperature heating grid (C. Betzold) 15:50 – 16:05 Vögelebichl Innsbruck – Monitoring and simulation of two multi-family houses with heat pump, PV and collectors (F. Ochs) 16:05 – 16:20 Monitoring of Energy plus buildings with different use (F. Bockelmann) **Prototype technologies and heat pump integration options** 16:20 – 16:35 Façade integrated PV-coupled heat pump system for space cooling (A. Heinz) 16:35 – 16:50 Integrated heat pump (IHP) prototypes for NZEB (V. Baxter) **Conclusions** 16:50 – 17:00 Lessons learned (C. Wemhoener)

6. Workshop D1 (20:00~22:00 KST/13:00~15:00 CEST/07:00~09:00 EDT)

Title	Comfort and Climate Box Solutions for warm and humid climates
Organizer	Heat Pump Centre, Oakridge National Laboratory (ORNL) and BDH (in the Netherlands)
Theme	The demand for comfort cooling is growing rapidly in many parts of the world, especially in emerging countries, and stated policies will not be able to curb electricity use for cooling, which is set to grow threefold by 2070 relative to 2019, according to IEA. There are great possibilities to increase the energy efficiency and the share of renewable electricity used for comfort cooling, by combining heat pumping technologies with energy storages and integrated control. The purpose of the workshop is to develop a proposal for a new international collaboration project (i.e. Annex) aiming at speed up deployment of such solutions, so called "Comfort and Climate Boxes" for warm and humid climates – solutions that are efficient, affordable, applicable and scalable.
Program	**Introduction to the theme and challenges - presentations** • General introduction – Monica Axell and Caroline Haglund Stignor, Heat Pump Centre • "Low Carbon and Energy Efficient Cooling in Warm and Humid Areas"– Chiara Delmastro, IEA • "Consumer awareness and use of energy efficient cooling applications in India" – Shika Bhasin, CEEW, India • "Low Carbon and Energy Efficient Cooling in Warm and Humid Areas" - Wang Sheng, GREE, China • "Challenges and opportunities to realize "Comfort and Climate Box solutions" in United States and Beyond" - Kashif Nawaz, ORNL, US **Workshop session** • Presentation of draft Objectives and Scope of a future annex, Kashif Nawaz, ORNL, US • Definition about tasks, means and deliverables from a future annex – group discussion **Summary and next steps**

7. Workshop D2 (22:00~24:00 KST/15:00~17:00 CEST/09:00~11:00 EDT)

Title	Large demonstration project for flexibility by heat pumps (Annex 57)
Organizer	Senior Consultant Svend Pedersen (Danish Technological Institute, Denmark)
Theme	Annex 57 aim is to focus on the implementation of heat pumps in district heating and cooling systems. The main focus areas are 1) the creation of possible flexibility in the thermal network and electrical grids. 2) the possibilities of increasing larger share of renewable energy and excess heat as well as to reduce the CO2 emissions in the heating systems by using heat pumps.
Program	• "Introduction of IEA HPT's Annex 57 Flexibility by implementation of heat pump in multi-vector energy systems and thermal networks" by Svend Pedersen Danish Technological Institute • "Hybrid Energy Networks in a international and national perspective" by Peter Sorknäs Aalborg University • "Experiences from creation of flexibility with heat pumps in district heating grids" by Wibke Messenburg Danish technical University • "Potentials of flexible heat pump operation on a district scale" by Dr.-Ing. Young Jae Yu • Discussion

GLOBAL STUDENT VIDEO COMPETITION

We would like to invite all students who will join our conference to participate in the HPC 2020 Global Student Video Competition. This competition provides an excellent opportunity to create a video that will be awarded at the conference. It aims to exchange creative ideas and relevant knowledge on the topics such as heat pump application, environmental issues, energy, or what students do in the laboratory. The winners, as listed below, will be announced online on the HPC 2020 conference website.

Awards

- Gold Medal (Overall championships) : $300 Award and Certificate
- Silver Medal : $200 Award and Certificate
- Bronze Medal : $100 Award and Certificate

Important Dates

- **March 15, 2021** Open submission for participants
- **March 31, 2021** Closed Submission for participants
- **April 15, 2021** Video Submission deadline (secretariat@hpc2020.org)
- **April 18, 2021** Displayed on the conference homepage
- **April 28, 2021** Announcement of the winners online at the conference website and closing ceremony.

Recommended Categories

- Heat pump applications
- Environmental issues
- Energy
- Research activity in the laboratory
- Etc.

Submission

The competition is open for the students who have finished registration for the HPC 2020.
Students who wish to participate in this competition, please submit the form below through the link below by March 31, 2021.

- Format : Presentation files will be accepted in MP4
- Presentation Time : Less than 3 minutes
- Video Submission : secretariat@hpc2020.org by April 15, 2021.

PROGRAM INFORMATION

- Conference Topics
- Program at a Glance
- Session Timetable
  - Oral Session Tuesday, April 27, 2021
    Wednesday, April 28, 2021
    Thursday, April 29, 2021
  - Poster Session April 27-29, 2021
- Plenary Lectures
- Keynote Lectures
- Technical Program

CONFERENCE TOPICS

Within the conference program, participants will encounter numerous cutting-edge presentations on the following issues:

- Recent Advances on Heat Pumping Technologies
- Environment-friendly Technology
- Systems and Components
- Field Demonstration and Multi-disciplined Applications
- Research and Development
- Policy, Standards, and Market
- International Activities

PROGRAM AT A GLANCE

※ For detailed information about the workshop program on Monday, April 26, 2021, please refer to the page 29.

Date/Time			Mon. April 26	Tuesday, April 27			Wednesday, April 28			Thursday, April 29		
Session Room			Online Workshop	Room A	Room B	Room C	Room A	Room B	Room C	Room A	Room B	Room C
KST (UTC+9)	EDT (UTC-4)	CEST (UTC+2)										
08:30 ~ 09:00				Registration								
09:00 ~ 10:00	(Day -1) 20:00 ~21:00	02:00 ~ 03:00		Opening Ceremony 09:00~09:20 (KST)			Session 4 : 09:00~10:20 (KST)			Session 9 : 09:00~10:20 (KST)		
10:00 ~ 11:00	(Day -1) 21:00 ~22:00	03:00 ~ 04:00		Plenary Lecture 1 (Policy and market) 09:20~10:35 (KST)			Low GWP Refrigerants (3)	Ground Source and Storage	Sorption Heat Pumps (1)	Variable Refrigerant Flow Heat Pumps and Air-conditioners	Heat Exchangers (2)	Food Storage and Display
				Coffee Break and Poster Session 10:35~10:45 (KST)			Coffee Break and Poster Session 10:20~10:40 (KST)					
11:00 ~ 12:00	(Day -1) 22:00 ~23:00	04:00 ~ 05:00		Plenary Lecture 2 (Technology) 10.45~12:00 (KST)			Session 5 : 10:40~12:00 (KST)			Session 10 : 10:40~12:00 (KST)		
							Low GWP Refrigerants (4)	Market and Policy for Heat Pumps (2)	Electrochemical Related	Sorption Heat Pumps (3)	Dehumidifcation Technology	Heat Pump Performance
12:00 ~ 13:00	(Day -1) 23:00 ~24:00	05:00 ~ 06:00		Lunch and Poster Session 12:00~13:00 (KST)								
13:00 ~ 14:00	00:00 ~ 01:00	06:00 ~ 07:00		Session 1 : 13:00~14:20 (KST)			Session 6 : 13:00~14:20 (KST)			Session 11 : 13:00~14:20 (KST)

PLENARY LECTURES 1

Plenary Session 1-1 : Policy and market

- Date/Time : Tuesday, April 27, 2021, 09:20~09:45 (KST/UTC+9)
- Venue : Room A (Tamna Hall, 8F)
- Session Chair : Taesung Kim (Sungkyunkwan University, South Korea)

Heat Pumping Technologies in Clean Energy Transitions

Mechthild Wörsdörfer
IEA Director of Sustainability, Technology and Outlooks, France

Abstract

Heating and cooling in buildings account for almost 15% of total global energy-related CO2 emissions, or 5 gigatons per year. While nearly 60% of global buildings heat provision relies on direct fossil fuel combustion, heat pumps could already supply more than 90% of heat demand with a lower carbon footprint than any fossil alternative. The deployment of heat pumps in new, well-insulated buildings in many places such as the United States or Europe shows that the heat pump market is taking off. Yet, deployment is uneven across market segments. To meet the Paris Agreement, the IEA defined a 3-pillar action plan. First, achieving greater deployment rates across all applications (including in retrofits, district energy systems and industrial processes) would tap into early emissions reduction opportunities. Second, the integration of heat pumps with power systems is essential to ensure their scalability and operability with high shares of variable renewables in the electricity generation mix. Last, enhancing heat pumps is key so that they could become multi-service providers that can operate in a variety of climate contexts (such as hot and humid, cold or multi-seasonal climates) while taking advantage of next generation designs (such as refrigerant-free, evaporative or solid-state applications).

Biography

Heating Mechthild Wörsdörfer (@MWorsdorfer) joined the IEA on 1 October 2018 as Director of Sustainability, Technology and Outlooks (STO). Ms Wörsdörfer plans and co-ordinates the IEA's work on energy sustainability, encompassing clean energy technologies and climate change policy. Previously, Mechthild held several senior management positions in the European Commission, where she coordinated the work on the 2030 Energy and Climate Framework, the Clean Energy Package and the 2050 Energy Roadmap. She had been involved with the IEA for a number of years as IEA Governing Board Representative for the EU, and served in the Cabinet of Commissioners, in charge of industry, competitiveness, trade and digital economy.

PLENARY LECTURES 1

Plenary Session 1-2 : Policy and market

- Date/Time : Tuesday, April 27, 2021, 09:45~10:10 (KST/UTC+9)
- Venue : Room A (Tamna Hall, 8F)
- Session Chair : Taesung Kim (Sungkyunkwan University, South Korea)

The European Legal Framework is Well Set for a Massive Roll-out of Heat Pumps - but More Efforts are Needed!

Martin Forsén
President of European Heat Pump Association, Sweden

Abstract

The present European Commission has, since they entered office in 2019, significantly raised the ambition in policies related to energy and climate actions. The European green deal including a European renovation wave of buildings, circular economy action plan and a strategy for energy system integration are all essential parts of the plan to make Europe the first climate neutral continent by 2050. The aim of the renovation wave is to double the current rate of renovation. Renovations shall be implemented adhering to the energy efficiency first principle as well as the need to decarbonize while increasing the use of renewable energy sources. Electrification of the heating sector will play a central role and in particular by a wide introduction of heat pumps. The energy system integration strategy is expecting an increase of the share of electricity-based heating to double by 2030 and to reach 50-70% by 2050. The tremendous push for decarbonization and electrification will have considerable impact on the revision of existing regulations. This presentation will give an overview of the overarching targets, policies and ongoing revisions of existing regulations as well as the possibilities and challenges faced by the heat pump industry.

Biography

Martin received his Master of Science in mechanical engineering at the Royal Institute of Technology in Stockholm 1997. After a short time at the electric utility company Vattenfall he got back to the university as a researcher, where he stayed until he was hired as President of the Swedish Heat Pump Association 2003. After ten years at the association, Mr Forsén was recruited as Manager International Affairs for NIBE in 2013. Mr Forsén has for the last decade been an active member of the European Heat Pump Association. He has been a member of the board for several years and serves as President for the Association.

PLENARY LECTURES 1

Plenary Session 1-3 : Policy and market

- Date/Time : Tuesday, April 27, 2021, 10:10 ~10:35 (KST/UTC+9)
- Venue : Room A (Tamna Hall, 8F)
- Session Chair : Taesung Kim (Sungkyunkwan University, South Korea)

Korean Policy for Green World and Heat Pumping Technologies

Min Soo Kim
President of Society of Air-conditioning and Refrigerating Engineers of Korea,
NOC Chair, South Korea

Abstract

Responses to climate change have permeated everyday life in the 21st century, as countries are increasingly faced the threat of global warming and natural disasters. Even in the wake of the COVID-19 pandemic, attitudes towards climate change have been mostly unanimous as international cooperation remains tight.

Governments are increasingly implementing green policies in an effort to reduce emissions and to stimulate economic recovery. Recently, U.S. released a climate change plan worth USD1.7 trillion to completely phase out nonrenewable energy and achieve net-zero emissions by 2050. Meanwhile, China pledged to achieve carbon neutrality before 2060, hitting peak emissions before 2030. In Europe, the European Commission announced the European Green Deal as a community-wide policy in December 2019 to make Europe the world's first climate-neutral bloc by 2050.

South Korea also released the New Deal policy in 2020 amid the COVID-19 pandemic situation, outlining targets in renewable energy and ICT infrastructure through the Green New Deal and Digital New Deal. Through the Green New Deal, the Korean government will invest KRW73.4 trillion for transition to a low-carbon, green economy by making additional advancements in mobility, energy, and other supporting climate-friendly technology.

In 2019, renewable energy accounted for 15,791 MW of electricity in Korea, about 13% of total power generation. Out of this, solar energy accounted for 67% of the renewable energy. To accelerate the green transition, the Korean government announced a 3020 renewable energy plan by which it will generate 20% of energy from renewable sources by 2030. In addition, the Korean Hydrogen Roadmap will be used to build a hydrogen economy for the public and private sector by 2040.

To achieve net zero emissions, heating and cooling energy, which accounts for about half of total energy consumption, must be reduced. For this, a heat pump is essential; however, there are many obstacles to adequately supply heat pumps in Korea such as high gas permeability, low energy prices, and sedentary culture. As shown in the examples of geothermal and hydrothermal heat pumps, designation of renewable energy sources can promote the growth of the heat pump industry in Korea. The designation of renewable energy sources for heat pump covering all heat sources will be of paramount help in achieving the net-zero emissions.

Biography

Min Soo KIM received the B.S. (1985), M.S. (1987), and Ph.D. (1991) degrees in mechanical engineering at Seoul National University. He is a Professor of the Department of Mechanical Engineering at Seoul National University since 1994. He serves as chair of the Department of Mechanical Engineering. His major is thermal engineering including refrigeration and air conditioning. He spent three years from 1992 to 1994 at the National Institute of Standards and Technology (NIST) in U.S. as a guest researcher. He has more than 240 journal papers and more than 440 conference papers together with about 40 patents in the field of thermal engineering and refrigeration. He is a member of ASME, ASHRAE, IIR, KSME, and SAREK.

In 2010, he served as Policy Advisor to Minister of the Ministry of Education, Science and Technology, and during 2011-2013, he was a member of Presidential Advisory Council on Education, Science & Technology. He was delegate of Korea to the International Institute of Refrigeration (IIR), and he served as vice president of the Management Committee of IIR and serves now as president of the General Council of IIR.

He got the Outstanding Academic Award from the Society of Air-conditioning and Refrigerating Engineers of Korea (SAREK) in 2006, Asian Academic Award from SAREK/CAR/JSRAE (2012), Outstanding Academic Award from Korean Society of Mechanical Engineers (KSME) (2013), Best Industry-University Cooperation Award from the College of Engineering at SNU (2015), and Minister Award from the Ministry of Land, Infrastructure, and Transport (2016). He was designated as 70 Excellent PhDs of College of Engineering at Seoul National University (2016) and he received Presidential Citation by the Ministry of Public Administration and Security (2017).

PLENARY LECTURES 2

Plenary Session 2-1 : Technology

- Date/Time : Tuesday, April 27, 2021, 10:45 ~11:10 (KST/UTC+9)
- Venue : Room A (Tamna Hall, 8F)
- Session Chair : Taesung Kim (Sungkyunkwan University, South Korea)

Heat Pump System Technology Trend

Saikee Oh
Executive Vice President / Center Director of LG Electronics, South Korea

Abstract

The role of heat pump in reducing greenhouse gases.
Some fundamental bottlenecks of traditional air-source heat pumps.
The cutting-edge heat pump technology to overcome these problems.

Biography

Education

Department of Mechanical Engineering
- Bachelor : Seoul National University (~Fab. 1989)
- Master : KAIST (~Fab. 1991)
- Ph.D. : KAIST (~Fab. 1997)

Professional Activities

LG Electronics
- H&A R&D Center Director (2020~)
- Air Solution R&D Lab. Director (2018 ~ 2019)
- System Air Conditioning Research / Engineering Division Leader (2014 ~ 2017)
- Air Conditioning & Energy Solution Lab. Director (2013)
- Entering LG Electronics (Mar. 1994)

Research Interests

Department of Mechanical Engineering
- Inverter Heat Pump (Air to Air, Air to Water)
- Indoor Air Quality
- Energy Saving HVAC Control

PLENARY LECTURES 2

Plenary Session 2-2 : Technology

- Date/Time : Tuesday, April 27, 2021, 11:10~11:35 (KST/UTC+9)
- Venue : Room A (Tamna Hall, 8F)
- Session Chair : Taesung Kim (Sungkyunkwan University, South Korea)

Ensuring a Safe Refrigerant Transition

Xudong Wang
Vice President of Air-Conditioning, Heating, and Refrigeration Institute, United States

Abstract

The global industry is transitioning to environmentally friendly low global warming potential (GWP) refrigerants. To date, most of promising low GWP refrigerants are flammable. Implementation of these refrigerants in the field requires necessary steps to ensure safety. The presentation will summarize the US industry activities on transitioning to low GWP refrigerants. The content will cover the current status on relevant code and standard development, research and remaining efforts needed in the transition to low-GWP refrigerants in the future.

Biography

Dr. Xudong Wang is the vice president of research at AHRI. He closely works with AHRI Members to develop research programs addressing common issues and challenges that the HVACR industry faces. He has initiated and managed multiple research programs related to assess low GWP refrigerants' performance, compatibility and safety. He holds a Ph.D. in Mechanical Engineering from the University of Maryland at College Park. Dr. Wang is a member of the American Society of Heating, Refrigerating, and Air-Conditioning Engineers ASHRAE.

PLENARY LECTURES 2

Plenary Session 2-3 : Technology

- Date/Time : Tuesday, April 27, 2021, 11:35 ~12:00 (KST/UTC+9)
- Venue : Room A (Tamna Hall, 8F)
- Session Chair : Taesung Kim (Sungkyunkwan University, South Korea)

Clean and Safe Air by HVAC systems
– Laws and Advanced Technologies in Japan

Noboru Kagawa
Professor of National Defense Academy, Japan

Abstract

Experience of health problems and pandemics changes the design of HVAC systems frequently. Accumulated knowledge can improve the HVAC technologies. Related laws and new technologies in Japan will be overviewed.

Biography

Prof. Noboru Kagawa is a Technical adviser and the former president of the Japan Society of Refrigerating and Air Conditioning Engineers, JSRAE, a member of the Executive committee and the Management committee of IIR, and the Leadership councillor of ASHRAE AASA. He works as a professor in Department of Mechanical Systems Engineering of National Defense Academy of Japan. His major fields of study are thermophysical properties of refrigerants, Stirling engine and refrigerator, and refrigerants management. He is also the chair of the 2nd IIR Conference of HFOs and Low GWP Blends, HFO2021 will be held at Osaka in June 2021.

KEYNOTE LECTURES

Tuesday, April 27

- **The Influence of Different Water-injection Methods on Water Vapor High Temperature Heat Pump**

- Bin Hu (Shanghai Jiao Tong University, China)

- **Next Stop: the Mass Market! Heat Pumps on the Verge of Large Scale Deployment in Europe**

- Thomas Nowak (European Heat Pump Association AISBL, Belgium)

- **The low-GWP refrigerant challenge**

- Didier Coulomb (International Institute of Refrigeration, France)

- **Air-Conditioning and Cooling**

- J.B.V. Reddy (Government of India, India)

- **Augmented Reality Acoustics of Air Heat Pumps - APP Development and Methods**

- Gerwin H.S. Drexler-Schmid (AIT - Austrian Institute of Technology, Austria)

- **Numerical Analysis of the Vortex Tube Characteristics Used Within a High Temperature Heat Pump**

- Constantin Zenz (Austrian Institute of Technology, Austria)

- **Development and Implementation of Industrial High Temperature Heat Pumps for Waste Scrubbing Process**

- Gilbong Lee (Korea Institute of Energy Research, South Korea)

- **Design of a Grey Water Heat Recovery System in Order to Satisfy the Domestic Hot Water Demand of a Block of Dwellings**

- Emilio Navarro-Peris (Universidad Politecnica de Valencia, Spain)

- **Test Results of a Rotation Heat Pump and Further Developments**

- Andreas Längauer (ecop Technologies GmbH, CEO, Austria)

Wednesday, April 28

- **Residential Split Heat Pump Using Low GWP Refrigerants**

- Bo Shen (Oak Ridge National Lab, United States)

- **Disproportionation Risk Study for HFO-1123 Compositions as Low-GWP Refrigerants**

- Hidekazu Okamoto (AGC Inc., Japan)

- **Numerical Simulation of Two-phase Flow Distribution in a Vertically Installed Refrigerant Distributor**

- Ji Hwan Jeong (Pusan National University, South Korea)

- **Trends and Recent R&D Activities on Fuel Driven Sorption Heat Pumps**

- Peter Schossig (Fraunhofer Institute Solar Energy Systems ISE, Germany)

- **Half-term Results from IEA HPT Annex 52 - Long-term Performance Monitoring of Large GSHP Systems**

  - Signhild Gehlin (Swedish Geoenergi Center, Sweden)

- **A Novel Geothermal Heat Pump System Integrated with Underground Thermal Storage for Shifting Building Electric Demands**

  - Xiaobing Liu (Oak Ridge National Laboratory, United States)

- **NEDO R&D Project for Innovative Thermal Management**

  - Tetsusiro Iwatsubo (New Energy and Industrial Technology Development Organization (NEDO, Japan)

- **Evaluation of Solar Heat Source and Sink in Multi-functional Heat Pump Operation**

  - Carsten Wemhoener (HSR University of Applied Sciences Rapperswil, Switzerland)

- **Seasonal Thermal Energy Storage for Large Scale District Heating**

  - Carlos Infante Ferreira (Delft University of Technology, Netherlands)

- **Impact of the Weather Forecast on a Predictive Controller Performance : Experimental Studies with a Residential Heat Pump for Space Cooling**

  - Thibault Péan (IREC, UPC, Spain)

- **Membrane-Based Air Dehumidification Using Organic Ionic Liquid Desiccant**

  - Bamdad Bahar (Xergy Inc., United States)

- **An Overview of Hydrogen Compressors for Heat Pump Systems**

  - Bamdad Bahar (Xergy Inc., United States)

- **Study on the Frosting Phenomena between Concavity and Convexity Plate under Forced Convection**
  - The Prediction of Frost Layer Growth using the Observation from the Frost and Defrost Multi-cycle Experiment -

  - Masafumi Katsuta (Waseda University, Japan)

- **Environmentally Friendly Steam Generation Using VHTHPs at a Pharmaceutical Research Facility**

  - Tor-Martin Tveit (Olvondo Technology AS, Norway)

- **Experimental Analysis of a High Temperature Heat Pump Using Stored Heat from a Solar Thermal System.**

  - Miguel Ramirez Stefanou (Tecnalia, Spain)

Thursday, April 29

- **Impact of Variable Speed Components on the Seasonal Performance of a Residential Air-Source Heat Pump**

  - Fatih Meral (Purdue University, Ray W. Herrick Laboratories, United States)

- **Effect of Evaporator and Condenser in the Analysis of Adsorption Chiller**

  - Jae Dong Chung (Sejong University, South Korea)

- **Categorization of Industrial Heat Pump for Integrated Simulation Technology**

  - Jongsoo Jeong (Waseda University, Japan)

- **Dynamic Performance Tests of a Heat Pump Cycle Integrated Latent Heat Thermal Energy Storage for Optimized DHW Generation**

- Klemens Marx (AIT Austrian Institute of Technology, Austria)

- **Refrigerant Circuitry Optimization of Heat Exchangers for Charge Reduction and Robust Performance in Reversible Heat Pump Application**

- Zhenning Li (University of Maryland, United States)

- **Comparison on Vacuum Membrane Dehumidification Systems with Moisture Selective Dense Membrane**

- Minsung Kim (Chung-Ang University, South Korea)

- **Working Fluid Selection of Organic Rankine Cycle for a Liquid Desiccant System**

- Hye-Won Dong (Hanyang University, South Korea)

- **Cost Optimized Design of Ground Probe Fields with Solar Regeneration**

- Carsten Wemhoener (HSR University of Applied Sciences Rapperswil, Switzerland)

- **Risk Assessment of Built-in Refrigerated Display Cabinet Using A3 Refrigerant**

- Koji Yamashita (the Japan Refrigeration and Air Conditioning Industry Association, Japan)

- **Energy Performance Estimation and Verification of an Industrial Waste Heat Recovery Heat Pump**

- Katsumi Hashimoto (Central Research Institute of Electric Power Industry)

- **Deep learning-based Refrigerant Charge Fault Detection Method of Air-source Heat Pump System**

- Yong Hwan Eom (Seoul National University, South Korea)

- **From Smarties, Ice-cream and Flowers**

- Thomas Nowak (European Heat Pump Association AISBL, Belgium)

ORAL SESSION

TUESDAY, APRIL 27, 2021

※ THE LIVE STREAM SCHEDULE IS BASED ON KOREA STANDARD TIME (KST / UTC +9).

Room A (Tamna Hall)

Tuesday, April 27 | Room A (Tamna Hall, 8F)

09:00-09:20	**Opening Ceremony**	Host: Taesung Kim (Sungkyunkwan University, South Korea)
	- Welcome Address (Stephan Renz / IEA HPT TCP Chair, Switzerland) - Opening Remark (Min Soo Kim / NOC Chair, President of Society of Air-conditioning and Refrigerating Engineers of Korea, South Korea) - Congratulatory Remarks (Hee-ryong Won / Governor of Jeju Province, South Korea)	
09:20-10:35	**Plenary Lecture I - Policy and Market**	Session Chair: Taesung Kim (Sungkyunkwan University, South Korea)
09:20-09:45	Plenary Lecture 1-1	**Heat Pumping Technologies in Clean Energy Transitions** Mechtild Worsdorfer, Director for Sustainability, Technology & Outlooks, IEA, France
09:45-10:10	Plenary Lecture 1-2	**The European Legal Framework is Well Set for a Massive Roll-out of Heat Pumps - but More Efforts are Needed!** Martin Forsen, President of European Heat Pump Association, Sweden
10:10-10:35	Plenary Lecture 1-3	**Korean Policy for Green World and Heat Pumping Technologies** Min Soo Kim, NOC Chair of HPC 2020, President of Society of Air-conditioning and Refrigerating Engineers of Korea, South Korea
10:35-10:45	Coffee Break and Poster Session	

Tuesday, April 27 | ROOM A (Tamna Hall, 8F)

10:45-12:00	**Plenary Lecture II - Technology**	Session Chair: Taesung Kim (Sungkyunkwan University, South Korea)
10:45-11:10	Plenary Lecture 2-1	**Heat Pump System Technology Trend** Saikee Oh, Executive Vice President / Center Director of LG Electronics, South Korea
11:10-11:35	Plenary Lecture 2-2	**Ensuring a Safe Refrigerant Transition** Xudong Wang, Vice President of Air-Conditioning, Heating, and Refrigeration Institute, US
11:35-12:00	Plenary Lecture 2-3	**HVAC Systems against COVID-19** Noboru Kagawa, Professor of National Defense Academy, Japan
12:00-13:00	Lunch and Poster Session	

Tuesday, April 27 | Room A (Tamna Hall, 8F)

Session 1A: Low GWP Refrigerants (1) - Natural

Session Chair : Bin Hu (Shanghai Jiao Tong University, China)

13:00-13:20	Keynote	[135]	The Influence of Different Water-injection Methods on Water Vapor High Temperature Heat Pump Di Wu (Shanghai Jiao Tong University), Bin Hu (Shanghai Jiao Tong University) † , R.Z Wang (Shanghai Jiao Tong University)
13:20-13:35		[297]	Annual Performance Assessment of Heat Pump Water Heaters Applying Various Refrigerants Takaoki Suzuki (Waseda University), Zheng Ge (Waseda University), Muhamad Yulianto (Waseda University), Yoichi Miyaoka (Waseda University), Seiichi Yamaguchi (Waseda University), Kiyoshi Saito (Waseda University) †
13:35-13:50		[136]	Benefits and Reliability of Air to Water Heat Pump in Residential Applications, using R290 Refrigerant and Alternative Design Solution to Guarantee High Safety Level with Standard Components Sergio Maria Capanelli (Carel Industries Spa) † , Biagio Lamanna (Carel Industries Spa)
13:50-14:05		[170]	Medium Capacity Low Charge Ammonia Chiller and Heat Pump Valentin Salgado Fuentes (Technical University of Denmark) † , Wiebke Brix Markussen (Technical University of Denmark), Erasmus Damgaard Rothuizen (Technical University of Denmark), Jóhannes Kristófersson (Danish Technological Institute), Claus Madsen (Danish Technological Institute), Brian Elmegaard (Technical University of Denmark)
14:05-14:20		[172]	High-temperature Vapor Compression Heat Pump using Butane (R600) - Development of a Prototype and First Measurements Manuel Verdnik (Graz University of Technology) † , René Rieberer (Graz University of Technology)
14:20-14:40	Coffee Break and Poster Session		

Tuesday, April 27, 2021 | Room A (Tamna Hall, 8F)

Session 2A: Market and Policy for Heat Pumps (1)

Session Chair : Jussi Hirvonen (Finnish Heat Pump Association SULPU ry, Finland)

14:40~15:00	Keynote	[267]	Next Stop: The Mass Market! Heat Pumps on the Verge of Large Scale Deployment in Europe Thomas Nowak (European Heat Pump Association AISBL) †
15:00~15:15		[150]	Disruption to Heat Business Models: From Shifting Boxes to Selling Comfort Cate Lyon (Delta Energy & Environment)) † , Lindsay Sugden (Delta Energy & Environment) † , Roxanne Pieterse (Delta Energy & Environment)
15:15~15:30		[238]	The Role of Heat Pumps in the Decarbonisation of the Heating Sector in Europe Martin Forsen (NIBE Energy Systems), Laure Meljac (NIBE Energy Systems) †
15:30~15:45		[164]	Today's One Million Heat Pumps are Already in Essential Role in Smart Energy Transition Towards Carbon Neutral Finland Jussi Hirvonen (Finnish Heat Pump Association SULPU ry) †
15:45~16:00		[352]	Diffusion Barriers and Strategies for Heat Pump Systems with Integrated Storage and Photovoltaic in Austrian 1-2 Family Dwellings: an Explorative Investigation for the IEA HPT Annex 55/ECES Annex 34 Therese Guttmann (Austrian Institute of Technology) † , Thomas Schoberer (Forschung Burgenland GmbH), Caroline Haglund Stignor (Research Institutes of Sweden), Johann Emhofer (Austrian Institute of Technology)
16:00~16:10	Break		

Tuesday, April 27, 2021 | Room A (Tamna Hall, 8F)

Session 3A: Low GWP Refrigerants (2)

Session Chair: Didier Coulumb (IIR Director, France)

16:10~16:30	Keynote	[357]	The low-GWP Refrigerant Challenge Didier Coulomb (International Institute of Refrigeration)
16:30~16:45		[247]	Increasing Flammable Refrigerant Charge Size without Compromising Safety Laure Meljac (NIBE) † , Martin Forsen (NIBE), Daniel Colbourne (c/o HEAT GmbH)
16:45~17:00		[141]	Is HFO the Last Range of Synthetical Refrigerant? Kenneth Hoffmann (GEA Refrigeration) † , Jan Gerritsen (GEA Refrigeration), Armin Hafner (NTNU)
17:00~17:15		[198]	Very Low GWP Refrigerant for Heat Pump Sarah Kim (Arkema inc) † , Laurent Abbas (Arkema France), Leping Zhang (Danfoss China), Drew Turner (Danfoss LLC)
17:15~17:30		[214]	Improving Risk Assessment of Refrigerant Leakage Hazards: Going beyond Physical Testing Mahmood Thabaddor (Underwriters Laboratories LLC) † , Sangamesh Hosur (UL India Pvt Ltd.) †

Room B (Halla Hall)

Tuesday, April 27 | Room A (Tamna Hall, 8F)

09:00-09:20	**Opening Ceremony**	Host: Taesung Kim (Sungkyunkwan University, South Korea)
09:20-10:35	**Plenary Lecture I - Policy and Market**	Session Chair: Taesung Kim (Sungkyunkwan University, South Korea)
10:35-10:45	Coffee Break and Poster Session	
10:45-12:00	**Plenary Lecture II - Technology**	Session Chair: Taesung Kim (Sungkyunkwan University, South Korea)
12:00-13:00	Lunch and Poster Session	

Tuesday, April 27 | Room B (Halla Hall, 8F)

Session 1B: Air Conditioning and Cooling

Session Chair: Mitsuhiro Fukuta (Shizuoka University, Japan)

13:00~13:20	Keynote	[356]	Air-Conditioning and Cooling J.B.V. Reddy (Department of Science and Technology, Government of India)
13:20~13:35		[113]	Application of Improved Cooling & Heating System to Long-Range Electric Vehicles for Higher Power Efficiency Jae Yeon Kim (Hyundai Motors), Taesung Kim (Sungkyunkwan University) † , Yeon Ho Kim (Hyundai Motors), Jea Wan Kim (Hyundai Motors)
13:35~13:50		[035]	Study on the Smart Operation Approach of an Air Conditioner when Occupants Go Out Myung Sup Yoon (Korea Testing Laboratory) † , Won Sik Yoon (Korea Testing Laboratory)
13:50~14:05		[245]	The Study of Secondary Loop System with Efficient and Flammable Refrigerants in MAC Inguk Hwang (Hanonsystems) † , Haejun Lee (Hanonsystems), Gumbae Choi (Hanonsystems), Jaeyeon Kim (Hyundai Motor Group), Manju Oh (Hyundai Motor Group)
14:05~14:20		[262]	A Development of AHP, the Integrated Climate System Module for EV Dae Bok Keon (Hanon System), Jae Chun Ryu (Hanon System), Ki Young Shin (Hyundai Motor Company), Sung Je Lee (Hanon System), Dong Woo Hwang (Hanon System) †
14:20-14:40	Coffee Break and Poster Session		

Tuesday, April 27, 2021 | Room B (Halla Hall, 8F)

Session 2B: Acoustic Signatures of Heat Pumps

Session Chair: Christoph Reichl (AIT Austrian Institute of Technology, Austria)

14:40~15:00	Keynote	[192]	Augmented Reality Acoustics of Air Heat Pumps - APP Development and Methods Gerwin H.S. Drexler-Schmid (AIT - Austrian Institute of Technology) † , Christian H. Kasess (Austrian Academy of Sciences), Brigitte Blank-Landeshammer (AIT - Austrian Institute of Technology), Christian Köfinger (AIT - Austrian Institute of Technology), Johann Emhofer (AIT - Austrian Institute of Technology), Holger Waubke (Austrian Academy of Sciences), Christoph Reichl (AIT - Austrian Institute of Technology) †

15:00~15:15		[068]	Simultaneous Energy Efficiency and Acoustic Evaluation of Heat Pump Systems Using Dynamic Simulation Models Christian Vering (RWTH Aachen University) † , François Bessac (CETIAT) † , Roberto Fumagalli (Polimi), Henrik Hellgren (RI.SE), Thore Oltersdorf (Fraunhofer ISE), Svend Pedersen (DTI), Christoph Reichl (AIT)
15:15~15:30		[160]	Acoustic Characterisation of an Air-To-Water Heat Pump for Different Operating Conditions: Inter-laboratory Results Thomas Fleckl (AIT), François Bessac (CETIAT) † , Roberto Fumagalli (Polimi), Henrik Hellgren (RI.SE), Thore Oltersdorf (Fraunhofer ISE), Svend Pedersen (DTI), Christoph Reichl (AIT)
15:30~15:45		[088]	Frosting and Defrosting Behavior of Evaporators Thomas Fleckl (Center for Energy, AIT Austrian Institute of Technology), Christoph Reichl (Center for Energy, AIT Austrian Institute of Technology) † , Mirza Popovac (Center for Energy, AIT Austrian Institute of Technology), Felix Hochwallner (Center for Energy, AIT Austrian Institute of Technology), Peter Wimberger (Institute of Applied Physics, Vienna University of Technology), Felix Linhardt (Department of Geography, Kiel University), Johann Emhofer (Center for Energy, AIT Austrian Institute of Technology)
15:45~16:00		[184]	Heat Pump Noise - Seasonal Averaging and Operation Dependence Ola Gustafsson (RISE Research Institutes of Sweden) † , Henrik Hellgren (RISE Research Institutes of Sweden), Caroline Haglund Stignor (RISE Research Institutes of Sweden)
16:00~16:10	Break		

Tuesday, April 27, 2021 | Room B (Halla Hall, 8F)

Session 3B: Heat Pump Analysis - Components and Cycles

Session Chair: Thomas Fleckl (AIT Austrian Institute of Technology, Austria)

16:10~16:30	Keynote	[067]	Numerical Analysis of the Vortex Tube Characteristics used within a High Temperature Heat Pump Michael Lauermann (Austrian Institute of Technology), Constantin Zenz (Austrian Institute of Technology) † , Mirza Popovac (Austrian Institute of Technology)
16:30~16:45		[108]	Analysis of the Refrigerant Maldistribution of Propane Evaporating in Brazed Plate Heat Exchangers as a Function of Operating Conditions Emilio Navarro-Peris (Universitat Politecnica de Valencia) † , Lucas Alvarez (Universitat Politecnica de Valencia), Paloma Albaladejo (Universitat Politecnica de Valencia), Lena Schnabel (Fraunhofer Institute for Solar Energy Systems ISE), Jose Miguel Corberan (Universitat Politecnica de Valencia)
16:45~17:00		[050]	Performance Analysis of a Combined Cooling and Power Cycle Philipp Wagner (Graz University of Technology) † , Rene Rieberer (Graz University of Technology)
17:00~17:15		[193]	Analysis of a Directly Gas-fired Absorption Heat Pump with an Improved Condensing Boiler Technology Philipp Wagner (Graz University of Technology) † , Rene Rieberer (Graz University of Technology)
17:15~17:30		[179]	Simulation-based Eco-economic Assessment of Heat Pump Systems for Refurbishing All-electric Non-residential Buildings with Complex Energy Demand Structures Laura Maier (RWTH Aachen University) † , Xuchao Ying (RWTH Aachen University), Konstantin Finkbeiner (RWTH Aachen University), Sarah Henn (RWTH Aachen University), Jan Richarz (RWTH Aachen University), Markus Nürenberg (RWTH Aachen University), Tanja Osterhage (RWTH Aachen University), Dirk Müller (RWTH Aachen University)

Room C (Ara Hall)

Tuesday, April 27 | Room A (Tamna Hall, 8F)

09:00-09:20	**Opening Ceremony**	Host: Taesung Kim (Sungkyunkwan University, South Korea)
09:20-10:35	**Plenary Lecture I - Policy and Market**	Session Chair: Taesung Kim (Sungkyunkwan University, South Korea)
10:35-10:45	Coffee Break and Poster Session	
10:45-12:00	**Plenary Lecture II - Technology**	Session Chair: Taesung Kim (Sungkyunkwan University, South Korea)
12:00-13:00	Lunch and Poster Session	

Tuesday, April 27 | Room C (Ara Hall, 8F)

Session 1C: Heat Pump Applications

Session Chair: Akio Miyara (Saga University, Japan)

13:00~13:20	Keynote	[240]	Development and Implementation of Industrial High Temperature Heat Pumps for Waste Scrubbing Process Gilbong Lee (Korea Institute of Energy Research), Beomjoon Lee (Korea Institute of Energy Research), Junhyun Cho (Korea Institute of Energy Research), Ho-Sang Ra (Korea Institute of Energy Research), Young-Jin Baik (Korea Institute of Energy Research), Eun Seok Wang (Korea Institute of Energy Research), Hyung-Ki Shin (Korea Institute of Energy Research), Young-Soo Lee (Korea Institute of Energy Research) † , Chulwoo Roh (Korea Institute of Energy Research)
13:20~13:35		[180]	Long-term Evaluation of an Office Building with Large-scale Heat Pump and aquifer System in Southern Sweden Tommy Walfridson (Energy and Circular economy, RISE Research Institutes of Sweden) † , Martin Larsson (Energy and Circular economy, RISE Research Institutes of Sweden), Jessica Benson (Energy and Circular economy, RISE Research Institutes of Sweden), Oskar Räftegård (Energy and Circular economy, RISE Research Institutes of Sweden), Ola Gustafsson (Energy and Circular economy, RISE Research Institutes of Sweden), Caroline Haglund Stignor (Energy and Circular economy, RISE Research Institutes of Sweden), Lovisa Axelsson (Energy and Circular economy, RISE Research Institutes of Sweden), Pia Tiljander (Energy and Circular economy, RISE Research Institutes of Sweden)
13:35~13:50		[343]	Thermodynamic Analysis of Refrigerant Selection for High Temperature Heat Pump Cycles Takenobu Kaida (Central Research Institute of Electric Power Industry (CRIEPI)) †
13:50~14:05		[117]	Approaching Optimal High Pressure by Charge Management in Transcritical CO2 Heat Pump Water Heater Yu-Jia He (Tongji University), Xing-Yu Liang (Tongji University), Jia-Hao Cheng (Tongji University), Liang-Liang Shao (Tongji University) † , Chun-Lu (Tongji University)
14:05~14:20		[134]	Results of an Interlaboratory Comparison on Four Different Heat Pumps: Standards on the Test Stand Ivan Malenkovic (Fraunhofer Institute for Solar Thermal Systems (ISE)) † , Urs Gumbel (Fraunhofer Institute for Solar Thermal Systems (ISE)), Christoph Thoma (Fraunhofer Institute for Solar Thermal Systems (ISE)
14:20-14:40	Coffee Break and Poster Session		

Tuesday, April 27, 2021 | Room C (Ara Hall, 8F)

Session 2C: Space and Hot Water Heat Pumps

Session Chair: Michele Mondot (CETIAT, France)

14:40~15:00	Keynote	[079]	Design of a Grey Water Heat Recovery System in Order to Satisfy the Domestic Hot Water Demand of a Block of Dwellings Emilio Navarro-Peris (Universidad Politecnica de Valencia) † , Estefania Hervas-Blasco (Universitat Politecnica de Valencia), Jose Miguel Corberan (Universitat Politecnica de Valencia), Ximo Masip (Universitat Politecnica de Valencia)
15:00~15:15		[059]	Field Performance of Domestic Heat Pumps for Heating and Hot Water in Switzerland Cordin Arpagaus (NTB University of Applied Sciences and Technology Buchs), Ralph Kuster (NTB University of Applied Sciences and Technology Buchs) † , Manuel Prinzing (NTB University of Applied Sciences and Technology Buchs), Matthias Berthold (NTB University of Applied Sciences and Technology Buchs), Mick Eschmann (NTB University of Applied Sciences and Technology Buchs), Stefan Bertsch (NTB University of Applied Sciences and Technology Buchs)
15:15~15:30		[255]	Air-to-water Heat Pumps as a Substitution of Oil-boiler in a Non-retrofitted Multi-family Building of the 70's. In-situ Monitoring, Actual Energy Balance and Performance Omar Montero Dominguez (University of Geneva), Carolina De Sousa Fraga (University of Geneva), Pierre Hollmuller (University of Geneva), Simon Callegari (University of Geneva) †
15:30~15:45		[273]	CO2 Emission Savings of Heat-pumps in the Residential Sector. Case Study for Multifamily Buildings in Geneva Elliot Romano (University of Geneva) † , Carolina Fraga (University of Geneva), Pierre Hollmuller (University of Geneva)
15:45~16:00		[270]	Which Performance Indicators Should We Provide to Policy Makers to Switch from Gas Boilers to Air to Water Heat Pumps? Carolina Fraga (Services Industriels de Geneve) † , Alisa Freyre (Services Industriels de Geneve), Pierre Hollmuller (Université de Genève), Rodrigo De Pablo (Services Industriels de Geneve), Matthias Rüetschi (Services Industriels de Geneve)
16:00~16:10	Break		

Tuesday, April 27, 2021 | Room C (Ara Hall, 8F)

Session 3C: New Heat Pump Technologies

Session Chair: Maurizio Pieve (ENEA. Italy)

16:10~16:30	Keynote	[100]	Test Results of a Rotation Heat Pump and Further Developments Bernhard Adler (ecop Technologies GmbH), Andreas Längauer (ecop Technologies GmbH) † , Christian Rakusch, (ecop Technologies GmbH)
16:30~16:45		[272]	High Efficiency Low Temperature Lift Heat Pump with Novel Oil-free, Gas-bearing Turbo Compressor Dominic Zajonc (Lucerne University of Applied Sciences and Arts) † , Stefan Flück (Lucerne University of Applied Sciences and Arts), Edward J. Lucas (Lucerne University of Applied Sciences and Arts), Andreas Lehr (Teqtoniq GmbH), Beat Wellig (Lucerne University of Applied Sciences and Arts)
16:45~17:00		[229]	Experimental Investigation of a Rolling Piston Compressor Operated with a Hydrocarbon Refrigerant Mixture Melanie Cop (Technische Universität Dresden) † , Ramona Nosbers (Technische Universität Dresden), Christiane Thomas (Technische Universität Dresden), Ullrich Hesse (Technische Universität Dresden)

17:00~17:15	[163]	Research and Development for 200°C Compressed Water Heat Pump using Exhaust Heat with Low GWP Refrigerant for Industrial Use Ryosuke Suemitsu (Mitsubushi Heavy Industries Thermal Systems, Ltd) † , Masanobu Sakai (Mitsubushi Heavy Industries Thermal Systems, Ltd), Yoshie Togano (Mitsubushi Heavy Industries Thermal Systems, Ltd), Naoki Kobayashi (Mitsubishi Heavy Industries, Ltd), Hiroyuki Yuki (Mitsubushi Heavy Industries Thermal Systems, Ltd), Yasushi Hasegawa (Mitsubushi Heavy Industries Thermal Systems, Ltd), Kazuki Wajima (Mitsubushi Heavy Industries Thermal Systems, Ltd), Kenji Ueda (MHI Bingshan Refrigeration (Dalian) Co., Ltd.)
17:15~17:30	[239]	Lubrication Management of a Reversible Compressor-expander-unit in a Combined HP-ORC-plant Daniel Steger (Institute of Process Machinery and Systems Engineering, Friedrich-Alexander-Universität Erlangen-Nürnberg (FAU)) † , Markus Zwiefler (Institute of Process Machinery and Systems Engineering, Friedrich-Alexander-Universität Erlangen-Nürnberg (FAU)), Eberhard Schlücker (Institute of Process Machinery and Systems Engineering, Friedrich-Alexander-Universität Erlangen-Nürnberg (FAU))

ORAL SESSION

WEDNESDAY, APRIL 28, 2021

※ THE LIVE STREAM SCHEDULE IS BASED ON KOREA STANDARD TIME (KST / UTC +9).

Room A (Tamna Hall)

Wednesday, April 28, 2021 | Room A (Tamna Hall, 8F)

Session 4A: Low GWP Refrigerants (3)

Session Chair: Yunho Hwang (University of Maryland, United States)

09:00~09:20	Keynote	[230]	Residential Split Heat Pump Using Low GWP Refrigerants Bo Shen (Oak Ridge National Lab) † , Moonis Ally (Oak Ridge National Lab)
09:20~09:35		[055]	A3 Refrigerant R290 Leak and Ignition Testing for a Packaged Terminal Air-conditioner (PTAC) Xudong Wang (Air-Conditioning, Heating and Refrigeration Institute) † , George Hunter (UL LLC)
09:35~09:50		[017]	Solid State (Metal Hydride) Refrigerant Based Air Conditioner and Freezer Systems Bamdad Bahar (Xergy Inc.) † , William TomHon (Xergy Inc.), Matt Golben (Xergy Inc.), Jacob Zerby (Xergy Inc.), Mark Golben (Xergy Inc.)
09:50~10:05		[204]	Alternate Refrigerants for Heat Pump Water Heater Applications Kashif Nawaz (Oak Ridge National Laboratory) † , Bo Shen (Oak Ridge National Laboratory), Van Baxter (Oak Ridge National Laboratory), Omar Abdelaziz (Oak Ridge National Laboratory)
10:05~10:20		[111]	Performance Evaluation of Light Commercial Air Conditioning and Heat Pump System Using Low GWP Refrigerants Joshua Hughes (The Chemours Company) † , Minsoo Kim (Air Solution Laboratory, LG Electronics)
10:20~10:40			Coffee Break and Poster Session

Wednesday, April 28, 2021 | Room A (Tamna Hall, 8F)

Session 5A: Low GWP Refrigerants (4)

Session Chair: Hideaki Maeyama (Heat pump & Thermal Storage Technology Center of Japan, Japan)

10:40~11:00	Keynote	[213]	Disproportionation Risk Study for HFO-1123 Compositions as Low-GWP Refrigerants Hidekazu Okamoto (AGC Inc.) † , Hiroki Hayamizu (AGC Inc.), Tetsuo Otsuka (AGC Inc.), Katsuya Ueno (AGC Inc.)
11:00~11:15		[139]	Modeling of Megawatt R1233zd (E) High Temperature Heat Pump System Bin Hu (Shanghai Jiao Tong University) † , R.Z. Wang (Shanghai Jiao Tong University), Hua Liu (Gree Electric Appliances), Zhiping Zhang (GREE Electric Appliances), Hongbo Li (Gree Electric Appliances)
11:15~11:30		[128]	Study on Layer Short Mechanism and Discharge Pattern in Refrigerant Compressor for Refrigerants with Disproportionation Reaction Like HFO-1123 Hideyuki Fujimoto (Shizuoka University), Mitsuhiro Fukuta (Shizuoka University) † , Masaaki Motozawa (Shizuoka University)

11:30~11:45		[138]	Clarification of the Disproportionation Reaction of HFO-1123 and Evaluation of the Reaction Inhibitor Zhihua Zhang (The University of Tokyo) † , Makoto Ito (The University of Tokyo), Chaobin Dang (The University of Tokyo), Eiji Hihara (The University of Tokyo)
11:45~12:00		[336]	Experimental Investigation of Heat Transfer Coefficient of R1234yf During Condensation Inside Multiport Mini-channel Tube Jong-Taek Oh (Chonnam National University) † , Quang Vu Pham (Electric Power University)
12:00-13:00			Lunch and Poster Session

Wednesday, April 28, 2021 | Room A (Tamna Hall, 8F)

Session 6A: Heat Transfer

Session Chair: Sheng Wang (Gree Electric Appliances, Inc. of Zhuhai, China)

13:00~13:20	Keynote	[022]	Numerical Simulation of Two-phase Flow Distribution in a Vertically Installed Refrigerant Distributor Jihwan Jeong (Pusan National University) † , Siyoung Choi (Pusan National University), Hyoin Lee (Pusan National University)
13:20~13:35		[345]	Experimental Investigation of Local Nucleate Boiling Heat Transfer and Mixing Ratio on Copper Surface about Mixture R 32 / R 1234ze (E) Riku Fukuju (The University of Electro-Communications), Koji Enoki (The University of Electro-Communications) † , Kiyoshi Saito (Waseda University)
13:35~13:50		[279]	Effects of Tube Shape on Boiling Heat Transfer of Low-pressure Refrigerant R1233zd (E) Outside Horizontal Tubes Sho Fukuda (Kyushu Sangyo University) † , Yuki Shimizu (Mitsubishi Heavy Industries Thermal Systems, Ltd.), Naoya Miyoshi (Mitsubishi Heavy Industries Thermal Systems, Ltd.), Yasushi Hasegawa (Mitsubishi Heavy Industries Thermal Systems, Ltd.)
13:50~14:05		[294]	High-resolution Surface Plasmon Resonance Imaging of an Evaporating Droplet on the Surface Chan Ho Jeong (Chung-Ang University), Hyung Joo Lee (Chung-Ang University), Seong Hyuk Lee (Chung-Ang University) †
14:05~14:20		[312]	Lubricant-impregnated Surfaces (LIS) Incorporated with the Oil Supply System for Enhanced Durability and Condensation Heat Transfer Performance Youngsuk Nam (Kyung Hee University) † , Donghyun Seo (Kyung Hee University), Jaehwan Shim (Kyung Hee University), Choongyeop Lee (Kyung Hee University) †
14:20-14:40			Coffee Break and Poster Session

Wednesday, April 28, 2021 | Room A (Tamna Hall, 8F)

Session 7A: Sorption Heat Pumps (2)

Session Chair: Peter Schossig (Fraunhofer ISE, Germany)

14:40~15:00	Keynote	[176]	Trends and Recent R&D Activities on Fuel Driven Sorption Heat Pumps Peter Schossig (Fraunhofer Institute Solar Energy Systems ISE), Gerrit Fueldner (Fraunhofer Institute Solar Energy Systems ISE) † , Angeles Rivero Pacho (University of Warwick), Steven Metcalf (University of Warwick), Kyle Gluesenkamp (ORNL), Zhiyao Yang (ORNL), Andrea Frazzica (CNR-ITAE), Marcello Aprile (Politecnico di Milano), Tommaso Toppi (Politecnico di Milano), Mario Motta (Politecnico di Milano), Robert E. Critoph (University of Warwick), Edo Wiemken (Fraunhofer Institute Solar Energy Systems ISE)
15:00~15:15		[181]	Design of a Gas-driven Hybrid Adsorption Heat Pump Coupled to Geothermal Heat Exchangers for Retrofitting Applications Andrea Frazzica (Consiglio Nazionale delle Ricerche) † , Valeria Palomba (Consiglio Nazionale delle Ricerche), Antonino Bonanno (Consiglio Nazionale delle Ricerche), Davide La Rosa (Consiglio Nazionale delle Ricerche), Stefan Löwe (Fahrenheit GmbH), Ralph Herrmann (Fahrenheit GmbH)
15:15~15:30		[133]	Assessment of Standardized Test and Performance Evaluation Methods for Fuel Driven Sorption Heat Pumps Ivan Malenkovic (Fraunhofer Institute for Solar Thermal Systems (ISE)) † , Patrizia Norina Melograno (Politecnico di Milano) † , Peter Schossig (Fraunhofer Institute for Solar Thermal Systems (ISE))
15:30~15:45		[341]	Dynamic Simulations of an Absorption Refrigeration System for Automobile Application Hai Trieu Phan (French Atomic Energy and Alternative Energy Commission CEA) † , Mathilde Wirtz (French Atomic Energy and Alternative Energy Commission CEA), Julien Hergott (Faurecia Clean Mobility), François Boudehenn (French Atomic Energy and Alternative Energy Commission CEA)
15:45~16:00		[191]	CHP-Waste Heat Utilization with Small-scaled Absorption-Resorption Chillers for Supermarket Refrigeration Oliver Ziegler (Technische Universität Dresden) † , Ullrich Hesse (Technische Universität Dresden), Christiane Thomas (Technische Universität Dresden)
16:00~16:10			Break

Wednesday, April 28, 2021 | Room A (Tamna Hall, 8F)

Session 8A: Ground Source Heat Pumps

Session Chair: Signhild Gehlin (Swedish Geoenergi Center, Sweden)

16:10~16:30	Keynote	[045]	Half-term Results from IEA HPT Annex 52 - Long-term Performance Monitoring of Large GSHP Systems Signhild Gehlin (Swedish Geoenergi Center) † , Jeffrey Spitler (Oklahoma State University)
16:30~16:45		[098]	Ground Source Heat Pump Systems for Energy Efficient Building Retrofitting Michael Lauermann (AIT Austrian Institute of Technology GmbH) † , Johann Emhofer (AIT Austrian Institute of Technology GmbH), Karl sen. Ochsner (Ochsner Wärmepumpen GmbH)
16:45~17:00		[243]	It works! - Long-term Performance Measurement of Ground Source Heat Pump Systems Franziska Bockelmann (Steinbeis-Innovationszentrum (SIZ) Energie+) † , Christian Kley (TU Braunschweig)
17:00~17:15		[351]	Initial Stage of Thermal Response Tests Combined with Transient Numerical Model – a Foundation of Short-term Ground Storage of Cold for Effective Cooling of Office Buildings Kamil Kwiatkowski (Euros Energy), Jakub Garbacik (Euros Energy) † , Tomasz Walczak (Euros Energy)

Room B (Halla Hall)

Wednesday, April 28, 2021 | Room B (Halla Hall, 8F)

Session 4B: Ground Source and Storage

Session Chair: Jeffrey Spitler (Oklahoma State University, United States)

09:00~09:20	Keynote	[056]	A Novel Geothermal Heat Pump System Integrated with Underground Thermal Storage for Shifting Building Electric Demands Xiaobing Liu (Oak Ridge National Laboratory) † , Liang Shi (Purdue University), Ming Qu (Purdue University)
09:20~09:35		[044]	Three Years' Performance Monitoring of a Mixed-use Ground Source Heat Pump System in Stockholm Jeffrey Spitler (Oklahoma State University) † , Signhild Gehlin (Swedish Geonergy Center)
09:35~09:50		[326]	Feasibility of Using Ground Source Heat Pumps in Heating and Cooling of Residential Buildings Seama Koohi-Fayegh (OntarioTech University) †
09:50~10:05		[282]	Performance Analysis of Ground Source Heat Pump System with Vertical Borehole Heat Exchangers Affected by Rapid Groundwater Flow Hobyung Chae (Hokkaido University) † , Katsunori Nagano (Hokkaido University), Yoshitaka Sakata (Hokkaido University), Takao Katsura (Hokkaido University), Takeshi Kondo (Nikken Sekkei Research Institute)
10:05~10:20		[325]	Development of LNG Vaporization Systems Applying Hybrid Ground Source Heat Pumps Combined Ground Heat Exchangers with Air-water Heat Exchangers Takao Katsura (Hokkaido University) † , Yutaka Shoji (Hokkaido University), Hitoshi Akai (Hokkaido University), Katsunori Nagano (Hokkaido University), Jun Shishido (Tohoku Electric Power Co., Inc.), Mitsuhiro Ishikawa (Hokkaido Electric Power Co., Inc.), Yuichi Yashima (Tohoku Electric Power Co., Inc.), Koji Tanifuji (Zeneral Heatpump Industry Co., Ltd.)
10:20~10:40	Coffee Break and Poster Session		

Wednesday, April 28, 2021 | Room B (Halla Hall, 8F)

Session 5B: Market and Policy for Heat Pumps (2)

Session Chair: Tetsushiro Iwatsubo (New Energy and Industorial Technology Development Organaization, Japan)

10:40~11:00	Keynote	[048]	NEDO R&D Project for Innovative Thermal Management Tetsusiro Iwatsubo (New Energy and Industrial Technology Development Organization (NEDO)) † , Yuka Ogasawara (New Energy and Industrial Technology Development Organization (NEDO)), Toshihiko Ota (New Energy and Industrial Technology Development Organization (NEDO)), Masanori Kobayashi (New Energy and Industrial Technology Development Organization (NEDO))
11:00~11:15		[036]	Numerical Investigation on PCM-to-refrigerant Heat Exchangers for Thermal Energy Storage Yunho Hwang (University of Maryland) † , Yiyuan Qiao (University of Maryland), Tao Cao (University of Maryland), Jiazhen Ling (University of Maryland), Vikrant Aute (University of Maryland)
11:15~11:30		[222]	Roadblocks to Heat Pump Use in Residential Buildings with Model Predictive Control for Demand Response and Ancillary Markets and Potential Solutions Ramanunni Parakkal Menon (Concordia University) † , Jessen Page (HES-SO Valais/Wallis), Frederic Amblard (HES-SO Valais/EPFL)

11:30~11:45		[252]	A Techno-Economic Assessment of Air-Source Heat Pumping Technologies in the Canadian Residential Sector Justin Tamasauskas (CanmetENERGY/Natural Resources Canada) † , Stephanie Breton (CanmetENERGY/Natural Resources Canada), Martin Kegel (CanmetENERGY/Natural Resources Canada)
11:45~12:00		[010]	US Heat Pump Market Overview–2020 Melissa Lapsa (Oak Ridge National Laboratory) † , Jaewan Joe (Oak Ridge National Laboratory), Mini Malhotra (Oak Ridge National Laboratory), Van Baxter (Oak Ridge National Laboratory)
12:00-13:00	Lunch and Poster Session		

Wednesday, April 28, 2021 | Room B (Halla Hall, 8F)

Session 6B: Residential Heat Pumps

Session Chair: Carsten Wemhöner (HSR University of Applied Sciences Rapperswil, Switzerland)

13:00~13:20	Keynote	[168]	Evaluation of Solar Heat Source and Sink in Multi-functional Heat Pump Operation Carsten Wemhoener (HSR University of Applied Sciences Rapperswil) † , Lukas Rominger (HSR University of Applied Sciences Rapperswil), Simon Büsser (HSR University of Applied Sciences Rapperswil), Roman Schwarz (HSR University of Applied Sciences Rapperswil)
13:20~13:35		[275]	Heat Pumps in Existing Residential Buildings Marek Miara (Fraunhofer ISE) † , Danny Günther (Fraunhofer ISE), Robert Langner (Fraunhofer ISE)
13:35~13:50		[047]	Effectiveness-based Air Flow Rate Optimization for a Residential Heat Pump in Seasonal Performance Conditions Minsu Park (LG Electronics), Min Soo Kim (Seoul National University) †
13:50~14:05		[093]	Energy Saving Potential of an Air Source Heat Pump Heating System Compared with a Radiant Floor Heating System with Ventilation in an Apartment Building Yu-Jin Hwang (Hanyang University), Yong-Kwon Kang (Hanyang University), Beom-Jun Kim (Hanyang University), Jae-Weon Jeong (Hanyang University) †
14:05~14:20		[127]	A Residential Heat Pump System for Cooling, Heating, Dehumidification and Outdoor Air Supply Xingyu Liang (Tongji University), Chen Yang (Tongji University), Jing Zhang (Tongji University), Xiang Cao (Tongji University), Liangliang Shao (Tongji University), Chunlu Zhang (Tongji University), Chun Yang (Emerson Commercial & Residential Solutions), Xiaoning Chen (Emerson Commercial & Residential Solutions), Hongfei Shu (Emerson Commercial & Residential Solutions) †
14:20-14:40	Coffee Break and Poster Session		

Wednesday, April 28, 2021 | Room B (Halla Hall, 8F)

Session 7B: Heat Pumps in Smart Grids and District Heating and Cooling Systems (1)

Session Chair: Svend Pedersen (Danish Technological Institute, Denmark)

14:40~15:00	Keynote	[308]	Seasonal Thermal Energy Storage for Large Scale District Heating Carlos Infante Ferreira (Delft University of Technology) † , Just Remmelts (Delft University of Technology), Sander Tensen (Eneco Industrial & Heat)
15:00~15:15		[281]	Investigation of Model Predictive Control for Fifth Generation District Heating and Cooling (5GDHC) Substations Simone Buffa (Eurac Research, Free University of Bolzano) † , Anton Soppelsa (Eurac Research), Mauro Pipiciello (Eurac Research), Gregor P. Henze (University of Colorado Boulder), Roberto Fedrizzi (Eurac Research)
15:15~15:30		[309]	Low Temperature District Heating based on Low Temperature Geothermal Heat (30oC) Carlos Infante Ferreira (Delft University of Technology) † , Sebastiaan Knepper (Delft University of Technology), Ivo Pothof (Delft University of Technology), Laure Itard (Delft University of Technology)
15:30~15:45		[253]	Replicable Water Source Heat Pumps for a Zero Carbon Future Nicky Jason Cowan (Star Renwable Energy) †
15:45~16:00		[151]	Electrification of Heat and Decarbonisation of the Electricity System: Sector Coupling is Creating Opportunities for Heat Pumps Cate Lyon (Delta Energy & Environment) † , Lindsay Sugden (Delta Energy & Environment) †
16:00~16:10	Break		

Wednesday, April 28, 2021 | Room B (Halla Hall, 8F)

Session 8B: Heat Pumps in Smart Grids and District Heating and Cooling Systems (2)

Session Chair: Emina Pasic (IEA HPT ExCo Delegate Sweden, Sweden)

16:10~16:30	Keynote	[072]	Impact of the Weather Forecast on a Predictive Controller Performance: Experimental Studies with a Residential Heat Pump for Space Cooling Thibault Péan (IREC, UPC) † , Ivan Bellanco (IREC), Jaume Salom (IREC)
16:30~16:45		[329]	Large Heat Pumps for Decarbonized District Heating Torben Funder-Kristensen (Danfoss A/S) † , Drew Turner (Danfoss A/S), Leping Zhang (Danfoss A/S)
16:45~17:00		[043]	Application of the DevOps Methodology on Heat Pump Controllers Stephan Göbel (RWTH Aachen University), Markus Nürenberg (RWTH Aachen University) † , Philipp Mehrfeld (RWTH Aachen University), Dirk Müller (RWTH Aachen University)
17:00~17:15		[131]	Possibilities and Constraints of Grid Flexible Control of Todays and Tomorrows Heat Pumps Markus Lindahl (RISE Research Institutes of Sweden), Tommy Walfridson (RISE Research Institutes of Sweden) † , Jessica Benson (RISE Research Institutes of Sweden) † , Oskar Räftegård (RISE Research Institutes of Sweden), Ola Gustafsson (RISE Research Institutes of Sweden), Caroline Haglund Stignor (RISE Research Institutes of Sweden)
17:15~17:30		[301]	Control Strategy Assessment of a Small GSHP Sourced DH System with End User DHW Booster Heat Pumps Wim Boydens (Ghent University) † , Sigrid Feyaerts (KU Leuven), Annelies Vandermeulen (KU Leuven/VITO/EnergyVille), Lieve Helsen (KU Leuven/EnergyVille) †

Room C (Ara Hall)

Wednesday, April 28, 2021 | Room C (Ara Hall, 8F)

Session 4C: Sorption Heat Pumps (1)

Session Chair: Reinhard Radermacher (University of Maryland, United States)

09:00~09:20	Keynote	[023]	Membrane-Based Air Dehumidification Using Organic Ionic Liquid Desiccant Bamdad Bahar (Xergy Inc.) † , Harish Opradishta (Xergy Inc.), Mark Stutman (Xergy Inc.), Xiaobing Liu (Oakridge National Laboratory), Jason Woods (National Renewable Energy Laboratory)
09:20~09:35		[206]	Semi-open Absorption Water Heater: Experimental Results Kyle R. Gluesenkamp (Oak Ridge National Laboratory) † , Navin Kumar (Oak Ridge National Laboratory), Ahmad Abu-Heiba (Oak Ridge National Laboratory), Viral K. Patel (Oak Ridge National Laboratory), Zhiyao Yang (Purdue University), Saeed Moghaddam (University of Florida), Rohit Bhagwat (University of Florida), Sidharth Sanadhya (University of Florida), Michael Schmid (University of Florida), Richard Rode (University of Florida), Basil Anabtawi (University of Florida)
09:35~09:50		[016]	Water Transmission Mechanisms in Advanced Ionic Membranes for HVAC Applications Bamdad Bahar (Xergy Inc.) † , David McAndrews (Xergy Inc.), Taoli Gu (Xergy Inc.), Abhishek Bandlore (Xergy Inc.)
09:50~10:05		[201]	Dynamic Modelling and Design Optimization of a Heat-Pipe-Integrated Chemisorption Adsorber Zhiyao Yang (Purdue University), Ming Qu (Purdue University), Kyle Gluesenkamp (Oak Ridge National Lab) †
10:05~10:40	Coffee Break and Poster Session		

Wednesday, April 28, 2021 | Room C (Ara Hall, 8F)

Session 5C: Electrochemical Related

Session Chair: Van D. Baxter (Oak Ridge National Laboratory, United States)

10:40~11:00	Keynote	[021]	An Overview of Hydrogen Compressors for Heat Pump Systems Bamdad Bahar (Xergy Inc.) † , Samuel Dorman (Xergy Inc.), Jacob Zergy (Xergy Inc.), Mark Golben (Xergy Inc.), William Tomhon (Xergy Inc.)
11:00~11:15		[209]	Thermoelectric Heat Pump Performance Characterization Viral K. Patel (Oak Ridge National Laboratory) † , Kyle R. Gluesenkamp (Oak Ridge National Laboratory), Philip Boudreaux (Oak Ridge National Laboratory)
11:15~11:30		[124]	Study on a Combined Absorption Heat Pump System Driven by Low Temperature Heat Source Gabyong Kim (Korea University), Han Sol Jung (Korea University), Yong Tae Kang (Korea University) †
11:30~11:45		[014]	Electrochemical Compression of Ammonia/Hydrogen Blends for Heat Pump Applications Bamdad Bahar (Xergy Inc.) † , Ashish Chouhan (University of Delaware), Ajay Prasad (University of Delaware), Premanand Sivakumar (University of Delaware), Utsav Aryal (University of Delaware)
11:45~12:00		[350]	Experimental Study of PEMFC Conditioning Methods Joohee Song (Chung-Ang University), Minsoo Kim (Chung-Ang University), Dongkyu Kim (Chung-Ang University) †
12:00-13:00	Lunch and Poster Session		

Wednesday, April 28, 2021 | Room C (Ara Hall, 8F)

Session 6C: Heat Exchangers (1)

Session Chair: Masafumi Katsuta (Waseda University, Japan)

13:00~13:20	Keynote	[244]	Study on the Frosting Phenomena between Concavity and Convexity Plate under Forced Convection —The Prediction of Frost Layer Growth using the Observation from the Frost and Defrost Multi-cycle Experiment Masafumi Katsuta (Waseda University) † , Shota Ikutaya (Graduate School of Waseda University), Junya Yamagishi (Graduate School of Waseda University), Rio Asakawa (Graduate School of Waseda University), Yuki Terakado (Graduate School of Waseda University), Sangchul Bae (Waseda University)
13:20~13:35		[335]	Investigation on System Performance of Air Source Heat Pump Water Heater with Phase Change Material Zhanpeng Liu (Tongji University), Naiping Gao (Tongji University) † , Tiantian Wang (Tongji University), Hengyi Zhao (International Copper Association), Yifeng Gao (International Copper Association)
13:35~13:50		[140]	A Study on the Determination Method of Defrosting Start Time by Calculation of Frost Volume Jin Woo Yoo (Korea Institute of Machinery and Materials), Yoong Chung (Seoul National University), Dong Ho Kim (Korea Institute of Machinery and Materials), Seok Ho Yoon (Korea Institute of Machinery and Materials), Chan Ho Song (Korea Institute of Machinery and Materials), Kong Hoon Lee (Korea Institute of Machinery and Materials), Ook Joong Kim (Korea Institute of Machinery and Materials), Min Soo Kim (Seoul National University) †
13:50~14:05		[334]	Experimental Investigation of Condenser with Small Diameter Copper Tube in Air Source Heat Pump Water Heater Tiantian Wang (Tongji University), Naiping Gao (Tongji University) † , Zhanpeng Liu (Tongji University), Tingwei Fan (Gomon New Energy Ltd. of Jiangsu Province), Hengyi Zhao (International Copper Association), Yifeng Gao (International Copper Association)
14:05~14:20		[316]	Condensation Heat Transfer and Pressured Drop Characteristics of R-513A as An Alternative Refrigerant of R-134a Andreas Karageorgis (ElvalHalcor Company), George Hinopoulos (ElvalHalcor Company), Man-Hoe Kim (Kyungpook National University) †
14:20-14:40			Coffee Break and Poster Session

Wednesday, April 28, 2021 | Room C (Ara Hall, 8F)

Session 7C: Industrial Heat Pumps (1)

Session Chair: Rainer Jacobs (IZW e.V., Information Centre on Heat Pumps and Refrigeration, Germany)

14:40~15:00	Keynote	[004]	Environmentally Friendly Steam Generation Using VHTHPs at a Pharmaceutical Research Facility Tor-Martin Tveit (Olvondo Technology AS) † , Martin N. Johansson (AstraZeneca), Ron Zevenhoven (Åbo Akademi University)
15:00~15:15		[103]	Development and Lab-scale Performance Evaluation of a High Temperature Heat Pump for integration into a Power-to-Heat-to-Power System Miguel Ramirez (Tecnalia) † , Felipe Trebilcock Kelly (Tecnalia), Xabier Peña (Tecnalia), Asier Martinez-Urrutia (Tecnalia), Abdelrahman Hassan (Universitat Politècnica de València)
15:15~15:30		[156]	Design and Experimental Results of a Two-Stage Steam Producing Industrial Heat Pump Andrew Marina (TNO) † , Simon Smeding (TNO), Anton Wemmers (TNO), Simon Spoelstra (TNO), Peter Kremers (IBK B.V.)
15:30~15:45		[216]	Experimental Comparison of R1224yd (Z) and R1233zd (E) in a High Temperature Heat Pump Cordin Arpagaus (NTB University of Applied Sciences and Technology Buchs) † , Stefan Bertsch (NTB University of Applied Sciences and Technology Buchs)
15:45~16:00		[306]	Heat Pump Assisted Drying of Flower Bulbs Carlos Infante Ferreira (Delft University of Technology) † , Sjors Wagenaar (Delft University of Technology)
16:00~16:10			Break

Wednesday, April 28, 2021 | Room C (Ara Hall, 8F)

Session 8C: High Temperature Heat Pumps

Session Chair: Benjamin Zühlsdorf (Danish Technological Institute, Denmark)

16:10~16:30	Keynote	[104]	Experimental Analysis of a High Temperature Heat Pump Using Stored Heat from a Solar Thermal System Miguel Ramirez Stefanou (Tecnalia) † , Neil J. Hewitt (Ulster University), Asier Martinez-Urrutia (Tecnalia), Nikhilkumar Shah (Ulster University)
16:30~16:45		[062]	Theoretical Investigation of High-temperature Heat Pump Cycles for Steam Generation Cordin Arpagaus (NTB University of Applied Sciences and Technology Buchs), Frédéric Bless (NTB University of Applied Sciences and Technology Buchs) † , Stefan Bertsch (NTB University of Applied Sciences and Technology Buchs)
16:45~17:00		[075]	High Temperature Heat Pumps for Drying – First Results of Operation in Industrial Environment Veronika Wilk (AIT Austrian Institute of Technology GmbH) † , Franz Helminger (AIT Austrian Institute of Technology GmbH), Michael Lauermann (AIT Austrian Institute of Technology GmbH), Bernd Windholz (AIT Austrian Institute of Technology GmbH), Andreas Sporr (AIT Austrian Institute of Technology GmbH)
17:00~17:15		[340]	Part Load Capability of a High Temperature Heat Pump with Reversed Brayton Cycle Johannes Oehler (German Aerospace Center (DLR)) † , Jens Gollasch (German Aerospace Center (DLR)), A. Phong Tran (German Aerospace Center (DLR)), Eberhard Nicke (German Aerospace Center (DLR))
17:15~17:30		[097]	Analysis of a Steam Generating High Temperature Heat Pump for Industrial Waste Heat Recovery Sabrina Dusek (Austrian Institute of Technology GmbH) † , Michael Lauermann (Austrian Institute of Technology GmbH), Franz Helminger (Austrian Institute of Technology GmbH), Veronika Wilk (Austrian Institute of Technology GmbH)

ORAL SESSION

THURSDAY, APRIL 29, 2021

※ THE LIVE STREAM SCHEDULE IS BASED ON KOREA STANDARD TIME (KST / UTC +9).

Room A (Tamna Hall)

Thursday, April 29, 2021 | Room A (Tamna Hall, 8F)

Session 9A: Variable Refrigerant Flow Heat Pumps and Air-conditioners

Session Chair: Sophie Hosatte (Natural Resources Canada – CanmetENERGY, Canada)

09:00~09:20	Keynote	[210]	Impact of Variable Speed Components on the Seasonal Performance of a Residential Air-Source Heat Pump Fatih Meral (Purdue University, Ray W. Herrick Laboratories) † , Oliver Obst (Purdue University, Ray W. Herrick Laboratories), Eckhard Groll (Purdue University, Ray W. Herrick Laboratories), Nicholas P. Salts (Purdue University, Ray W. Herrick Laboratories)
09:20~09:35		[112]	A Parameter-estimation Model for Variable Refrigerant Flow Heat Pump Systems Aziz Mbaye (Polytechnique Montréal) † , Massimo Cimmino (Polytechnique Montréal)
09:35~09:50		[196]	Investigation of VRF System under Cooling Mode through Field Testing and Machine Learning-based Modeling Hanlong Wan (University of Maryland), Tao Cao (University of Maryland), Yunho Hwang (University of Maryland) † , Heunghee Bae (LG Electronics), Saikee Oh (LG Electronics)
09:50~10:05		[082]	Experimental and Mechanistic Numerical Analysis of a Variable Speed Residential Heat Pump Unit with an Expansion Work-Recovery Device Riley B. Barta (Purdue University, Ray W. Herrick Labs) † , Ammar M. Bahman (Purdue University, Kuwait University), Lennart Stania (Purdue University, Ray W. Herrick Labs), Davide Ziviani (Purdue University, Ray W. Herrick Labs), Eckhard A. Groll (Purdue University, Ray W. Herrick Labs)
10:05~10:20		[283]	Next-Generation Residential Space Conditioning System in the United States Ammi Amarnath (Electric Power Research Institute) † , Sara Beaini (Electric Power Research Institute), Aaron Tam (Electric Power Research Institute), Jerine Ahmed (Southern California Edison Company)
10:20~10:40	Coffee Break and Poster Session		

Thursday, April 29, 2021 | Room A (Tamna Hall, 8F)

Session 10A: Sorption Heat Pumps (3)

Session Chair: Brian Fricke (Oak Ridge National Laboratory, United States)

10:40~11:00	Keynote	[086]	Effect of Evaporator and Condenser in the Analysis of Adsorption Chiller Woo Su Lee (Sejong University), Jae Dong Chung (Sejong University) † , Moon Yong Park (Sejong University), Xuan Quang Duong (Sejong University), Ngoc Vi Cao (Sejong University)
11:00~11:15		[049]	Experimental Study on an Absorption Heat Pump Prototype Applied for Rural Residential Heating Ding Lu (Technical Institute of Physics and Chemistry, Chinese Academy of Sciences), Maoqiong Gong (Technical Institute of Physics and Chemistry, Chinese Academy of Sciences) † , Yin Bai (Technical Institute of Physics and Chemistry, Chinese Academy of Sciences), Yanxing Zhao (Technical Institute of Physics and Chemistry, Chinese Academy of Sciences), Xueqiang Dong (Technical Institute of Physics and Chemistry, Chinese Academy of Sciences)
11:15~11:30		[095]	Energy Performance Comparison of Two Different Types of Heat Pump-driven Liquid Desiccant-assisted Air-Conditioning Systems for an Apartment Building Jae-Hee Lee (Hanyang University), Hansol Lim (Hanyang University), Hye-Won Dong (Hanyang University), Jae-Weon Jeong (Hanyang University) †
11:30~11:45		[118]	Experimental Investigation on the Influence of Bubble Pump on the DAR Performance Hyung Won Choi (Korea University), Gawon Lee (Korea University), Jang Seok Lee (LG Electronics Inc.), Byung Ha Kang (Kookmin University), Yong Tae Kang (Korea University) †
11:45~12:00		[094]	Energy Benefits of Ventilation, Dehumidification, and Water Heating System Based on Liquid Desiccant Cycle Soo-Jin Lee (Hanyang University), Hansol Lim (Hanyang University), Yong-Kwon Kang (Hanyang University), Jae-Weon Jeong (Hanyang University) †
12:00-13:00	Lunch and Poster Session		

Thursday, April 29, 2021 | Room A (Tamna Hall, 8F)

Session 11A: Industrial Heat Pumps (2)

Session Chair: Jun Young Choi (Korea Testing Laboratory, Korea)

13:00~13:20	Keynote	[322]	Categorization of Industrial Heat Pump for Integrated Simulation Technology Jongsoo Jeong (Waseda University), Akihiro Ichikawa (Waseda University), Yoichi Miyaoka (Waseda University) † , Takaoki Suzuki (Waseda University), Seiichi Yamaguchi (Waseda University), Kiyoshi Saito (Waseda University)
13:20~13:35		[232]	Experimental Setup and Test of a Desalination System Using a Heat Pump Soo Kwang Yang (Pusan National University), Hae Eun Song (Pusan National University), Young Chull Ahn (Pusan National University) †
13:35~13:50		[342]	Experimental Investigation of Parameters Affecting Drying Time and Power Consumption of a Heat Pump Tumble Dryer Mehdi Rasti (Pusan National University), Su-Il Park (LG Electronics), Geun-Hyung Lee (LG Electronics), Ji Hwan Jeong (Pusan National University) †
13:50~14:05		[241]	Method for a Quick Economic Assessment of Vapor Compression Heat Pumps Dominik Seliger (TU Wien) † , Daniel Lange (TU Wien), Veronika Wilk (AIT), Jürgen Fluch (AEE INTEC), Karl Ponweiser (TU Wien)

14:05~14:20		[271]	Heat Pump and Thermal Energy Storage Integration in Non-continuous Processes – An Application to the Food Industry Raphael Agner (Lucerne University of Applied Sciences and Arts), Edward J. Lucas (Lucerne University of Applied Sciences and Arts) † , Lorenz P. Rast (Lucerne University of Applied Sciences and Arts), Jan A. Stampfli (Lucerne University of Applied Sciences and Arts), Beat Wellig (Lucerne University of Applied Sciences and Arts)
14:20-14:40	Coffee Break and Poster Session		

Thursday, April 29, 2021 | Room A (Tamna Hall, 8F)

Session 12A: Heat Pumps combined with Thermal Energy Storage and Recovery

Session Chair: Marion Bakker (NL Delegate, Netherlands)

14:40~15:00	Keynote	[178]	Dynamic Performance Tests of a Heat Pump Cycle Integrated Latent Heat Thermal Energy Storage for Optimized DHW Generation Klemens Marx (AIT Austrian Institute of Technology) † , Johann Emhofer (AIT Austrian Institute of Technology), Tilman Barz (AIT Austrian Institute of Technology), Johannes Krämer (AIT Austrian Institute of Technology), Philipp Mascherbauer (AIT Austrian Institute of Technology), Luisa F. Cabeza (Universitat de Lleida), Gabriel Zsembinszki (Universitat de Lleida), Andreas Strehlow (AKG Verwaltungsgesellschaft mbH), Birgo Nitsch (AKG Verwaltungsgesellschaft mbH), Michael Wiesflecker (OCHSNER Wärmepumpen GmbH), Raimund Zitzenbacher (OCHSNER Wärmepumpen GmbH)
15:00~15:15		[307]	Heating System based on Heat Recovery from Sewage Carlos Infante Ferreira (Delft University of Technology) † , Maneesh Avadhani (Delft University of Technology), Roland van Rooyen (Gemeente Rotterdam)
15:15~15:30		[008]	Range of Application of Heat Pumps - Implementation of Heat Pumps with Different Heat Sources Franziska Bockelmann (Steinbeis-Innovationszentrum (SIZ) energie+) † , Markus Peter (Steinbeis-Innovationszentrum (SIZ) energie+), Mathias Schlosser (Steinbeis-Innovationszentrum (SIZ) energie+)
15:30~15:45		[254]	In-situ Analysis of a Centralized Wastewater Heat Pump for a Complex of High Energy Standard Buildings Simon Callegari (University of Geneva) † , Fleury De Oliveira Filho (University of Geneva), Pierre Hollmuller (University of Geneva), Carolina De Sousa Fraga (University of Geneva)
15:45~16:00	Break		

Thursday, April 29, 2021 | Room A (Tamna Hall, 8F)

16:00~17:00 Closing Ceremony

Host: Minsung Kim (Chung-Ang University, South Korea)

- Opening Speech (Per Jonasson, IOC Chair, Sweden)
- Award Ceremony (Per Jonasson, IOC Chair, Sweden)
  - Ritter von Rittinger Award
  - Global Student Video Competition
- Conference Report & Closing Speech (Minsung Kim, Secretary General, Korea)
- The 14th IEA Heat Pump Conference (HPC 2023) (Brian A. Fricke, Chair of U.S. National Organizing Committee, U.S.)
- Closing Remarks(Minsung Kim, Secretary General, Korea)

Room B (Halla Hall)

Thursday, April 29, 2021 | Room B (Halla Hall, 8F)

Session 9B: Heat Exchangers (2)

Session Chair: Ed Vineyard (U.S. Department of Energy, United States)

09:00~09:20	Keynote	[109]	Refrigerant Circuitry Optimization of Heat Exchangers for Charge Reduction and Robust Performance in Reversible Heat Pump Application Vikrant Aute (University of Maryland) † , Zhenning Li (University of Maryland), Jiazhen Ling (University of Maryland)
09:20~09:35		[332]	Proof-of-Concept Testing of Adhesive Joints for HVAC&R Applications Haotian Liu (Purdue University) † , Patrick J. Geoghegan (Oak Ridge National Laboratory), Justin A. Weibel (Purdue University), Davide Ziviani (Purdue University), Eckhard A. Groll (Purdue University)
09:35~09:50		[344]	Effect of Shape Change in the Flow Dirction of Mini-channel on the Flow Patterns Haruki Mitarai (The University of Electro-Communications), Tetsuya Kobayashi (The University of Electro-Communications), Koji Enoki (The University of Electro-Communications) † , Kousaku Nishida (MAYEKAWA MFG. Co. Ltd), Ikurou Akada (MAYEKAWA MFG. Co. Ltd)
09:50~10:05		[314]	Refrigerant Circuitry Optimization of an Outdoor Unit Heat Exchanger based on Partial Load Operating Conditions Shehryar Ishaque (Kyungpook National University), Man-Hoe Kim (Kyungpook National University) †
10:05~10:20		[110]	A Dynamic Model for Microchannel Heat Exchanger under Frost Conditions Jiazhen Ling (University of Maryland) † , Lingzhe Wang (University of Maryland), Rohit Dhumane (Modine Manufacturing Company), Vikrant Aute (University of Maryland)
10:20~10:40	Coffee Break and Poster Session		

Thursday, April 29, 2021 | Room B (Halla Hall, 8F)

Session 10B: Dehumidification Technology

Session Chair: Bamdad Bahar (Xergy Inc., United States)

10:40~11:00	Keynote	[003]	Comparison on Vacuum Membrane Dehumidification Systems with Moisture Selective Dense Membrane Hyunjeong Lim (Hyundai Motor Co.), Jinwook Lee(Chung-Ang University), Donik Ku (Chung-Ang University), Sangmi Choi (LG Electronics Inc.), Soyeon Kim (Chung-Ang University), Minkyu Jung (Chung-Ang University), Jihun Lim (Chung-Ang University), Minsung Kim (Chung-Ang University) †
11:00~11:15		[026]	Active Humidity Control for Refrigeration Applications Bamdad Bahar (Xergy Inc.) † , Jacob Zerby (Xergy Inc.)
11:15~11:30		[090]	Theoretical Analysis of Mass Transfer in a Vacuum Membrane Dehumidification System Hye-Jin Cho (Hanyang University), Seong-Yong Cheon (Hanyang University), Su Liu (Hanyang University), Jae-Weon Jeong (Hanyang University) †
11:30~11:45		[091]	Empirical Analysis of Dehumidification Performance of a Hollow-Fiber-Membrane Dehumidifier Seong-Yong Cheon (Hanyang University), Jae-Weon Jeong (Hanyang University) † , Hye-Jin Cho (Hanyang University), Jinyoung Ko (Hanyang University)
11:45~12:00		[054]	Membrane based Pervaporation for Heating and Cooling Bamdad Bahar (Xergy Inc.) † , Harish Opradishta (Xergy Inc.), Mark Stutman (Xergy Inc.), William Tomhon (Xergy Inc.)
12:00-13:00	Lunch and Poster Session		

Thursday, April 29, 2021 | Room B (Halla Hall, 8F)

Session 11B: Heat Pumps in HVAC Systems

Session Chair: Ji Hwan Jeong (Pusan National University, South Korea)

13:00~13:20	Keynote	[092]	Working Fluid Selection of Organic Rankine Cycle for a Liquid Desiccant System Hye-Won Dong (Hanyang University), Beom-Jun Kim (Hanyang University), Li-Hua Lin (Hanyang University), Jae-Weon Jeong (Hanyang University) †
13:20~13:35		[071]	Experimental Investigations of Two Types of the Dual-loop Heat Pump Systems for Ventilation Heat Recovery Lei Wang (Beijing University of Technology), Guoyuan Ma (Beijing University of Technology) † , Anna Ma (Beijing University of Technology), Xiaoya Jia (Beijing University of Technology), Yu Liu (Beijing University of Technology), Feng Zhou (Beijing University of Technology)
13:35~13:50		[175]	Analysis of the Impact of Different HVAC Configurations and Control Strategies on Primary Energy and Cost Savings for an Office Building Mara Magni (Universität Innsbruck) † , Fabian Ochs (Universität Innsbruck)
13:50~14:05		[145]	Fundamental Study on a Green Roof Building Air-conditioning System – Experimental Analysis of Summer Mode using a Reduction Model Apparatus Tzu Wei Yeh (Kokushikan University) † , Toshio Otaka (Kokushikan University) †
14:05~14:20		[224]	Single Source "Solar Thermal" Heat Pump for Residential Heat Supply: Performance with an Array of Unglazed PVT Collectors Korbinian Kramer (Fraunhofer ISE), Christian Schmidt (Fraunhofer ISE), Arim Schäfer (Fraunhofer ISE) †
14:20-14:40	Coffee Break and Poster Session		

Thursday, April 29, 2021 | Room B (Halla Hall, 8F)

Session 12B: Nearly Zero Energy Buildings

Session Chair: Stephan Renz (Beratung Renz Consulting, Switzerland)

14:40~15:00	Keynote	[167]	Cost Optimized Design of Ground Probe Fields with Solar Regeneration Carsten Wemhoener (HSR University of Applied Sciences Rapperswil), Simon Buesser (HSR University of Applied Sciences Rapperswil), Lukas Rominger (HSR University of Applied Sciences Rapperswil)
15:00~15:15		[066]	Control Optimization of a Double Stage Heat Pump with Desuperheater in Multi-family NZEBs Fabian Ochs (University of Innsbruck) † , Nicola Franzoi (University of Innsbruck), William Monteleone (University of Innsbruck), Georgios Dermentzis (University of Innsbruck)
15:15~15:30		[042]	Control Strategies for Modulating Heat Pumps in a Plus Energy Building Christina Betzold (Technische Hochschule Nuernberg Georg Simon Ohm) † , Susanna Bordin (Technische Hochschule Nuernberg Georg Simon Ohm), Arno Dentel (Technische Hochschule Nuernberg Georg Simon Ohm), Gunnar Harhausen (Technische Hochschule Nuernberg Georg Simon Ohm)
15:30~15:45		[165]	Energy Flexibility of Capacity-controlled Air-source Heat Pumps using Rule-based Control in Residential nZEB Carsten Wemhoener (HSR University of Applied Sciences Rapperswil) † , Lukas Rominger (HSR University of Applied Sciences Rapperswil), John Clauß (Norwegian University of Science and Technology, SINTEF Community), Laurent Georges (Norwegian University of Science and Technology)
15:45~16:00	Break		

Thursday, April 29, 2021 | Room A (Tamna Hall, 8F)

16:00~17:00	**Closing Ceremony**	Host: Minsung Kim (Chung-Ang University, South Korea)

Room C (Ara Hall)

Thursday, April 29, 2021 | Room C (Ara Hall, 8F)

Session 9C: Food Storage and Display

Session Chair: Eckhard Groll (Purdue University, United States)

09:00~09:20	Keynote	[122]	Risk Assessment of Built-in Refrigerated Display Cabinet Using A3 Refrigerant Koji Yamashita (the Japan Refrigeration and Air Conditioning Industry Association) †, Yoshihisa Sakamoto (the Japan Refrigeration and Air Conditioning Industry Association), Toshimasa Kato (the Japan Refrigeration and Air Conditioning Industry Association), Shigeki Ishihara (the Japan Refrigeration and Air Conditioning Industry Association), Akira Kobayashi (the Japan Refrigeration and Air Conditioning Industry Association), Hidekazu Kainuma (the Japan Refrigeration and Air Conditioning Industry Association), Takaharu Hasegawa (the Japan Refrigeration and Air Conditioning Industry Association), Katsuyuki Osawa (the Japan Refrigeration and Air Conditioning Industry Association), Hiroshi Nagai (the Japan Refrigeration and Air Conditioning Industry Association), Keiko Hosaka (the Japan Refrigeration and Air Conditioning Industry Association)
09:20~09:35		[250]	Performance Evaluation by Simulation of Refrigerated Display Cabinets Using HFO Refrigerant Koichi Kitamura (Waseda University), Yoichi Miyaoka (Waseda University) †, Takaoki Suzuki (Waseda University), Kosuke Bizen (Waseda University), Seiichi Yamaguchi (Waseda University), Kiyoshi Saito (Waseda University), Tadao Watanabe (Fuji Electric), Takahiro Iwasaki (Fuji Electric), Koji Takiguchi (Fuji Electric)
09:35~09:50		[286]	Evaluation of Interaction between Load of Refrigerated Display Cases and Air Conditioners in a Grocery Store Using CFD Chenghao Wei (Yokohama National University) †, Miwako Fujita (Chubu Electric Power, Co., Inc.), Daisuke Narumi (Yokohama National University)
09:50~10:05		[025]	Electrochemical Inerting (Oxygen Control) for Food Preservation Bamdad Bahar (Xergy Inc.) †, Jacob Zerby (Xergy Inc.)
10:05~10:20		[027]	Pervaporation Membrane for Refrigerator Vegetable Tray Applications Bamdad Bahar (Xergy Inc.) †, Jacob Zerby (Xergy Inc.), Anderson Bortoletto (Sub-zero Group Inc.)
10:20~10:40			Coffee Break and Poster Session

Thursday, April 29, 2021 | Room C (Ara Hall, 8F)

Session 10C: Heat Pump Performance

Session Chair: Guoyuan Ma (Beijing University of Technology, China)

10:40~11:00	Keynote	[130]	Energy Performance Estimation and Verification of an Industrial Waste Heat Recovery Heat Pump Toshihiko Okuno (Science Inc.), Takashi Kuwabara (Science Inc.), Jun Shishido (Tohoku Electric Power Co., Inc.), Katsumi Hashimoto (Central Research Institute of Electric Power Industry) † , Akira Koyama (Science Inc.)
11:00~11:15		[346]	Load-based Testing Methodology for Evaluating Advanced Heat Pump Control Design Parveen Dhillon (Ray W. Herrick Laboratories, Purdue University) † , W. Travis Horton (Ray W. Herrick Laboratories, Purdue University), James E. Braun (Ray W. Herrick Laboratories, Purdue University)
11:15~11:30		[123]	Economical and Environmental Data Analysis of Hybrid HVAC System of Air Source Heat Pump and Natural Gas Furnace for Cold Climate – Canada Gulsun Demirezen (Ryerson University) † , Khalid Ullah (Ryerson University), Amirali Rokn (Ryerson University), Alan S. Fung (Ryerson University)
11:30~11:45		[102]	Dynamic Modeling and Charge Minimization Study of a Packaged Propane Heat Pump with External Flow Reversal for Cold Climates Tyler Shelly (Purdue University), Davide Ziviani (Purdue University) † , Riley Barta (Purdue University), Eckhard Groll (Purdue University)
11:45~12:00		[101]	An Air-water Dual-source Heat Pump System for Shrimp Ponds Jia-Hao Cheng (Tongji University), Peng Gao (Tongji University), Xiang Cao (Tongji University), Peng Shao (Tongji University), Liang-Liang Shao (Tongji University), Chun-Lu Zhang (Tongji University) †
12:00-13:00	Lunch and Poster Session		

Thursday, April 29, 2021 | Room C (Ara Hall, 8F)

Session 11C: Advanced Controls and Modelling

Session Chair: Veronika Wilks (AIT Austrian Institute of Technology GmbH, Austria)

13:00~13:20	Keynote	[096]	Deep Learning-based Refrigerant Charge Fault Detection Method of Air-source Heat Pump System Yong Hwan Eom (Seoul National University), Sung Bin Hong (Seoul National University), Jin Woo Yoo (KIMM), Min Soo Kim (Seoul National University) †
13:20~13:35		[339]	Energy Saving Pre-cooling Pattern Search of an Inverter Air Conditioner Using a Deep Reinforcement Learning Algorithm Myung Sup Yoon (Korea Testing Laboratory) † , Won Sik Yoon (Korea Testing Laboratory)
13:35~13:50		[236]	Application of a Deep Reinforcement Learning Algorithm in Household Inverter Air-conditioner Temperature Control Myung Sup Yoon (Korea Testing Laboratory) † , Won Sik Yoon (Korea Testing Laboratory), Jong-Seok Lee (Yonsei University)
13:50~14:05		[032]	Optimization of Phase Change Thermal Energy Storage Unit based on a New Thermal Resistance Model Lingkun Liu (Gree Electric Appliances, Inc. of Zhuhai), Xiangfei Liang (Gree Electric Appliances, Inc. of Zhuhai) †
14:05~14:20		[074]	Model Calibration of an Air Source Heat Pump System for Transient Simulations in Modelica Philipp Mehrfeld (RWTH Aachen University, E.ON Energy Research Center, Institute for Energy Efficient Buildings and Indoor Climate) † , Markus Nürenberg (RWTH Aachen University, E.ON Energy Research Center, Institute for Energy Efficient Buildings and Indoor Climate), Dirk Müller (RWTH Aachen University, E.ON Energy Research Center, Institute for Energy Efficient Buildings and Indoor Climate)
14:20-14:40	Coffee Break and Poster Session		

Thursday, April 29, 2021 | Room C (Ara Hall, 8F)

Session 12C: Smart Applications of Heat Pumps

Session Chair: Rolf-Iver Hagemoen,(EHPA, Norway)

14:40~15:00	Keynote	[268]	From Smarties, Ice-cream and Flowers Thomas Nowak (European Heat Pump Association AISBL) † , Eirini Litina (European Heat Pump Association)
15:00~15:15		[203]	Evaluation of a Lab Scale Low Charge Heat Pump Circuit Using Propane Lena Schnabel (Heating and Cooling Technologies), Clemens Dankwerth (Heating and Cooling Technologies) † , Timo Methler (Heating and Cooling Technologies), Simon Braungardt (Heating and Cooling Technologies), Thore Oltersdorf (Heating and Cooling Technologies), Christian Sonner (Heating and Cooling Technologies), Marek Miara (Heating and Cooling Technologies), Peter Schossig (Heating and Cooling Technologies)
15:15~15:30		[183]	Heat Pumps for nZEB in a Nordic Climate – Comparison of Field Data with Predicted Performance and LCC Analysis of Different Heat Pump Heating and Ventilation Systems Caroline Haglund Stignor (RISE Research Institutes of Sweden), Ola Gustafsson (RISE Research Institutes of Sweden), Markus Lindahl (RISE Research Institutes of Sweden), Svein Ruud (RISE Research Institutes of Sweden) †
15:30~15:45		[310]	Performance Analysis of a Vapor Extraction Heat Pump System for District Heating/Cooling Applications Aziz Mbaye (He-Tech Suisse), Malick Kane (University of Applied Sciences and Engineering, HES//SO Fribourg) †
15:45~16:00	Break		

Thursday, April 29, 2021 | Room A (Tamna Hall, 8F)

16:00~17:00 **Closing Ceremony**

Host: Minsung Kim (Chung-Ang University, South Korea)

POSTER SESSION

APRIL 27-29, 2021

Lobby (8F)

Track 1: Residential and Building applications

1 [013] Experimental Research on Air-source Heat Pump Using Heat Pipes as Heat Radiator
Shuxue Xu(Beijing University of Technology) † , Guoyuan Ma(Beijing University of Technology),Yueyue Shao(Beijing University of Technology),Yueyue Wang(Beijing University of Technology)

Abstract

Membrane heat pump using vacuum membrane dehumidification (VMD) systems have been investigated recently due to the potential of significant enhancement of energy efficiency. The principal of VMD systems lie in the nature of selective transmission of moisture through dense membrane. The driving force of separation is the vapor pressure gradient between feed and permeate side of a membrane, and the vapor is discharged to the atmosphere through a vacuum compressor. In this paper, performance analysis of three different type of VMD systems – a bypass air mixed type, a water vapor discharge type, and a condenser combined type – are compared to evaluate the performance under same temperature and humidity condition. From the simulation, water vapor discharge VMD shows the best dehumidification COP than others. Further, some conditions like ambient air temperature and relative humidity conditions or minimum vapor pressure difference which are assumed in the basic simulation are varied to simulate in depth. Simulation results are discussed at a practical application point of view.

Keywords: Vacuum membrane dehumidification; Dense membrane; Vacuum compressor; Dehumidification COP;

1. Introduction

These days, cooling demand is rapidly increasing due to global warming and globally increased cooling demand [1]. However, conventional vapor compression cycle which has been widely used for cooling leads acceleration of global warming and ozone depletion because of refrigerants it uses. It is necessary to find new technologies from the different point of traditional ones. Most widely used traditional technology for cooling was vapor compression technology. Vapor compression cycles can supply space cooling to maintain a comfortable environment within buildings. Since it was started to use for artificial active cooling, many researchers tried to improve its efficiency and it contributed greatly to energy savings so far. However, it is not enough to satisfy increasing cooling demand due to the improvement of a standard of living. Heating, ventilation and air conditioning (HVAC) system is regarded as an important technology and it accounts for almost 40% of global energy consumption [2]. Moreover, conventional refrigerants used in vapor compression cycles cause global climate change and the ozone layer depletion when they are released to the atmosphere. Some alternative refrigerants have low global warming potential, but they still have issues of toxicity, low efficiency, flammability or high equipment cost. To approach this problem by the new way, alternative systems are considered to replace classical vapor compression cycle.

According to Building Technologies Office in US Department of Energy, non-traditional technologies were evaluated by energy saving potential, installing and operational cost, complexity and realization possibility, etc [3]. From the report, moisture selective membrane was introduced as a key material to reduce energy

E-mail address: minsungk@cau.ac.kr.

consumption during cooling and dehumidification. So far, its potential of cooling for residential and commercial buildings in all climate regions was studied but yet to be realized as a commercial system.

As a successive study of the technical progress, this study investigated three types of vacuum membrane dehumidification systems by comparing their dehumidification COP. Simulation results were analyzed and compared under several reference conditions.

2. Description of Vacuum Membrane Dehumidification (VMD) System

A membrane is a selective barrier which is used to separate specific species from a mixture. Two sides of the membrane are referred as the feed side and the permeate side. Depending on existence of pores, a membrane can be classified into porous membrane or dense membrane. Porous membrane consists of physical pores sized from micro- to nanoscale. However, dense membrane consists of nanochannels without physical pores, where only a selected gas can pass through with a theoretical background of a solution-diffusion model [4]. When material of the dense membrane is hydrophilic ions, only water vapor can be separated from the air (Fig. 1). In this case, the vapor pressure difference between both sides of the membrane acts as the driving force [5-7]. Therefore, the water vapor can move to the other side by the water vapor pressure gradient. It means that separation can occur even if the absolute pressure of the feed side is lower than the permeate side.

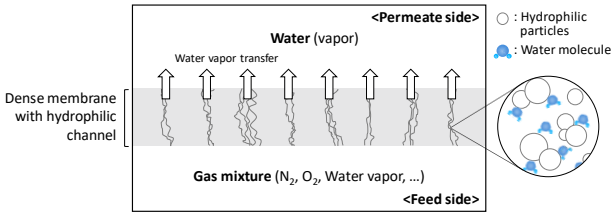

Fig. 1. Structure and vapor separation process of a dense membrane

VMD systems introduced from previous studies consist of a water selective dense membrane and a vacuum compressor [8]. Suction of the vacuum compressor is located at the permeate side of the membrane. Since the vapor pressure at the permeate side is lower than that of humid air, water vapor can be separated through the membrane, and the dehumidified air is supplied to conditioned space. As a simple configuration, direct compression vacuum membrane dehumidification system (D-VMD) is presented in Fig. 2.

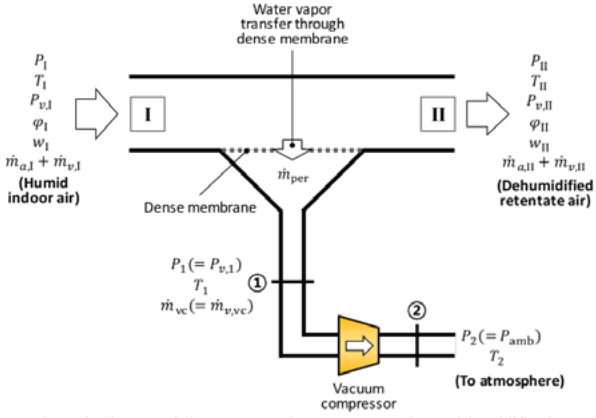

Fig. 2. Schematic diagram of direct compression vacuum membrane dehumidification system

As only water vapor is separated from the humid indoor air by vapor pressure difference, the permeate side pressure of the vacuum compressor inlet can be set below.

$$P_1 = P_{v,II} - \Delta P_{v,min} \quad (1)$$

where $\Delta P_{v,\min}$ is required minimum vapor pressure difference for separation. Since humid air is dehumidified continuously while passing the membrane surface, $\Delta P_{v,\min}$ is obtained based on the exit vapor pressure $P_{v,II}$ where the difference of vapor pressure is the minimized. Thus, $\Delta P_{v,\min}$ can be called pinch point vapor pressure difference which is conceptually the same as pinch point temperature difference in the general heat exchanger.

Since air temperature is kept constant and only absolute humidity (w_I) is decreased during the separation process, the mass flow rate of permeated water vapor can be calculated as below. Assuming that water vapor selectivity of the membrane is infinite, the only water vapor will pass the vacuum compressor.

$$\dot{m}_{vc} = \dot{m}_{per} = (w_I - w_{II})\dot{m}_{a,I} \tag{2}$$

Then the permeated water vapor is compressed to atmospheric pressure (P_{amb}) by the compressor and discharged outwards. However, since vapor pressures ($P_{v,I}$, $P_{v,II}$) are typically very low in a few kilopascals, very high compression ratio (r_{vc}) of 60~100 is required to eject the compressed water vapor, which makes D-VMD system unrealistic. To resolve the high compression ratio issue, several other modified VMD systems like bypass air mixed type, water vapor discharge type, and condenser combined type were proposed.

2.1. Bypass air mixed vacuum membrane dehumidification system (B-VMD)

Figure 3 presents a bypass air mixed VMD (B-VMD) system [9]. As shown in this figure, a portion of dehumidified air is bypassed to the permeate side through a throttling valve.

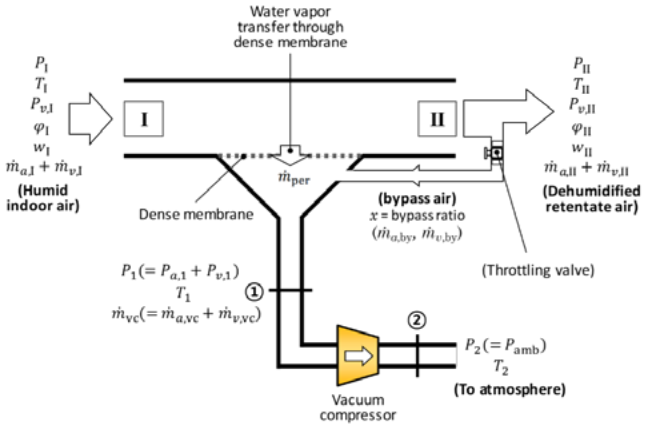

Fig. 3. Schematic diagram of bypass air mixed vacuum membrane dehumidification system

When bypass ratio x is defined by the fraction of bypassed retentate air to the permeate side, the dry air pressure of compressor inlet side ($P_{a,1}$) is multiplication of the bypass ratio and pressure of retentate air ($P_{a,II}$). Therefore, the total pressure of the vacuum compressor inlet side (P_1) becomes higher than the case of D-VMD. Since the vapor pressure of the permeate side is still lower than the feed side like Eq. (1), the vapor can be transferred from the feed side to the permeate side.

$$P_1 = P_{a,1} + P_{v,1} = xP_{a,II} + P_{v,II} - \Delta P_{v,min} \tag{3}$$

When two species are mixed at the same volume, volume flow rates of each material are calculated based on ideal gas law. At the compressor inlet side, the ratio of water vapor volume flow rate to the total flow rate is equal to the ratio of corresponding partial pressure as in Eq. (4).

$$\frac{\dot{V}_{v,1}}{\dot{V}_{a,1}+\dot{V}_{v,1}} = \frac{P_{v,1}}{P_{a,1}+P_{v,1}} \tag{4}$$

By combining Eq. (6) and ideal gas relation, bypass ratio (x) is derived as below.

$$x = \frac{P_{v,II}\dot{n}_{a,II} - P_{a,II}\dot{n}_{per} - \Delta P_{v,min}\dot{n}_{a,II}}{P_{a,II}\dot{n}_{v,II}} \quad (5)$$

Thus, the total mass flow rate through the vacuum compressor is presented as below.

$$\dot{m}_{vc} = \dot{m}_{a,vc} + \dot{m}_{v,vc} = \dot{m}_{a,by} + \dot{m}_{v,by} + \dot{m}_{per} = (x\dot{n}_{a,vc})M_a + (x\dot{n}_{v,vc})M_v + (w_I - w_{II})\dot{m}_{a,I} \quad (6)$$

In B-VMD system, since the mixture of permeated vapor and bypassed air is compressed by the vacuum compressor, compression ratio can be reduced in a reasonable level. However, as the flow rate through the vacuum compressor ($\dot{m}_{vc}$) increases, the vacuum compressor will consume more power.

2.2. Water vapor discharge vacuum membrane dehumidification system (W-VMD)

Figure 8 shows is water vapor discharge VMD (W-VMD) [10]. As seen in the figure, two membrane exchangers are located both at inlet and exit of the vacuum compressor. As in the previous configuration, the water vapor is permeated from the humid air through dense membrane 1. And the vacuum compressor pressurizes the water vapor higher than the vapor pressure of ambient side ($P_{v,III}$, $P_{v,IV}$). Then, the pressurized water vapor passes to the ambient side through dense membrane 2, which enables water vapor separation out of indoor air. As the water vapor is transferred through dense membrane 2, the state IV becomes the highest vapor pressure part of the ambient side. The compressor exit pressure is given as in Eq. (7), where the $P_{v,IV}$ is set slightly higher than $P_{v,III}$ because some permeated water vapor from the vacuum compressor is added to the ambient air stream.

$$P_2 = P_{v,IV} + \Delta P_{v,min} \quad (7)$$

From this concept, compression ratio of the vacuum compressor is lower by 3~5 because water vapor both at the compressor inlet and exit transfers based on partial vapor pressure. Due to the reduced compression ratio, compressor exit temperature is lowered in an acceptable range. Therefore, the flow rate and power consumption is getting much smaller since only water vapor passes the vacuum compressor.

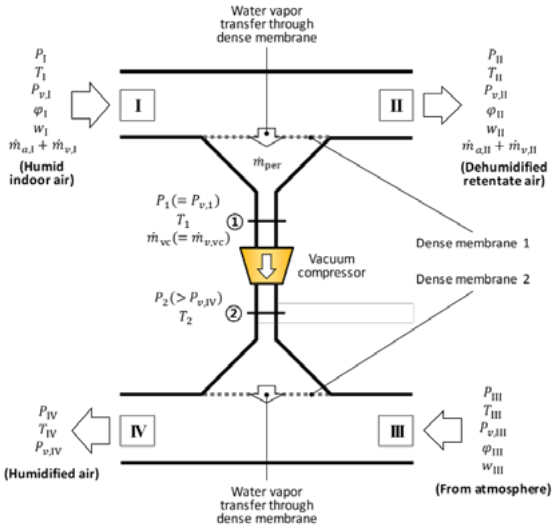

Fig. 4. Schematic diagram of water vapor discharge vacuum membrane dehumidification system

2.3. Condenser combined vacuum membrane dehumidification system (C-VMD)

The modified VMD model is a condenser combined VMD (C-VMD) system which is represented in Fig. 5 [11]. In this system, a condenser cooled by the ambient air is installed at the vacuum compressor exit, where

the compressed water vapor condenses to the liquid state. The condensed water is then rejected to the ambient by a condensed water pump.

In this system, the compressor elevates the vapor pressure to the saturation pressure (P_{cond}) where the condensation temperature (T_{cond}) becomes higher than the ambient air temperature (T_{amb}). Therefore, the compressor exit side pressure is defined as below.

$$P_2 = P_{cond} \tag{8}$$

Since compression ratio is lowered in a practical range for the same reason as the W-VMD system, the C-VMD system can be a potential candidate of the direct VMD systems.

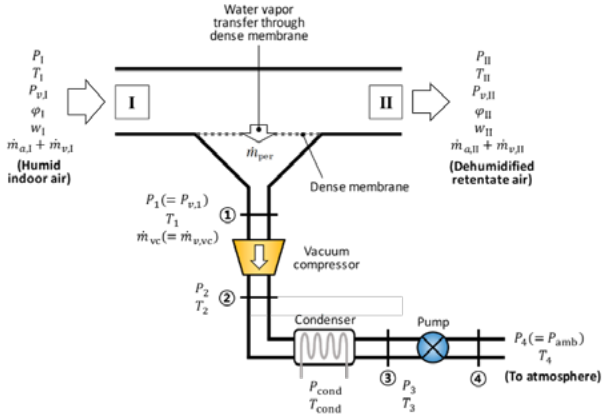

Fig. 5. Schematic diagram of condenser combined vacuum membrane dehumidification system

3. Simulation Methodology

Simulation conditions are set as in Table 1. In the VMD systems, dehumidification process is isothermal so no sensible cooling is considered, where dry bulb temperature of the retentate air and the feed air is the same.

Table 1 Simulation conditions for thermodynamic performance analysis of vacuum membrane dehumidification system

Location	Parameters	Values
Indoor air (Feed air) (I)[1)]	Dry bulb temperature (T_I) [°C]	27
	Relative humidity (φ_I) [%]	46.94
	Absolute humidity (w_I) [kgv/kga]	0.01045
	Mass flow rate ($\dot{m}_I$) [kg/s]	0.05
	Vapor pressure ($P_{v,I}$) [kPa]	1.6749
Retentate air (II)	Dry bulb temperature (T_{II}) [°C]	27
	Relative humidity (φ_{II}) [%]	32.59
	Absolute humidity (w_{II}) [kgv/kga]	0.00722
	Vapor pressure ($P_{v,II}$) [kPa]	1.1632
Ambient air (III)[2)]	Dry bulb temperature (T_{III}) [°C]	27 ~ 39
	Relative humidity (φ_{III}) [%]	40 ~ 90
	Absolute humidity (w_{III}) [kgv/kga]	0.00888 ~ 0.04123
	Vapor pressure ($P_{v,III}$) [kPa]	1.4272 ~ 6.3002
Membrane exchanger	Minimum vapor pressure difference ($\Delta P_{v,min}$) [kPa]	0.2 ~ 1.1
Vacuum compressor/Pump	Isentropic efficiency (η_{pump}, η_{vc}) [-]	0.8
Condenser	Temperature difference (ΔT) [°C]	3 ~ 7

[1)] The condition of indoor air are set based on ISO 5151 standard [12].
[2)] The specific condition of ambient air (35°C, 40.28% RH) is selected from ISO 5151 standard.

From the given total flow rate of feed air, $\dot{m}_I$= 0.05 kg/s, a set of absolute humidity (w) and vapor pressure (P_v) of indoor, retentate, and ambient air are calculated from each dry bulb temperature (T) and relative humidity (φ). The minimum vapor pressure difference ($\Delta P_{v,min}$) between the feed side and the permeate side is varied from 0.2 to 1.1 kPa. Isentropic efficiencies (η) of the compressor and the water pump are set as 0.8. For

the C-VMD model, temperature difference in a condenser (ΔT) is set as 5°C. The permeance of a dense membrane in the VMD systems is referred to σ. The selectivity of air is not considered, which means only water vapor but no air can pass the membrane during the separation. For the simulation, MATLAB software is used for the calculation by combining thermodynamic property database REFPROP 9.0 [13].

To simulate the W-VMD and C-VMD systems, the pressure of membrane permeate side is set equal to P_1 and calculated by Eq. (1) with the assumed minimum vapor pressure difference. Since there is only water vapor at the compressor inlet, it can be said that the total pressure is equal to the vapor pressure ($P_1 = P_{v,1}$). The vacuum compressor exit pressure (P_2) is different for each model. In the B-VMD, the mixture of dry air and water vapor is discharged to the ambient directly, so it is compressed to the atmospheric pressure. On the other hand, the exit pressure of W-VMD is calculated by Eq. (7) based on the vapor pressure of ambient air because there is one more membrane at the compressor exit side. In this case, the vapor pressure difference condition at this additional membrane mass exchanger must be satisfied as well. For C-VMD, P_2 is determined by the condenser temperature which is higher than the ambient air as in Eq. (8). Since the compressed water vapor is condensed by the ambient air, the discharge pressure should be at the saturated pressure of the condenser. Thus, the compression ratio (r_{vc}) of the vacuum compressor in each VMD systems is provided as below.

$$r_{vc} = \frac{P_2}{P_1} = \frac{P_2}{P_{v,II} - \Delta P_{v,min}} \tag{9}$$

Mass flow rates of feed air, retentate air and permeated water vapor are calculated by Eq. (2) and conditions in Table 1. Vacuum compressor mass flow rates for W-VMD and C-VMD are same as that of permeated water vapor, but it is different in B-VMD because the bypassed air is mixed with the permeated water vapor before it enters to the compressor. Therefore, mass flow rate through the vacuum compressor in B-VMD system is determined by Eq. (6). When isentropic efficiency of the vacuum compressor is given by η_{vc}, exit enthalpy is calculated as below.

$$h_2 = \frac{h_{2s} - h_1}{\eta_{vc}} + h_1 \tag{10}$$

From the compressor exit pressure and enthalpy, the exit temperature can be obtained. For the total work of C-VMD, work by the water pump in Eq. (12) is added to that of the vacuum compressor.

$$\dot{W}_{vc} = \dot{m}_{vc}(h_2 - h_1) \tag{11}$$

$$\dot{W}_{pump} = \dot{m}_{vc} \frac{v_{cond}(P_{amb} - P_{cond})}{\eta_{pump}} \tag{12}$$

The latent heat removed by the VMD systems can be calculated as below. For B-VMD system, $\dot{m}_{a,\mathrm{by}} h_{a,\mathrm{II}}$ is subtracted from the Eq. (13) due to feed air reduction by the bypassed air.

$$\dot{Q}_{lh} = (\dot{m}_a h_a + \dot{m}_v h_v)_I - (\dot{m}_a h_a + \dot{m}_v h_v)_{II} \tag{13}$$

COP_{DH} can be calculated by the total work and the total latent heat removed from the humid feed air passing the VMD system as in Eq. (14).

$$COP_{DH} = \frac{\dot{Q}_{total}}{\dot{W}_{total}} = \frac{\dot{Q}_{lh}}{\dot{W}_{vc}} \quad or \quad \frac{\dot{Q}_{lh}}{\dot{W}_{vc} + \dot{W}_{pump}} \tag{14}$$

4. Performance variation by ambient condition

From the above simulation models, the VDM systems are rated from W-VMD, C-VMD, to B-VMD in order of dehumidification performance. In this section, two VMDs of W-VMD and C-VMD which shows applicable performance among the three VMDs are compared as the variation of ambient air condition. For W-VMD, the ambient air is flowing at the permeate side of the membrane 2 at the compressor exit side. The discharged air from the compressor must have higher vapor pressure than that of the permeate side to pass through the membrane. In C-VMD, the vacuum compressor exit pressure (P_2) should be the saturation pressure at the condenser where saturation temperature is set higher by ΔT than ambient temperature. Thus, P_2 is closely related with T_{III}.

Figure 6 shows dehumidification performances simulated under various ambient temperatures. Ambient temperature is changed from 27°C to 39°C under relative humidity (φ_{III}) of 50%, 70%, and 90%. Since compressor exit pressure of the two systems are increased when both temperature and relative humidity increase, the vacuum compressor consumes more work to discharge the permeated vapor to the atmosphere, which results in degradation of COP_{DH}.

Additional simulation of C-VMD is conducted by varying the temperature difference at the condenser (ΔT). When changing the ΔT, the dehumidification performance of C-VMD is also changed because it affects the calculation of saturated vapor pressure. As shown in Fig. 7, when ΔT increases, COP_{DH} is decreased due to the rise of saturated vapor pressure. When we reduce ΔT by 3°C, C-VMD overtakes the performance of W-VMD in some cases of high humid condition in Fig. 7. This is because vacuum compressor exit pressure of W-VMD should be increased due to high vapor pressure of ambient air at the humid conditions. Surely, the larger the condenser size is, the better COP_{DH} becomes by reduced ΔT.

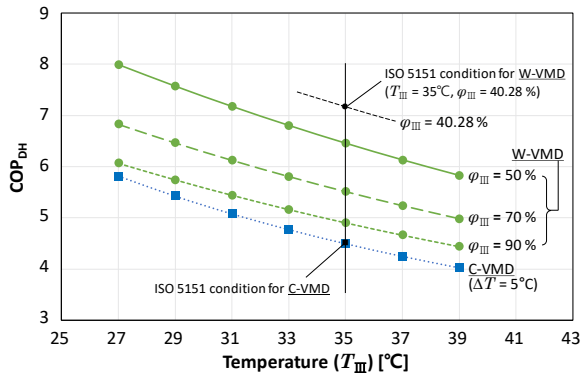

Fig. 6. Simulation results of W-VMD and C-VMD with various ambient temperature (TIII) and relative humidity (φIII) conditions

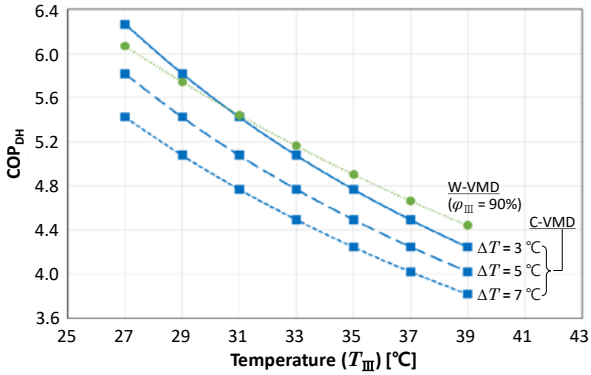

Fig.7. Simulation results of C-VMD with various ambient temperature (TIII) and ΔT conditions

Figure 8 presents a bar chart to compare dehumidification performance of the three VMD systems under selected combinations of ambient temperature and relative humidity. The minimum vapor pressure difference ($\Delta P_{v,min}$), the condenser temperature difference (ΔT), and bypass ratio (x) for B-VMD are fixed as 0.5 kPa, 5°C and 0.1266, respectively. As seen in the chart, the B-VMD system shows the lowest uniform COP_{DH} at all conditions since the performance of B-VMD is affected not by ambient condition but by bypass ratio. COP_{DH} of W-VMD shows a trend to decrease overall as increase of ambient temperature and humidity. As seen in the chart, COP_{DH} shows better performance at low ambient temperature. However, when comparing the humid case (T_{III}=29°C, φ_{III}=90%) and the hot dry condition (T_{III}=35°C, φ_{III}=40.28%), COP_{DH} of W-VMD shows higher value at the hot dry condition due to lower vapor pressure ($P_{v,III}$). Since vacuum compressor work in W-VMD depends on the exit side pressure which is a function of ambient vapor pressure, low ambient vapor pressure

will reduce vacuum compressor work and enhance dehumidification performance. COP_{DH} of C-VMD is continuously decreased as increase of ambient temperature because high ambient temperature requires high condenser temperature. But the performance of C-VMD is only a function of ambient temperature, and not influenced by ambient humidity. The difference between COP_{DH} of W-VMD and C-VMD is reduced in humid condition.

From the mathematical simulation in this study, W-VMD shows the best dehumidification performance among three VMD systems. In terms of COP_{DH}, W-VMD should be used for air conditioning, but there is some problem that must be overcome to use this system in practice. It is known that the vapor passes through the membrane by absolute vapor pressure gradient. However, since the total pressure of membrane 2 permeate side in W-VMD is higher about 30 times than the feed side, the total pressure difference may act as resistance of vapor transportation. Therefore, the membrane should have permeability high enough to transfer the desired mass flow of water vapor and also have durability to withstand the high-pressure difference.

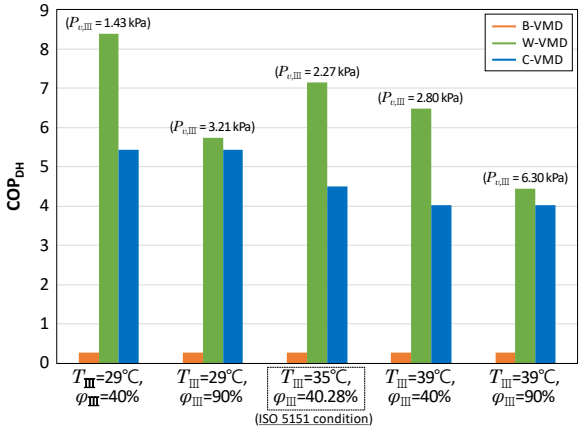

Fig. 8. Dehumidification performance of B-VMD, W-VMD, and C-VMD at selected temperature-humidity conditions of ambient air

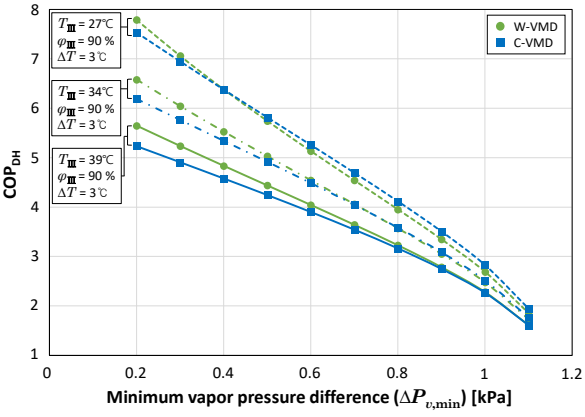

Fig. 9. Dehumidification COP variation by minimum vapor pressure difference

In contrast, C-VMD is practically simpler to implement than W-VMD from a technical point of view since only one membrane exchanger is required for C-VMD. With regard to the performance, C-VMD can compete COP_{DH} with W-VMD in a humid climate once the temperature difference of condenser (ΔT) is designed low. Figure 9 shows COP_{DH} of C-VMD and W-VMD about $\Delta P_{v,min}$ variation at 90% of relative humidity when ΔT is 3°C. In the figure, COP_{DH} of both systems tend to decrease as $\Delta P_{v,min}$ increases, but decline of C-VMD is smaller than that of W-VMD. Especially under low temperature condition, COP_{DH} of C-VMD exceeds W-

VMD partly. Therefore, considering the suitability of implementation, C-VMD can be an option to compete with the W-VMD system in humid climate.

5. Conclusion

Three VMD systems of bypass air mixed type (B-VMD), water vapor discharge type (W-VMD), and condenser combined type (C-VMD) are compared mathematically. In B-VMD system, a part of dehumidified air is bypassed to the vacuum compressor inlet, where the mixture of dry air and water vapor enters to the vacuum compressor. In contrast, since only water vapor exists at the vacuum compressor inlet in W-VMD and C-VMD, mass flow rate through the compressor is much smaller than the B-VMD case. In this manner, B-VMD shows much lower COP_{DH} than W-VMD and C-VMD by the simulation due to a large air flow through the compressor. W-VMD shows the highest dehumidification performance, but requires two membrane mass exchangers. To observe the performance under various climate condition, additional simulation was conducted for W-VMD and C-VMD.

As a recommendation of VMD system, W-VMD shows better performance overall than C-VMD. However, C-VMD shows comparable or better performance than W-VMD under hot and humid climate condition. Considering W-VMD requires two membrane mass exchanger, C-VMD can compete depending on the climate condition. Under the given minimum vapor pressure differences, $\Delta P_{v,\min}$ and compression ratio can be reduced for larger membrane size, which results in COP_{DH} enhancement. From the simulation, we can verify the performance of VMD systems at the design stage. For the experimental validation, the dense membrane having good performance is needed for small membrane size and high durability.

Nomenclature

COP	coefficient of performance [-]	φ	relative humidity [%]
h	enthalpy [kJ/kg]		
$\dot{m}$	mass flow rate [kg/s]	*Subscripts*	
$\dot{n}$	molar flow rate [kmol/s]	a	air
P_a	dry air partial pressure [kPa]	by	bypassed
P_v	vapor partial pressure [kPa]	cond	condenser
r	compression ratio [-]	DH	dehumidification
$\dot{V}$	volume flow rate [m^3/s]	I~IV	location of air flow
v	specific volume [m^3/kg]	lh	latent heat
$\dot{W}$	work [kW]	per	permeated
w	absolute humidity [kgv/kga]	s	isentropic
x	bypass ratio [mol/mol]	v	vapor
η	isentropic efficiency [-]	vc	vacuum compressor

Abstract

This paper presents a case study where steam at 1 MPa and 183°C (~140 psi/360°F) is produced using very high temperature heat pumps (VHTHPs) at a pharmaceutical research facility. Steam as an energy carrier has many benefits, and steam systems are also flexible when it comes to the primary source; steam can be generated using heat from combustion of fossil- or renewable fuels, nuclear reactors or directly from electricity. Generating steam using a heat pump can reduce greenhouse gas emissions. At full-scale operation the potential reduction in CO_2-emissions is more than 80%. The heat source for the heat pumps is mainly waste heat from cooling compressors at around 40°C (~100°F). The refrigerant is a natural refrigerant R-704 (Helium). Helium has both global warming potential (GWP) and ozone depletion potential (ODP) equal to zero and the toxicity and flammability classification of Helium is "A1". The working medium stays a gas throughout the cycle, which makes the heat pump process very suitable for use as VHTHPs while the heat pumps are highly adaptive to any changes in the sink or source temperatures.

1. Introduction

Health is central to a functioning society and connects us all. The pharma industry is a global industry given the possibility to provide health solutions valid to patients all around the globe. Being global in the health sector, one has to address the global issues affecting people's health. AstraZeneca recognises the strong connection between a healthy planet and healthy people and works with environmental protection. AstraZeneca's approach doing this is to follow the science, using science-based targets. The greenhouse gas emission targets are in line with limiting global warming to 1.5 degrees. A big part of lowering CO_2 emissions is to move from the use of fossil fuel to renewable energy. In the pharma industry steam is commonly used to provide the utility needed. Due to the temperature needed, steam is usually produced with fossil fuel, on site, and accounts for a large part of the energy usage at a pharma plant.

AstraZeneca Gothenburg have historically used fossil fuel for steam production with a switch from oil to natural gas in 1997. In 2018 a new switch took palace, this time from fossil natural gas to biogas, to produce steam with a low carbon fuel. A technical part of the upgrade was to pursuing steam production using high lift heat pumps - a more efficient, more robust, less expensive and if possible, even more sustainable solution.

To do this, the site has installed 3 high lift heat pumps. Each with a capacity of 500 kW_{th} at 10 bars steam system pressure and rejected heat from the chillers for the air condition as a heat source. Another one is schedule for 2020 with a capacity of 750 kW_{th}.

2. State-of-the-art of high and very high temperature heat pumps

There is no common acceptable definition of high temperature heat pumps (HTHP) or very high temperature heat pumps (VHTP). In their paper Arpagaus et al. [1] present some of the previous definitions and uses the definition as shown in the figure below.

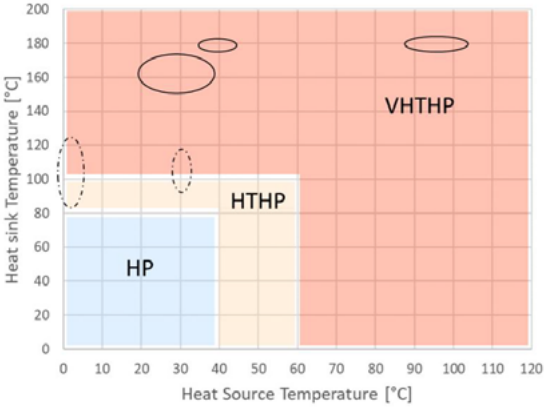

Figure 1. Classification of heat pumps according to the sink and source temperatures. The figure is adapted from Arpagaus et.al. [1]. The temperature range is extended to accommodate the possible temperatures for the HighLift heat pump. The solid line ellipses represent the temperatures for current HighLift installations, where the dotted ellipses represent earlier prototypes that are no longer in operation.

Arpagaus et al. identified more than thirteen manufacturers worldwide working on high temperature heat pumps in 2018. The technology, i.e. heat pump cycle and refrigerants, used in the heat pumps is diverse, though most use a single-stage vapour compressor cycle.

There is a lot of research and development in the field of high temperature heat pumps. For example, in the 12th IEA Heat Pump Conference (2017, Rotterdam), more than 40% of the presentations in the "industry" sessions discussed aspects of high temperature heat pumps. This indicates that there are likely more manufacturers with more mature high temperature heat pumps in the market today.

3. Environmental impact of heat pumps: energy use sustainability and environmental impact

In today's world, the increased availability of electricity from renewable sources may on one hand be intermittent but on the other hand is more predictable than the pricing levels for natural gas. In principle, HPs use a cheap renewable source for both input heat and electricity. System purchases are nonetheless often motivated by an attractive coefficient of performance (COP). Industry is increasingly implementing HP technology that circumvents the production of CO_2 when producing heat, although reaching sufficiently high temperatures may be challenging. A Stirling engine-based heat pump is one approach towards higher output temperatures. A challenge related to the goals of increasing output as well as efficiency, viz. the HighLift concept and its development, is that it conflicts with the thermodynamics that describes heat engines if the goals are simplified to having

- a higher temperature at the hot (water) side of the engine and a larger flow of heat carrier (helium) which can be achieved by raising the pressure of operation, and
- a higher coefficient of performance (COP_h), defined as heat output Q_{out} obtained per input of work (here electricity) W, with energy balance $Q_{out} = W + Q_{in}$, and $COP_h = Q_{out}/W$.

For an ideal, reversible heat engine the highest theoretical (Carnot) efficiency is defined as

$$COP_{Carnot} = \frac{Q_{out,reversible}}{W} = \frac{Q_{out,reversible}}{Q_{out,reversible} - Q_{in,reversible}} = \frac{T_H}{T_H - T_L} = \frac{1}{1 - \frac{T_L}{T_H}} \quad (1)$$

with the higher and lower temperatures of operation T_H and T_L, in K. This shows that raising the output heat temperature T_H with given T_L will inevitably result in a lower efficiency, or COP_h. For an engine that heats water from $T_L \sim 300$ K to $T_H \sim 450$ K the theoretical maximum COP equals $COP_{Carnot} = 3$. Current operation of the HighLift Stirling HP (500 kW per engine, heating water from 30°C to 180°C) gives a COP_h of 1.4 –

1.5: the goal is to raise that to COP_h 1.8 – 1.9 while heating water from 30°C to 200°C at an output of 750 kW. A more general approach of efficiency improvement of real systems involves suppressing irreversibilities that arise from

- friction between moving parts
- heat transfer across large temperature differences
- viscous flow friction in fluid flow lines and flow inlet/outlet section
- compression and expansion losses
- material losses as a result of leakage

Reducing friction between moving parts can achieved by proper design of rigid and flexible parts, and lubricant oils. Heat transfer is impossible without a temperature difference and a trade-off must be made (based on costs) between a large area for heat exchange operating with small temperature difference or vice versa: the first option gives higher losses. Viscous flow losses can be directly related to pressure drop and obviously a leakage of material at elevated pressure and temperature implies an obvious loss of energy. The first three listed will result in a production of entropy at a rate $\dot{S}_{gen}$ which can be used to quantify losses as $\dot{W}_{losses} = T^{\circ} \cdot \dot{S}_{gen}$ (J/s). Here, T° is the temperature of the surroundings, in K (here assumed = 288 K).

These losses imply that a larger work (electricity) input is needed for a given output heat target Q_{out} for a real system:

$$COP_h = \frac{\dot{Q}_{out}}{\dot{W}_{reversible} + \dot{W}_{losses}} = \frac{\dot{Q}_{in} + \dot{W}_{reversible} + \dot{W}_{internal\ losses}\left(1-\frac{T^o}{T}\right)}{\dot{W}_{reversible} + \dot{W}_{losses}} < \frac{\dot{Q}_{out,reversible}}{\dot{W}_{reversible}} \qquad (2)$$

with the (beneficial) complication that viscous friction results in heat that is taken up by a flow that is to be heated, which is not at all a full loss for a Stirling engine heat pump. Therefore, in (2) the internal losses that imply waste heat generation inside the Stirling engine are distinguished from external losses that cross the Stirling engine system boundary. For heat Q at temperature T produced from work W, the losses equate to W·(T°/T). It is clear that a larger electricity input is needed in order to cover for losses. See also Bejan (1997) [2] or Szargut et al. (1989) [3].

With an electrical-to-mechanical energy conversion efficiency η_{elec} = 95% and heat losses $\dot{Q}_{losses}$ to the surroundings found to be of the order of 20-30 kW, i.e. 5% of 500 kW for current operation, equation (2) can be reworked to

$$COP_h = \frac{\dot{Q}_{out}}{\dot{W}_{in}} = \frac{\dot{Q}_{in} - \dot{Q}_{losses} + \dot{W}_{in} - \dot{W}_{losses} + \dot{W}_{losses\ giving\ heat}}{P_{elec} \cdot \eta_{elec}} < \frac{\dot{Q}_{out,reversible}}{\dot{W}_{reversible}} \qquad (3)$$

correcting for input energy not contributing to raising the temperature of the water. Currently P_{elec} ~ 315 kW. Furthermore, heat transfer in the heat exchangers result in entropy production $\dot{S}_{gen} = \dot{Q} \cdot \frac{T_{hot} - T_{cold}}{T_{hot} \cdot T_{cold}}$ (with temperatures in K) giving losses $\dot{W}_{losses} = T^{\circ} \cdot \dot{S}_{gen}$, while pressure drop losses Δp (Pa) for (Helium) volume flow $\dot{V}$ (m^3/s) give additional (viscous friction) losses $\dot{W}_{losses} = \Delta p \cdot \dot{V}$. Following the above, a fraction (1 - T°/T) of the viscous friction losses will add to the useful heat output of the system.

Thus, (3) can be rewritten to give:

$$COP_h = \frac{\dot{Q}_{in} - \dot{Q}_{losses} + \dot{W}_{in} - \dot{W}_{losses} + \sum \Delta p \cdot \dot{V} \cdot \left(1-\frac{T^o}{T}\right)}{P_{elec} \cdot \eta_{elec}} < \frac{\dot{Q}_{out,reversible}}{\dot{W}_{reversible}} \qquad (4)$$

The assessment for the heat exchange applies to the regenerator as well: apart from viscous friction losses the heat transfer involves losses that can be estimated for the cycling heat transfer to/from the helium medium from/to the regenerator material matrix. For the heat transfer, with heat transfer $\dot{Q}$ to/from the helium with a temperature difference ΔT_{He} across the regenerator (here estimated ≈ the average value for average He temperature in the two respective heat exchangers – see also [4]) the entropy production can be estimated using the expression given above with an estimated cycle-average temperature difference $T_{hot} - T_{cold}$ ~ 15 K.

Using Ansys Fluent (v. 19.2) simulations for operation with pressure average 50 bar, amplitude 13 bar, frequency 10 s^{-1} it was found that 500 kW heat output operation will give $\dot{W}_{losses}$ = 30 - 35 kW for the two heat exchangers (being a bit higher for the low temperature heat exchanger than for the high temperature one). On top of this ~15 kW viscous flow losses occur inside the heat exchanger tubes. Pressure drop losses are much larger for the regenerator and inlet/outlet manifolds for that, giving ~ 40 kW viscous friction losses, while losses due to entropy generation in the regenerator add up to ~ 25 kW, with (cycle averaged) $T_{hot} - T_{cold}$ ≈ 15K. (Pressure drop losses are not considered for the side of the water that is heated as the pumping of this

is outside the Stirling engine system boundary.) Examples of calculated results are given in Figure 2, showing velocity intensity and temperature profiles.

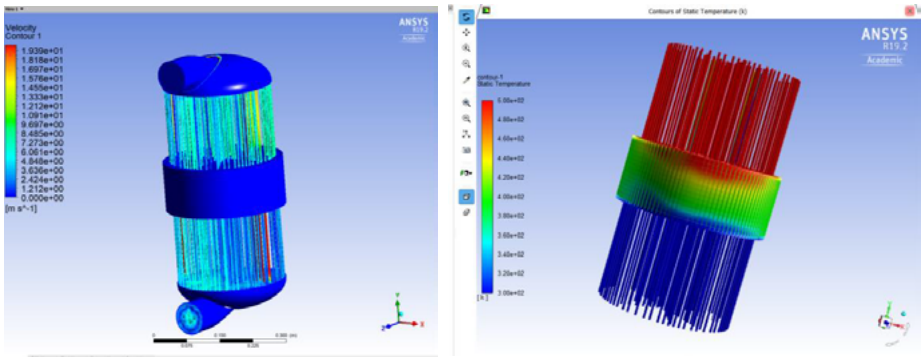

Figure 2. CFD simulated results for (cycle averaged) velocity (left) and temperature (right) for 500 kW heat output operation

A further source of losses are those related to real compression and expansion vs. ideal processes: for He the cycling expansion/compression from 37 to 63 bar gives losses of ~ 100 kW (the expansion stage giving somewhat larger values than the compression) – see [3, p119]. Fortunately these largely (~ 60%) imply generation of heat that stays inside the system (similar to the viscous friction losses), reducing the system losses to ~ 40 kW for this.

Combining all this gives with current operation with 300 kW effective power input that 45-50 kW of this is lost via entropy losses in the heat exchangers, while 55- 65 kW is lost in the regenerator plus ~ 40 kW compression/expansion losses. These add up to ~ 45% of the effective electricity input which, using the expressions for COP_h with heat input $\dot{Q}_{in}$ being of the order of 300 kW explains the value $COP_h = 1.4 – 1.5$. For the heat exchangers, a different design that gives small temperature gradients would be beneficial while for the regenerator the reduction of viscous flow losses is most beneficial. Indeed, such improvements are currently being implemented to the HighLift Stirling engines.

An issue that primarily relates to costs of operation are losses of helium. These are modest yet non-zero but won't give contribution to the enhanced greenhouse effect or ozone layer depleting as values for global warming potential (GWP) and ozone depletion potential are = 0.

4. The HighLift heat pump

The HighLift heat pump process is based on the Stirling cycle. For a more detailed description of the mechanical implementation see the previous work by the authors [5a]. Descriptions of other applications can be found in the papers in previous proceedings [6a, 7a]. Modern Stirling engine development starts with the work done by Philips Electronics BV in the Netherlands in the 1940s. See for instance the book by Finkelstein and Organ [8] for a historical review of the modern Stirling engine. The ideal Stirling cycle is a thermodynamic process that consists of four reversible process in series. A description of the ideal Stirling cycle is available in most introductions to technical thermodynamics, for instance in the book by Moran and Shapiro [9]. Compared to compression and absorption heat pumps, the working medium in a Stirling process is a gas throughout the process. This implies that the process is independent of the evaporation and condensation temperatures of the working medium. A common question from persons not familiar with the Stirling process is related to the choice of working medium. Even though the full story is more complicated, the efficiency of the choice of working medium can easily be seen from the equation below describing the reversible work of an ideal Stirling cycle by an ideal gas.

$$W = -m \cdot R \cdot (T_h - T_c) \cdot ln\left(\frac{V_1}{V_2}\right) \qquad (5)$$

where m is the mass of the working medium, R is the specific gas constant of the working medium, V is the volume, and T is the temperature. Subscripts "1" and "2" refer to initial and final states. As can be seen from the equation, the higher the value of the specific gas constant, the higher the work output from the cycle.

Noting that the specific gas constant for hydrogen, helium and air are approximately 4000, 2100 and 300 J/kgK respectively, it is easily understood why hydrogen and helium are prefered working media to air or nitrogen. The same argument is also valid for the reverse (heat pump) Stirling cycle.

The configuration of the heat pump is a double-acting alpha Stirling engine of the "Franchot" type. "Double-acting" means that the working medium is acting on both sides of the pistons. The Franchot type means in contrast to a "Rinia" or "Siemens" type configuration, one of the cylinders is always containing cold gas and one of the cylinders is hot gas.

5. The heat pump installation at AstraZeneca

The current HighLift heat pump installation at the R&D facility at AstraZeneca in Gothenburg, Sweden, consists of three heat pumps. These heat pumps are designed to deliver 500 kW of steam at full load, and the main motor is a 315 kW nominal power eight poles asynchronous motor. Below, two of the heat pumps in the heat pump room are shown.

Figure 3. Two of the three heat pumps currently installed at AstraZeneca's R&D facility in Gothenburg, Sweden. Heat is transferred to the heat pump from the heat recovery circuit and steam is delivered from the heat pumps' steam generators to the steam distribution system. The third heat pump is installed on the opposite side of the room.

Main components of the installations in addition to the heat pumps are the cold circuits, the hot circuits and the steam generators. The cold circuits are closed water circuits that transfer heat from the heat recovery system at the site to the heat pumps. The hot circuits are closed, pressurised water circuits that transfer heat from the heat pump to the steam generators. The steam generators are shell and plate heat exchangers that get feed water from the site's feed water tanks and generate steam by cooling the hot circuit from the heat pump. Steam thus generated is supplied directly to the steam distribution system at the site. The figure below (Fig 4) shows a simplified P&ID of the installation.

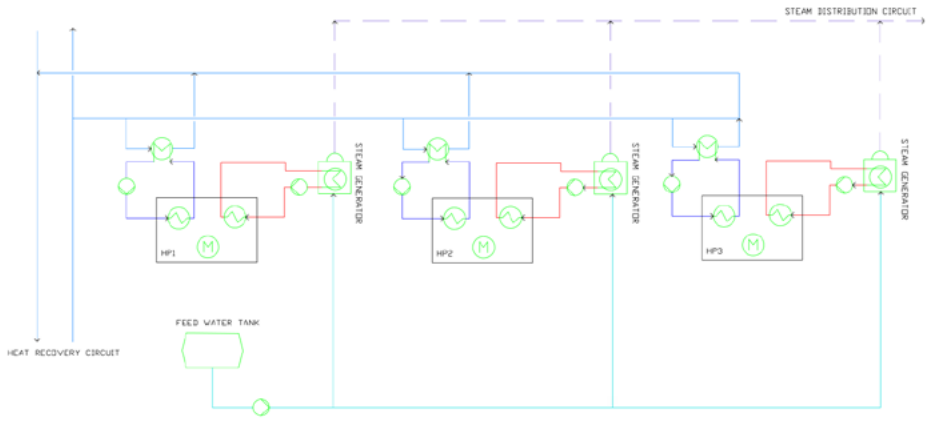

Figure 4. Simplified P&ID for the installation of the three heat pumps at the R&D facility. The cold heat source is a heat recovery circuit that is transferred indirectly to the heat pumps. The heat pump uses this heat to heat a hot circuit that circulates over a steam generator. The steam generator uses this heat to generate steam that is fed to the steam distribution circuit of the plant.

At the time of writing this, the heat pumps have been running for between 5000 and 6800 hours: pump #1 has a running time of 6800 hours, heat pump #2 5000 hours and heat pump #3 6500 hours respectively. The load has been varying, but the temperatures have remained quite constant. In order to present the performance of the heat pump, four cases have been selected from a two months period for heat pump #1. These are selected to have different load. Data for the cases is for a 30 hours period with 1-hour average values. The original data was sampled in 1s intervals except for the temperatures which were sampled in 10s intervals. In the following graphs the values are either based on average for all 30 hours or presented in form of intervals (box and whisker plots). The following figures (Fig. 5) show the average load for each period and the delivered heat as a function of the load for one heat pump.

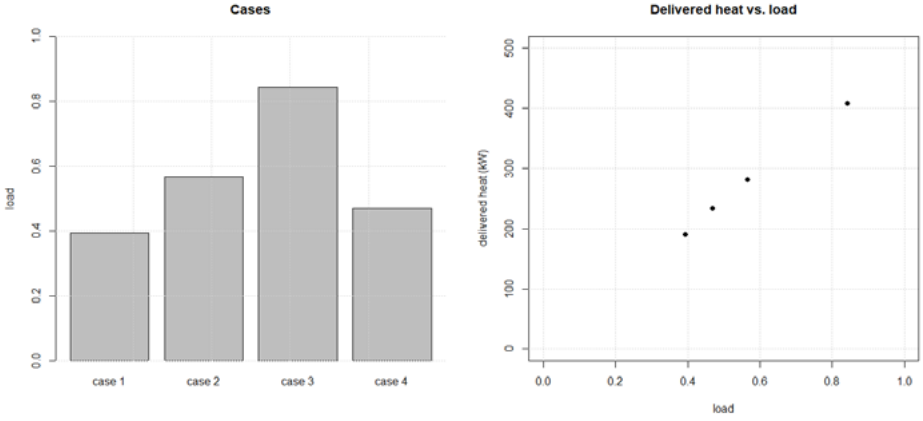

Figure 5. The load for the 4 cases for heat pump #1, where "1" equals full load. The loads and heat duty are average values for each of the cases.

The average temperatures of the external circuits are 183°C (363°F) and 27°C (75°F) on the hot and cold side respectively. The hot and cold side temperatures are presented in the two figures (Fig. 6 and Fig. 7) below.

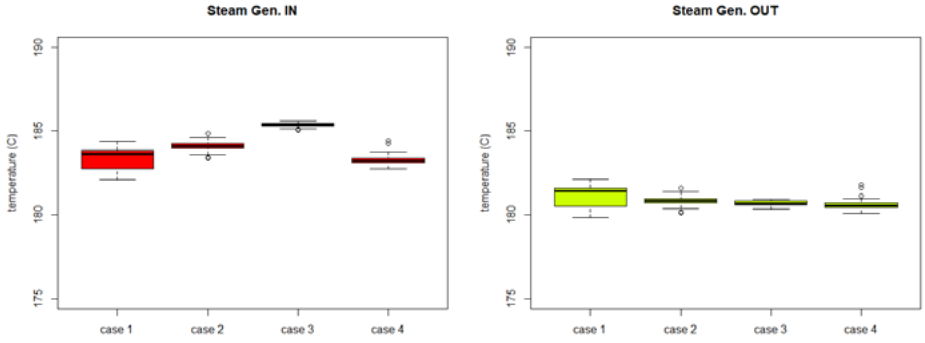

Figure 6. The temperatures of the hot circuit used to transfer heat from the heat pump to the steam generator. The hot water from the heat pump (steam gen. IN) enters the steam generator and heats the feedwater. The colder water is then returned to the heat pump.

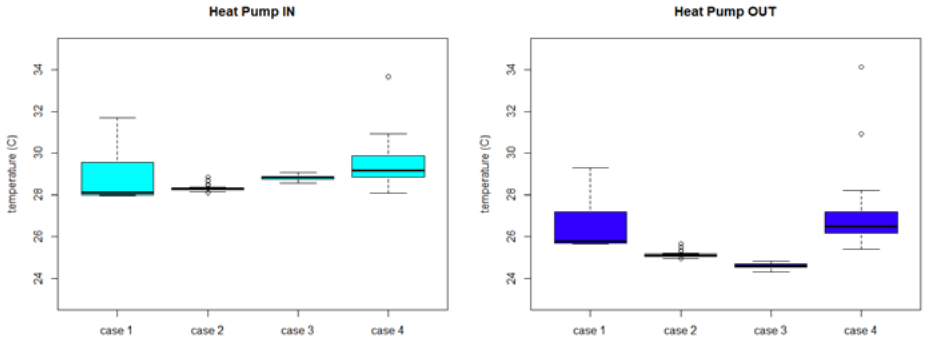

Figure 7. The heat is transferred from the heat recovery circuit to the heat pump via a closed circuit. The water enters the heat pump and is cooled down before returning to the heat exchanger between the closed circuit and the heat recovery circuit.

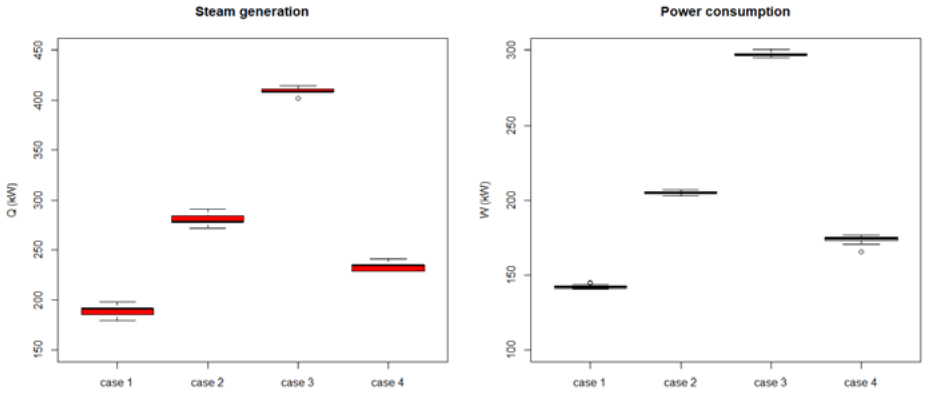

Figure 8. Steam generation and power consumption for the four cases. The steam generation is calculated from the flow of feed water, the feed water temperature and steam pressure. The power consumption is for the main motor and is sampled from the variable frequency drive.

As the conditions on the site are stable, the power consumption and the heat output are linear functions of the load. This can be seen in the figure above (Fig. 8), where the variations in the heat output (steam generation) and power consumptions for the four cases are presented.

The power consumption is only the consumption from the main motor that drives the heat pump measured from the variable frequency drive. In addition, two oil pumps add 1-2 kW of additional power that will not have major impact on the results. The system also has small circulation pumps running at partial load (0.75-2.2 kW full load) for the water circuits, which are not included in the analysis as they are not directly connected to the performance of the heat pump. Based on the power consumption and the steam generation, it is possible to estimate the coefficient of performance of the heat pumps as well as the system efficiency. This is presented in the figure (Fig. 9) below.

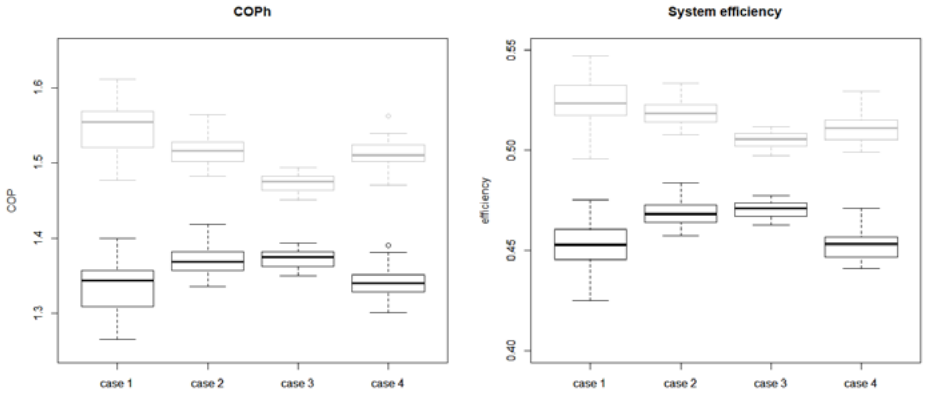

Figure 9. The coefficient of performance is defined as heat used to generated steam divided by the main motor consumption (i.e.$COP_h = Q_h/W$). The system efficiency is defined as the measured COP_h divided by the Carnot COP (i.e. $\eta_{system} = COP_h/COP_{carnot}$). The box and whisker plots in grey are estimated values for a fully thermally insulated heat pump.

During the operation of the heat pump, the heat loss has been higher than standard operation as large parts of the heat pump were not properly insulated. The heat loss has been estimated to approximately 30 kW, and the performance of a fully insulated heat pump is estimated and is shown in grey in the figures (Fig. 9) above.

6. Conclusions

A proven concept is described for a Stirling engine operated as an industrial-scale heat pump, delivering steam at 180°C. A brief assessment of losses and benefits is given, followed by technical performance data on the current installation at AstraZeneca's R&D centre in Sweden. Current activities involve improving system efficiency and reliability while increasing heat output from 500 to 750 kW, at the same time raising the TRL of the heat pump from level 7 to level 9.

Range of application of heat pumps - Implementation of heat pumps with different heat sources

Franziska Bockelmann*, Markus Peter, Mathias Schlosser*

Steinbeis-Innovationszentrum (SIZ) energie+, Mühlenpfordtstraße 23, 38106 Braunschweig, Germany

Abstract

Through the increasing use of heat pumps, the number of potentially usable low-temperature heat sources and associated heat exchangers on the market is increasing, too. Planners often do not have a sufficient overview of the available technologies and boundary conditions of the individual systems and components. Based on the current results and experiences together with the development of the pre-dimensioning program, further key aspects for the integration and use of heat pumps and various associated components will arise, which will be dealt with in the project “future:heatpump_II”. The following topics will be addressed in this article:

- compatibility of different heat pump technologies, such as absorption, adsorption or power-controlled heat pumps with different low-temperature heat sources and systems.
- consideration of a bivalent operating mode of two heat generators (e.g. heat pump and gas boiler). This is relevant, among other things, for concepts in multi-family and office buildings.
- integration of solar thermal energy for the regeneration of ground-coupled heat pumps.
- energy concepts and their planning with regard to the supply of buildings and districts by heat pumps.

Keywords: heat pump; low temperature heat source and heat exchanger system; system design; usage

1. Introduction

Heat pumps are an increasingly applied technology in the energy supply of buildings. This is also reflected in the sales figures and the variety of heat pumps available on the market. In order to maximize the potential of the entire energy supply system, the choice of the low-temperature heat source and the associated heat transfer system and the connection to the building is of crucial importance. In this context, the pre-dimensioning program WPSOURCE (developed as part of the R & D project "future:heatpump" at the Institute for Building Services and Energy Design (IGS) of the Technical University of Braunschweig) is a multifunctional tool that can be used in many areas for project-specific pre-selection and dimensioning of heat sources and heat exchanger systems for heat pumps.

On the basis of the results and experiences from the research project future: heatpump and the development of WPSOURCE, new key aspects arise with regard to the integration and application of heat pumps as well as various additional components that can be coupled with heat pumps. As part of the research project "future:heatpump_II", topics beyond the content of the research project future:heatpump will be dealt with. The processing and analysis of the selected aspects enable an extension of WPSOURCE and contribute to the increased use of heat pumps.

2. Pre-dimensioning program WP$_{SOURCE}$

In order to facilitate the evaluation of suitable heat pump systems together with their low-temperature heat sources (ground, water, air) and heat exchangers, as well as to promote the dissemination of heat pump technology in general, a clear compilation of different technological approaches is helpful. WP$_{SOURCE}$ is designed for the use by a broad range of users and considers different levels of detail and aspects in the planning of buildings and planning of heat pump systems. For this reason, flexibility and versatility is a key feature of WP$_{SOURCE}$ with the adjustments and settings.

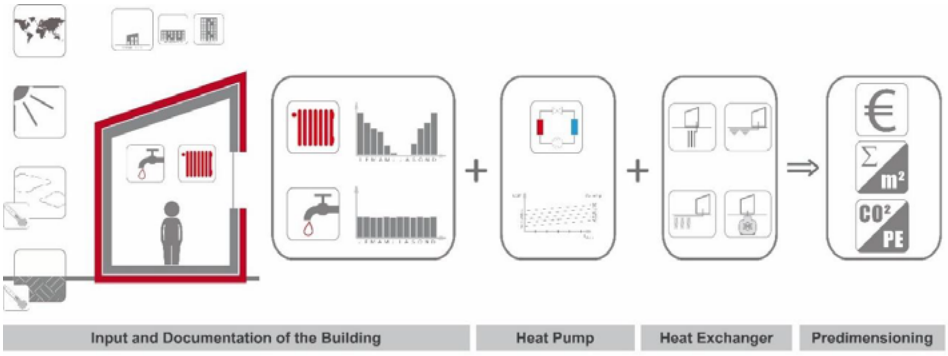

Fig. 1. Scheme for the structure and information flow in WP$_{SOURCE}$

The operation of WP$_{SOURCE}$ (Fig. 1) starts with the documentation and specification of the initial situation and the boundary conditions of the respective project. After entering general project data, the user enters known parameters such as the plot area, the type of building (single-family or multi-family house or office building) and its thermal standard as well as energy demand values, if applicable. In addition, the user specifies the heating and/or cooling system to be designed. From these inputs and other project-specific selection options for the building, the program determines the heating and cooling energy demand (kWh) as well as the heating and cooling capacity (kW).

In principle, a user with detailed knowledge of the basic data and of the heat pump system to be created can benefit from the program, as well as a user with only rough project information can. Depending on the level of information, the user can define the building, e.g. by means of data from an EnEV balance sheet (Energy Saving Regulation (Energieeinsparverordnung - EnEV) presents one of the most fundamental tools of the german federal government's energy and climate policy, it defines requirements and implementation tools for residential, non-residential buildings and refurbishments) [1], according to his own data on heating energy consumption or based on the building's type and year of construction.

Depending on the heating capacity requirement of the defined building, WP$_{SOURCE}$ uses heat pumps with corresponding performance for further calculation. The characteristics of the heat pumps implemented in the program were generated from data from a large number of devices currently on the market. The devices analytically generated for the program represent heat pumps of average quality for the respective output and are used for internal program calculations, e.g. of seasonal performance factor.

The required extraction energy from the low-temperature heat source is calculated using the average monthly coefficient of performance of the heat pump and the monthly heating requirement. This extraction energy forms an essential basis for the selection and (estimated) dimensioning of the low-temperature heat source.

On the basis of the inputs and the functions stored in the program, WP$_{SOURCE}$ derives the sizes required for pre-selection and approximate dimensioning of suitable low-temperature heat sources and associated heat exchangers for an individual application. Ecological (CO_2 emissions, primary energy) and economic factors (investment and operating costs) for the various low-temperature heat source/heat exchanger combinations are also documented.

Figure 2 shows an example of the user interface of WP$_{SOURCE}$. During the development, attention was paid to clarity and user-friendly operation.

Fig. 2: User interface for WPSOURCE (only in German available)

3. Extension of the pre-dimensioning program - additional applications and combinations of or with heat pumps

Today, heat pumps are no longer used exclusively to heat buildings as part of an energy supply concept for buildings. Within the framework of the development of climate-neutral building concepts, heat pumps are seen as a " fundamental element " and are combined with other components to form holistic supply concepts.

With the help of the WPSOURCE program and the extensions currently being implemented, e.g. bivalent systems or the integration of photovoltaics and solar thermal energy, the concept development and planning phase of buildings and systems is to be supported with a focus on sensible integration of regenerative energy sources and various energy producers. Therefore, it can support the dissemination of climate-neutral buildings in praxis.

Within the framework of the research project future:heatpump_II, solutions for additional topics will be developed and analyzed, which will be made available to the planner and user of the systems for practical use in an updated version of WPSOURCE. Different system combinations will be evaluated and meaningful results on their performance will be documented. In the course of the analyses and studies, the concepts under consideration are to be tested for their suitability for practice (meaningfulness and practicability). The results should scientifically prove which concepts are applicable for future buildings and which could possibly be too extensive.

In the following, the first results and work status of the key aspects of future:heatpump_II are summarized. During the project, the presented results for the different key aspects will be implemented in the pre-dimensioning program, so that at the end of the project a new extended version of the program with further energy concept approaches will be available.

3.1. Heat pump typologies and applicable low-temperature heat sources

As far as heat pump technologies are concerned, the current market situation in Germany can be characterised by different types of heat pump. The most common heat pump types can be classified as follows:

- Type of heat source (air, water, brine)
- Type of system to be heated, i.e. the heat sink (water or air)
- Type of driving energy (electric, gas)
- Type of compressor (thermal, electrical)
- Type of capacity control (On-Off, Inverter)

In addition to classic electric compression heat pumps, gas-operated heat pumps are increasingly being offered, although without high market shares yet, as well as different types of sorption heat pumps (thermally compressing absorption and adsorption heat pumps). (Fig. 3)

Gas-operated heat pumps are primarily an alternative to gas condensing boilers in existing buildings. Gas heat pumps and gas-powered sorption systems are based on gas condensing boiler technology, which is well established in Germany, and combine highly efficient gas condensing boiler technology with the use of environmental heat. Sorption heat pumps are currently only of minor importance on the market. Sorption technology is primarily used in refrigeration and is therefore more likely to be found on the market for cooling machines. In sorption technology, high temperatures are used as drive energy, mostly from waste heat from industrial processes (> 50°C or > 75°C). Low-temperature heat sources are therefore not suitable and can only be integrated as a heat source in conjunction with the gas-powered heat pump (driving energy: gas combustion).

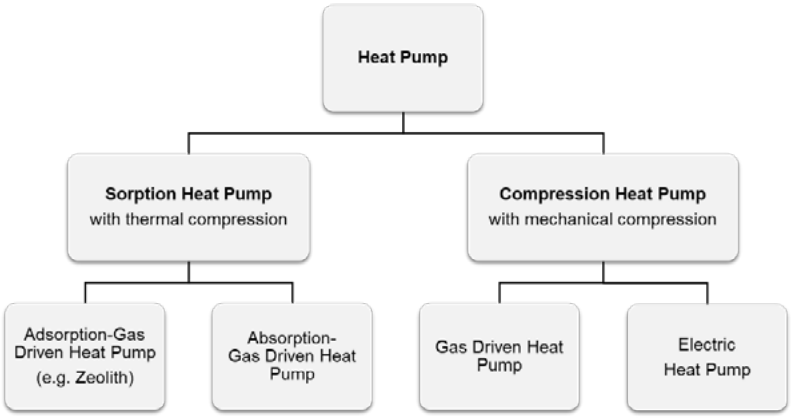

Fig. 3. Classification of heat pump types according to their drive technology

A comparison of the heat pump technologies mentioned shows that the mode of operation and the configuration of the individual designs differ only slightly from each other. All technologies can be used for space heating and domestic hot water production as well as for cooling in reversible operation. The fundamental difference between electric heat pumps and gas motor heat pumps is the type of compressor drive. The thermodynamic cycle is identical for both types. While in an electric compression heat pump an electric motor drives the compressor to compress the working fluid, in a gas heat pump this is done by a gas motor. In contrast to the electric drive, the heat generated by the operation of the gas engine is also used for heating, i.e. as useful heat. In addition to mechanical compressors, there is also so-called thermal compression. Sorption heat pumps use this process. A distinction is made here between absorption and adsorption heat pumps. Thermal compression in sorption heat pumps is based on the physical binding of a gas to a solid (adsorption) or the physical binding of a liquid or gas in a liquid (absorption). Both processes take place with the release of heat. With regard to the usability of different low-temperature heat sources with the heat pump technologies described, it can be seen that, in principle, all heat sources - outdoor air, brine and water - can also be used for gas-operated heat pumps, analogous to the electric heat pump (Fig. 4).

When dimensioning and planning a heat exchanger system, an advantage of gas-operated heat pumps (mechanical as well as thermal) becomes apparent. With this technology, the combustion heat can also be used and thus the source system is less stressed, i.e. less energy is withdrawn from it. For this reason, the heat exchanger system for using environmental heat with gas-operated heat pumps.can be made smaller in size than for conventional electric heat pumps.

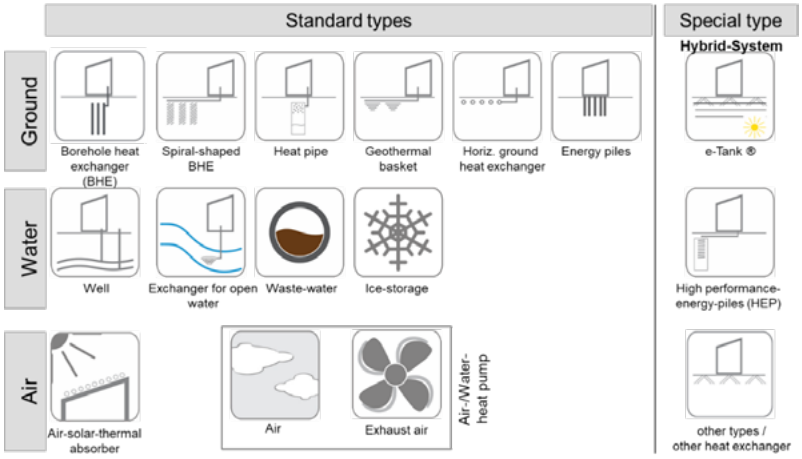

Fig. 4. Low temperature heat sources for heat pumps considered within the framework of future:heatpump and future:heatpump_II

Table 1 summarises the heat pump technologies considered here and presents their advantages and disadvantages. Assessments of the ecological and economic effects of the individual technologies depend, among other things, on current and future electricity and gas prices as well as CO_2 equivalents.

Table 1. Differences and fields of application of different heat pump technologies (main topics / information of the manufacturers)

	Electric heat pump	**Gas driven heat pump**	**Adsorption gas driven heat pump**	**Absorption gas driven heat pump**
Operating mode / medium	mechanical compressor / electrical	mechanical compressor / gas	thermal compressor / gas; (zeolite)	thermal compressor / gas
Temp. level of the source	Depending on source type (air, water, soil) -5 °C to 25°C			
Flow temperature	35 - 55 °C / 65 - 70 °C (heating / domestic hot water)			60 – 70 °C
Thermal capacity range (depending on heat pump, cascades possible)	4 – 300 kW	50 – 200 kW	up to 10 kW (products no longer available on the market)	20 – 45 kW (150 – 5000 kW, for district heating and technical industry)
Application	Residential buildings (single and multi-family houses) to non-residential buildings (office buildings, hospitals, ...) and district heating networks as well as production facilities	Multi-family houses (new construction), commercial and industrial, not residential buildings, existing buildings	single-family house construction	Apartment buildings, industry, commerce, hotels and service companies, existing buildings and for buildings with high water requirements
Advantages	all low-temperature heat sources can be used	for a simple and effective energetic renovation of gas heating systems, since the existing heat distribution and transfer system can largely be reused (existing gas infrastructure mostly usable). Use of combustion heat, therefore up to 40% smaller low-temperature heat source possible. Heat is available at different temperature levels.	hardly any mechanically moving parts, therefore particularly low-noise and low-maintenance	
Disadvantages	Investment costs and space requirements for source system	Gas connection and exhaust system required; mostly only air-water heat pumps on the market		

3.2. Bivalent heating operation mode of heat pump systems

With regard to heat pump systems, bivalent systems or a bivalent mode of operation are heating systems which, for example, combine an electric heat pump with another heat generator (e.g. gas or solid fuel boiler or district heating) and a control system.

The bivalent operation of two heat generators can be a good option for retrofitting existing heating systems. Also, for new office buildings and other non-residential buildings, as well as for new multi-family buildings, a heating system that permits the bivalent operation of a heat pump system is often expedient from both an ecological and an economic point of view. In this context, the heat pump is ideally used to cover a base load. The second heat generator serves to cover the peak load. Due to the low performance requirements, a classical bivalent operation in new single-family houses is rather rare.

The bivalent operation of a heat pump system can be reasonable for various reasons:

- The heat pump cannot provide the temperature required for room heating and/or domestic hot water all year round or can do so only very inefficiently.
- The minimum permissible heat source temperature for the heat pump is not reached during operation.
- The space requirement for the low-temperature heat source is not sufficient for monovalent operation.
- The heat pump cannot provide the heating output required for heating or domestic hot water all year round.
- As part of the energetic modernisation of a building, the existing heating system is supplemented by a heat pump. Renovation of the building shell reduces the heating load so that the existing boiler can be taken out of operation at a later date.
- By using different energy sources, bivalent systems offer a higher security of supply.

Different operating modes result from different applications (Fig. 5). Basically, the operating mode of a heat pump and an additional heat generator can be implemented as follows

- monovalent
  The heat is provided exclusively via the heat pump. A second heat generator is not operated and is not required.
- bivalent parallel
  Above the defined bivalence point (e.g. a defined outdoor temperature (frequently used), CO_2 emissions or the energy prices, etc.), heat is provided exclusively by the heat pump. Below the bivalence point, the second heat generator is operated parallel to the heat pump.
- bivalent partially parallel
  Above the bivalence point, heat is provided exclusively by the heat pump. Below the bivalence point, the second heat generator is operated parallel to the heat pump. If the outside temperature is below an additionally defined switch-off point, the heat pump is switched off and the entire heating heat is provided by the additional heat generator.
- bivalent alternative
  In this operating mode, heat is provided above the bivalence point exclusively by the heat pump. Below the bivalence point, the heat pump is switched off and the entire heating heat is provided by the second heat generator.

Within the framework of the research project and the implementation in the pre-dimensioning program, bivalent parallel operation is considered in addition to monovalent operation. Other modes of operation are named for information purposes, but are not analysed in detail for dimensioning purposes.

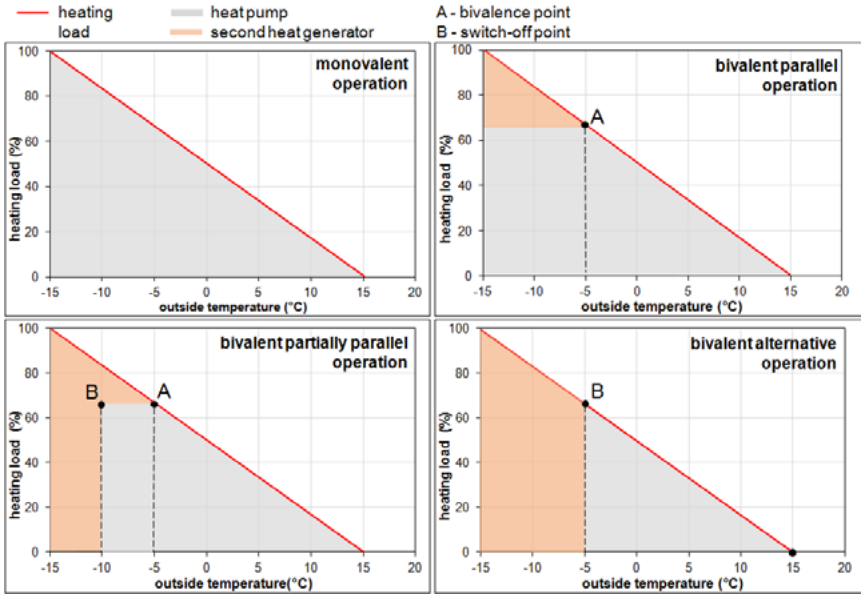

Fig. 5. Operating modes of a heat pump and an additional (second) heat generator

With regard to the integration of a bivalent operation and the associated control as well as the dimensioning of the system components, the expansion of WPsource is initially based on the specifications of DIN V 4701-10 [2] as well as the information sheet no. 57 of the Federal Association of the German Heating Industry (BDH) [3]. The outdoor temperature is used as the numerical value for the bivalence point.

For the dimensioning and the determination of the bivalence point the user has two alternatives at his disposal:

1. Direct determination of the bivalence point, i.e. the switching point of the heat pump to the second heat generator. In addition, the program and the location information are used to determine the share of the total heat requirement and the individual performance data for the generators, as well as the energy quantities that further influence the dimensioning of the low-temperature heat sources and the associated heat exchangers.

2. Determination of the share of the heat pump in the total capacity requirement. On this basis and the location and performance data of the heat pump, the program determines the bivalence point and the amounts of energy that further influence the dimensioning of the low-temperature heat sources and the associated heat exchangers.

Another application for bivalent operation is the integration of solar energy. Building services planners and/or architects are often interested in integrating the thermal use of solar energy not only to support domestic hot water, but also for space heating in the heat supply of single-family and multi-family houses. In addition to a gas condensing boiler or connection to district heating and other heat sources, solar thermal energy can also be used to heat domestic hot water or to support room heating in order to build up a bivalent heat supply. In the context of the extension of WPsource, solar support for domestic hot water and space heating is considered separately. In the project work and in WPsource, the thermal use of solar energy does not fall within the scope of a "classical" bivalent operation.

3.3. Integration of solar thermal energy for the regeneration of geothermal heat sources

The use of solar thermal collectors or absorbers in connection with ground-source heat pump systems has already been investigated in various research projects. For example, the relevance and effects of solar thermal regeneration of the soil were demonstrated in the projects “Terra-Solar-Quelle” and “GeoSolar-WP” [4-6] carried out at the Institute for Solar Energy Research in Hameln (ISFH). The concepts considered are

based on the fact that, starting from a heat pump, a solar system is integrated into the primary circuit (low-temperature heat circuit) of the heat pump. Since the temperature level of the primary circuit is lowered by the heat pump, a larger share of the available solar energy can be used in comparison to the classical installation. The reasons and objectives for the integration and use of thermal solar energy in connection with heat pump systems are based on

- a reduction in the required areas and/or depths of the ground system,
- a reduction in material and/or construction costs,
- the positive influence of regeneration on the operation of the heat pump,
- the achievement of balanced energy and temperature balances and partial compensation of the seasonal shifts between heat supply from the environment and heat demand, as well as
- the cost-benefit ratio of the measure(s).

The use of ground-coupled low-temperature heat sources to provide heat for heat pumps leads to demand-oriented heat extraction from the ground, which cannot always be compensated by natural heat fluxes or active heat input. This leads to long-term cooling effects of the subsurface, especially in geothermal borehole heat exchangers, which causes a negative influence on system efficiency or a larger heat exchanger. With the aid of solar thermal collectors or solar absorbers, regenerative, thermal energy can be injected into the ground in a targeted manner and heat extraction by a heat pump can be compensated. In this way, the soil can be regenerated and a long-term temperature decrease can be avoided. Additonally, the increase in the source temperature for the heat pump results in higher system coefficients of performance.

When dimensioning geothermal heat collectors, the targeted injection of thermal energy into the ground can contribute to reducing the required collector area. By avoiding critical frost and exhaustion conditions as a result of regeneration, a smaller distance between the collector pipes can be achieved. Since the high demand for unsealed surfaces represents a major obstacle to the use of surface collectors, the reduction of the required surface area through regeneration is of particular interest for the application of this technology.

When injecting thermal energy into the brine circuit of a heat exchanger system, the permissible inlet temperatures must be observed. For example, the inlet temperature to a surface collector must generally not exceed 25 °C. For this reason, unglazed collectors, usually solar absorbers, are generally used to regenerate the soil.

Table 2 summarizes key data and applications relevant for the regeneration of ground-coupled low-temperature heat sources.

Table 2. Differences and influences of solar regeneration of geothermal collectors and borehole heat exchangers

	Geothermal heat collectors [4]	**Borehole heat exchangers [5-6]**
The objective of regeneration	Reduction of the collector surface area with constant efficiency	Reduction of borehole length and improvement of system efficiency
Integration of solar thermal technology	Primary side series connection of the solar collectors or absorbers with Geothermal heat collectors	Primary-side series connection of solar collectors or absorbers with borehole heat exchangers
Investigated collector types	Swimming pool absorber, uncovered PVT- and facade collectors	unglazed collector (solar absorber)
Control	Inlet temperature of Geothermal heat collectors max. 25 °C	
Influence of regeneration	Avoidance of critical frost conditions and limitation of exhaustion conditions of the Geothermal heat collectors	Avoiding long-term cooling effects and increasing the annual coefficient of performance (COP)
Effect	Reduction of the collector surface up to 50%. Applicability independent of the type of soil. Good compensation measure for undersized Geothermal heat collectors.	Increase of the COP and increase of the minimum temperatures in the soil. Reduction of the borehole length by up to 30 %. In clearly undersized systems, the influence is significant. Otherwise, efficiency gains are in no economic relation to effort.

3.4. Applicability of heat pumps in local heating networks

Against the background of the energy transition, energy-efficient heat provision for space heating and domestic hot water is essential. Local heating networks with heat pumps will be an important infrastructure element for the heat supply of settlements and quarters in the future. Heat pumps can provide the required heat in comparison to fossil heat generators with low primary energy shares and, if correctly dimensioned, have high efficiency. They offer the possibility of spatial and temporal coordination of heat source, heat generation and heat demand via network design, network temperatures and heat storage. In this way, economically and technically optimised heat supply systems can be created.

The integration of heat pumps in local heating networks can enable the development of previously unused and natural low-temperature heat sources for heat supply. This can reduce primary energy and CO_2 emissions during heat generation.

Based on the basics developed in the project and the example networks considered, different scenarios for a future-oriented local heat supply of quarters with heat pumps can be developed. The concepts differ in the network temperatures, operating modes and usable low-temperature heat sources as well as in the areas of application.

Conventional local heating network with central heat pump

The implementation of conventional local heating networks is primarily of interest for areas with buildings that currently need to be supplied, where heat generation within the building and fuel-based heat generation are available, which require high inflow temperatures. This means that existing quarters with conventional heating systems, which generally also have high heat demand densities, can be considered. Residential and mixed areas with multi-family houses and commercial properties are particularly interesting for conventional local heating supply concepts. Due to the lower density of heat demand, supply areas with single-family housing only (especially new buildings) are less suitable. For consumers, the conversion to conventional local heating involves manageable investments, essentially in new heating technology (replacement of the old heating system with a local heating transfer station).

In conjunction with an environmental heat source, a central heat pump (covering the base load of the heat network) in conjunction with another heat generator provides flow temperatures between 60 °C and 85 °C. This temperature level of the local heating network is usually sufficient for space heating and domestic hot water heating. The return flow temperature is between 50 °C and 35 °C, depending on how much heat is removed. It can be deduced from the networks investigated that route lengths of about one and a half kilometres can be realised.

The potential heat sources for the heat pumps are geothermal borehole heat exchangers, groundwater and solar-thermal long-term heat storages. If the supply area offers the necessary infrastructure, waste water can also be used as a heat source.

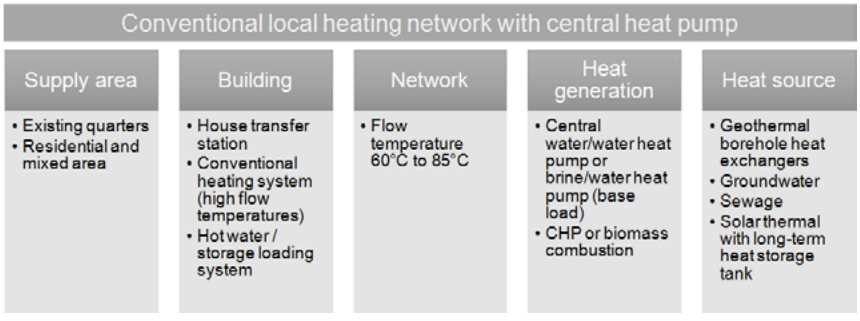

Fig. 6. Overview of a conventional local heating network with central heat pump

Low-temperature network with decentralised heat pumps (Cold local heating network)

A low-temperature network with decentralised heat pumps is particularly suitable for supplying new residential areas. The advantage of cold local heating is not necessarily the heat price, but the fact that the network can be integrated into supply areas characterised by low heat densities, uncertain demand structures

and possible extensions due to further settlements. With brine as the heat transfer medium, the networks usually provide temperatures in the range of 5 °C and around 20 °C. Due to the low heat losses, cold local heating networks can be operated efficiently even with low heat demands. No additional heat generator is required for normal network operation. If eco-electric power is used for the heat pumps, the heat supply can be operated CO_2-neutral. Cold local heating networks are particularly interesting because the heat consumption of buildings decreases due to building insulation and as a result the heat demand density is reduced, too. In order to ensure economic operation of the distribution network, it may be advisable in new housing estates to require a connection to the cold local heat.

The analysis of sample quarters suggests that pipeline lengths of at least one and one and a half kilometres can be achieved. The transport of the heat transfer medium in the distribution network is realised by the individual feed pumps of the decentralised heat pumps in the connected buildings. If there is no heat demand, the heat transfer medium in the distribution network is at a standstill. In order to prevent the temperature level from being lowered by heat exchangers between the heat source and the distribution network, the heat transfer medium from the low-temperature heat source flows directly through the distribution network. Depending on the local conditions, a number of environmental heat sources may be available that are sufficient to cover the required load and do not require an additional heat generator. Common heat sources in this context are geothermal borehole heat exchangers and agrothermal collectors as well as long-term heat storage units such as ice storage units or geothermal storage units.

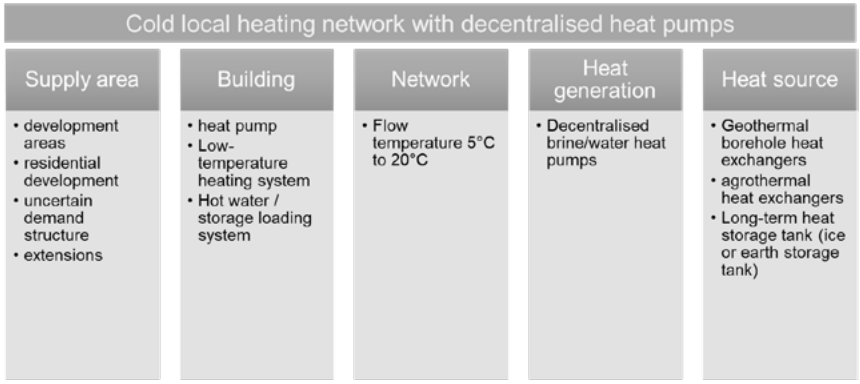

Fig. 7. Overview of a cold local heating network with decentralised heat pumps

Mixed networks

The conversion of an existing (conventional) local heating network to a mixed network with centralised and decentralised heat pumps can improve the efficiency and sustainability of the heat supply. During the winter months, the network is operated as a conventional local heating network with central heat generation and supply flow temperatures in the range of approx. 70 °C to 80 °C. A combined cogeneration unit together with a central heat pump serves as a heat generator. In the summer months, the network temperature is reduced to around 20 °C to 40 °C, and the space heating and domestic hotwater heating is provided by decentralised heat pumps in the connected buildings. The heating system with the cogeneration unit can be switched off during this time. Mixed networks offer the advantage of providing heat at demand-oriented temperature levels. Since the existing local heating routes are used, no work is usually required on the pipelines to convert to a mixed network. For the network operator, investment costs are usually relatively low.

In principle, all environmental heat sources used as heat sources for the heat pump can also be used for heat pump operation in a conventional local heating network. Due to the constant source temperatures of around 10 °C during the winter months, the use of geothermal borehole heat exchangers or groundwater is particularly suitable.

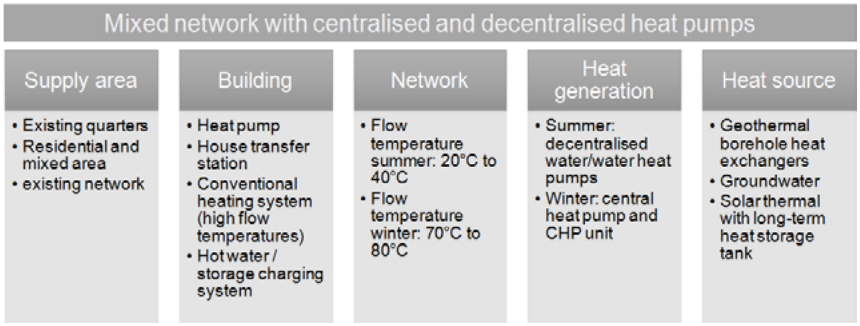

Fig. 8. Overview of a mixed network with centralised and decentralised heat pumps

4. Conclusion

Energy concepts with innovative systems and components such as solar thermal energy, photovoltaics, heat pumps and geothermal energy are increasingly being implemented in building technology. Design aids, such as dynamic simulation, are becoming increasingly important for these systems. The design and dimensioning aids currently available on the market for heat pumps and their low-temperature heat sources and heat exchangers are generally individual solutions that are often provided by manufacturers or suppliers of corresponding products. These design and dimensioning aids usually do not offer planners and architects the possibility of verifying the output results or providing an overview of the alternatives. In particular, the comparison of systems and individual components in different applications and their applicability is a unique characteristic of WPsource.

On the basis of the experiences and results from the research project future:heatpump, the follow-up project "future:heatpump_II" will mainly deal with topics and focal points which on the one hand support the application and expansion of heat pump systems and on the other hand serve the extended use of the WPsource program. The focus will be on other heat exchanger systems, the bivalent operation of heat pump systems, the regeneration of geothermal heat exchangers and the integration of photovoltaics and solutions for districts/quarters. The expansion will enable the programme to present more advanced concepts and approaches with heat pumps.

The current state of work in the area of the new thematic priorities shows that

- different heat pump technologies are available on the market, but the application is primarily focused on electric heat pumps. Gas-operated heat pumps are currently not very important on the market, but can be a sensible solution, e.g. for existing buildings with an existing gas connection.
- the use of bivalent heat pump systems can be a way of resolving the modernisation backlog in existing buildings. They make it easier for the plant operator to decide on future energy sources for heating the building. Bivalent systems can often be installed cost-effectively by extending existing heating systems. Bivalent heat pump systems are also of economic interest in new buildings, especially with high heating loads and different temperature requirements.
- a regeneration or coupling of ground heat exchangers (surface collectors and geothermal borehole heat exchangers) with thermal solar energy leads to a reduction of the collector surface or geothermal borehole heat exchanger length. In addition, the temperatures in the soil rises and the annual performance factors can be increased. Coupling with thermal solar energy has a significant positive influence on undersized systems. In other cases, the efficiency gain is not economically proportional to the effort required to use thermal solar energy to regenerate geothermal heat exchangers.
- a local heating network offers the possibility of a sustainable and economical heat supply with a high flexibility and expandability. In the sense of a future-oriented energy supply, the implementation possibilities of different heat pumps and environmental heat sources in local heating networks should be investigated and, where possible, applied to quarter solutions.

US Heat Pump Market Overview–2020

Jaewan Joe[a], Mini Malhotra[a], Melissa Lapsa[a]*, Van Baxter[a]

[a]Oak Ridge National Laboratory, P.O. Box 2008, Oak Ridge, TN, 37831, USA

Abstract

This paper provides an overview of the US heat pump market in 2020; discusses the key drivers and challenges that have been shaping the market; and discusses the underlying factors that are setting the direction for the research, development, and commercialization of heat pumping technologies in the United States. Following the 2006–2007 housing market collapse, the US heat pump market has shown steady growth since 2010. Air-source heat pump shipments reached nearly 3 million in 2018, a 12.2% increase over 2017 versus the 7.1% estimated growth rate of the global heat pump market. Owing to the recovering economy, growing construction market, relatively stable electricity prices, numerous financial incentives, and technological advancements, the demand for heat pumps has been increasing. The current focus of heat pump research and development in the United States includes development of next-generation systems and components, lower global warming potential refrigerant alternatives, and reduced cost for premium-efficiency technologies. The future heat pump market and technologies will be highly influenced by increasingly stringent minimum efficiency standards, incentive programs, technological innovations, and the national and global economy.

Keywords: Heat pumps; shipments; US market; construction market; research and development; efficiency standard

1. Heat Pump Market

1.1. Market trend

The market for heat pumps in the United States has shown healthy growth since 2010 following the 2006–2007 housing market collapse. Figure 1 shows the new single-family heating system market combined annual penetration rate of air-source heat pumps (ASHPs) and ground-source heat pumps (GSHPs). The market share of the ASHP and GSHP systems hovered between 20–30% from 1978 to 2005; since then it has relatively steadily increased to 41% [1]. In the US space heating market, heat pumps primarily compete with natural gas furnaces in addition to other traditional heating appliances like boilers, direct electric heating, etc. Figure 2 shows the annual shipments of ASHPs, gas warm air furnaces, oil warm air furnaces, and unitary air conditioners. ASHP shipments have shown a general increasing trend since 1998. From 2000 to 2006, annual ASHP shipments increased nearly 60% to 2.1 million units, then dropped and leveled off to about 1.7 million units annually between 2007 and 2013 during the housing market crash and recovery. In 2014, annual ASHP shipments surpassed the 2006 peak and have steadily increased in the intervening years, reaching nearly 3 million in 2018, while gas warm air furnaces have yet to fully recover to their 2006 shipment levels. Gas furnace shipments still outnumber ASHP shipments but the gap is much narrower.

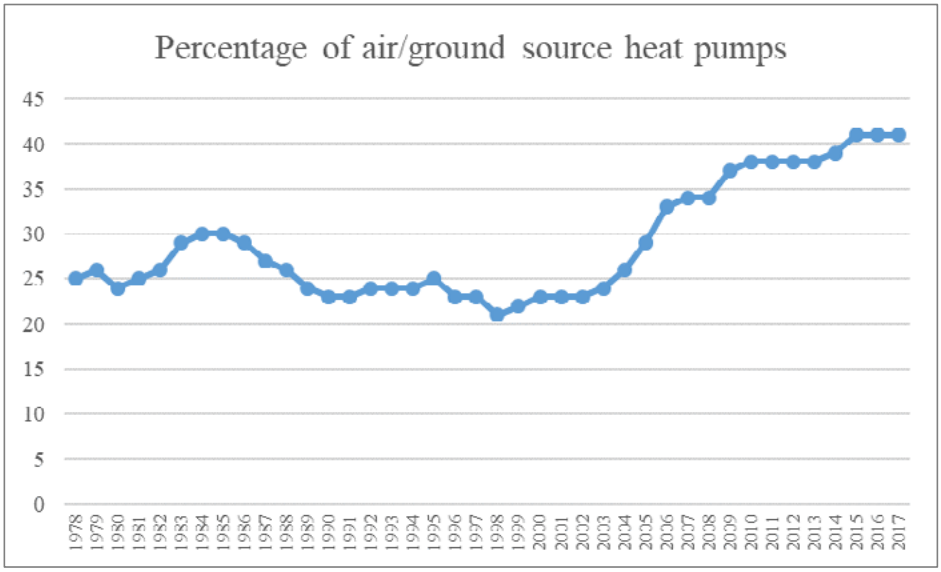

Figure 1 Penetration rate of heat pumps [1]

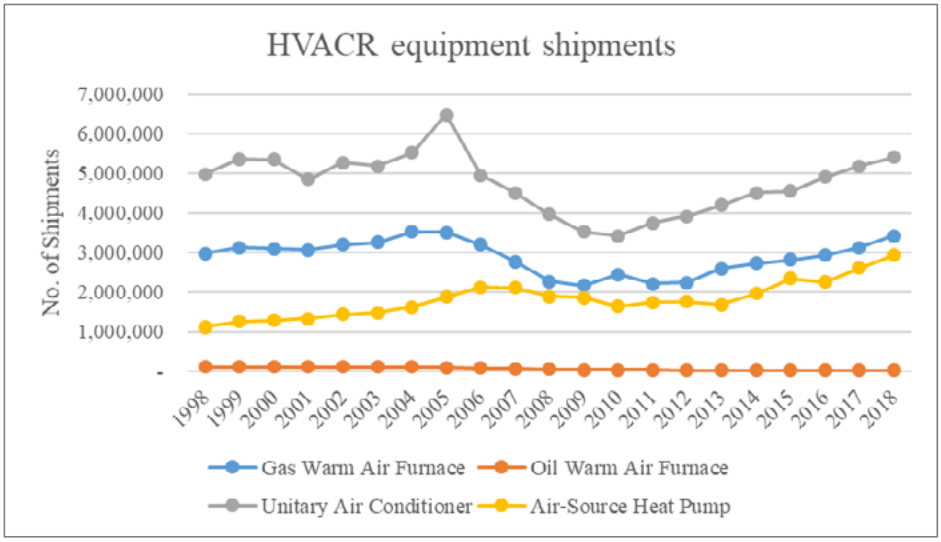

Figure 2 Heating, ventilation, air conditioning, and refrigeration (HVAC&R) equipment shipments [2]

Figure 3 illustrates the trend of annual shipments/installations of GSHPs based on 2003–2009 shipment data from the US Energy Information Administration (EIA) and 2010–2015 shipment estimates based on EnergyStar unit shipment and market penetration reports [3], [4]. Shipments of GSHPs have steadily increased since 2003, partly due to a 30% federal tax credit placed in service after 2008 and lasting through December 31, 2016. The federal tax credit was recently reinstated and will be available until 2021.

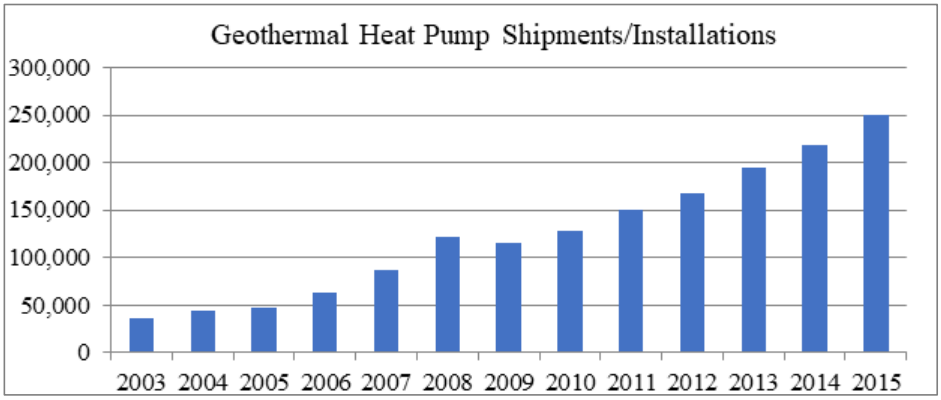

Figure 3 Geothermal heat pump shipments/installations [3], [4]

1.2. Market segments: residential, commercial, and industrial sectors

Despite the US housing market crisis in the late 2000s, heat pumps steadily increased their share of the new home market since 2004, reaching 41% in 2017 compared with only 25% in 1978 for single-family housing, as shown in Figure 1. As for multifamily housing, heat pump share was up to 48% in 2017, whereas competing technologies (forced-air furnace and hot water or steam heating) remained at 37% and 8%, respectively [1].

Similar to the residential market, commercial HP and air conditioner (AC) shipments (above 19.0 kW in capacity) in the United States have experienced some volatility over the past two decades due to economic conditions, fluctuating fuel prices, etc. Since the bottom of the market in 2009, total commercial HP and AC shipments have increased by 49% back up to slightly more than the 2006 level, approximately 312,000 units in 2017 and 2018 [2].

Total industrial HP installations in the United States was estimated at about 2,300 in 1994, growing to a conservatively estimated 5,000–7,000 by 2015/2016. Installations with lumber drying applications were responsible for about 75% of this total. Declining natural gas prices relative to electricity prices is the biggest impediment to this market, along with the 2006–2010 recession.

As mentioned previously, for building comfort cooling and space heating applications of ACs and HPs in the United States, the residential and commercial markets account for 96% and 4% of the total market, respectively; these percentages have varied only slightly (by 2%) over the past 18 years. The percentage distribution by capacity (Figure 4) has also stayed fairly consistent for decades as illustrated in [2].

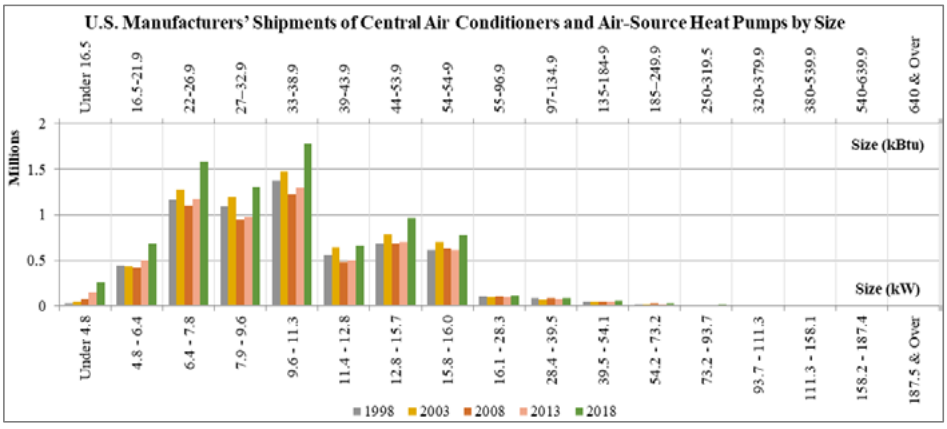

Figure 4 Central AC and ASHP shipment during 1998–2018 by system capacity [2]

2. Market Drivers

The primary appeal of heat pumps in the United States is the increased efficiency, which in turn saves energy and operating costs. Furthermore, it offers both heating and cooling functions, allowing consumers to potentially consolidate their equipment purchases. Also, the heat pump (electric) is the only option for some regions in the United States where natural gas is still not available to some residential and commercial building customers.

2.1. Electricity price

Electricity prices for residential building customers have gradually risen over the 2007–2018 period (Figure 5), whereas prices for other sectors (commercial buildings, transportation, and industry) remain relatively level or even slightly decreased. This trend is a barrier for the penetration of HP in residential sector. However, it drives the research and development (R&D) to improve the performance and efficiency.

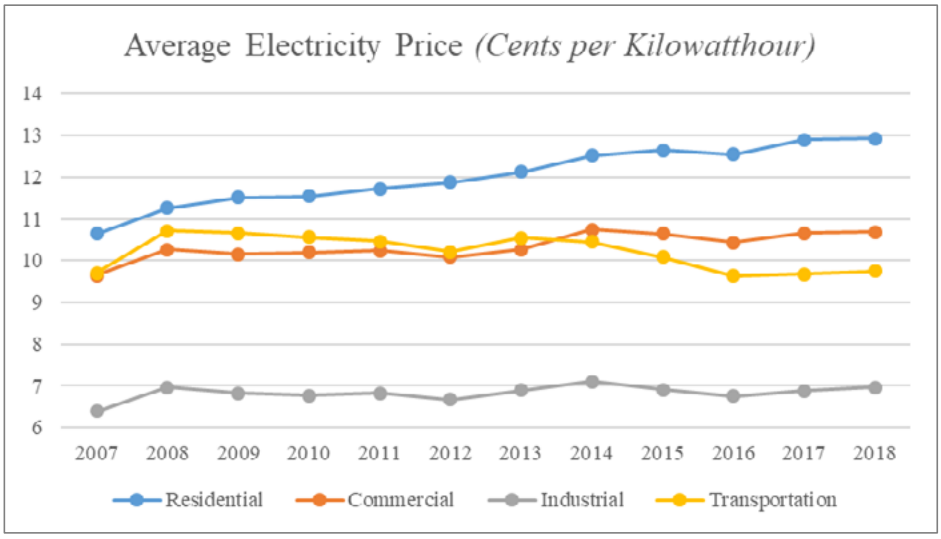

Figure 5 Average electricity price [5]

2.2. Installation cost

Comparisons of retail equipment cost, total installed cost, maintenance cost, and average life of HP technologies with other competing heating technologies for residential and commercial space heating and water heating (WH) are shown in Figure 7, respectively. These are obtained from the EIA's 2018 report on Technology Forecast Updates [6]. The underlying data is based on generic industry products from 2017 including government, R&D organizations, and manufacturers.

The cost comparison plots on the left side axes of the plots in the two figures show the min-max retail equipment cost ranges and total installed cost ranges (plotted along the primary vertical axis) for the typical capacity (plotted along the secondary vertical axis) of each technology type. Installed cost of the heat pump technologies are somewhat higher than those of most of the competing heating technologies. For the ground-source systems, the cost is driven by the drilling, trenching, and other activities required to install the ground loop heat exchanger. One significant advantage for the heat pumping options is that they can provide cooling in the summer as well while other space technologies require separate cooling system, which incur additional cost.

Figure 6 Comparison of heat pump technologies to other technologies: total installed costs with typical capacities and maintenance cost with average life for residential space heating (top) and water heating (bottom) [6].

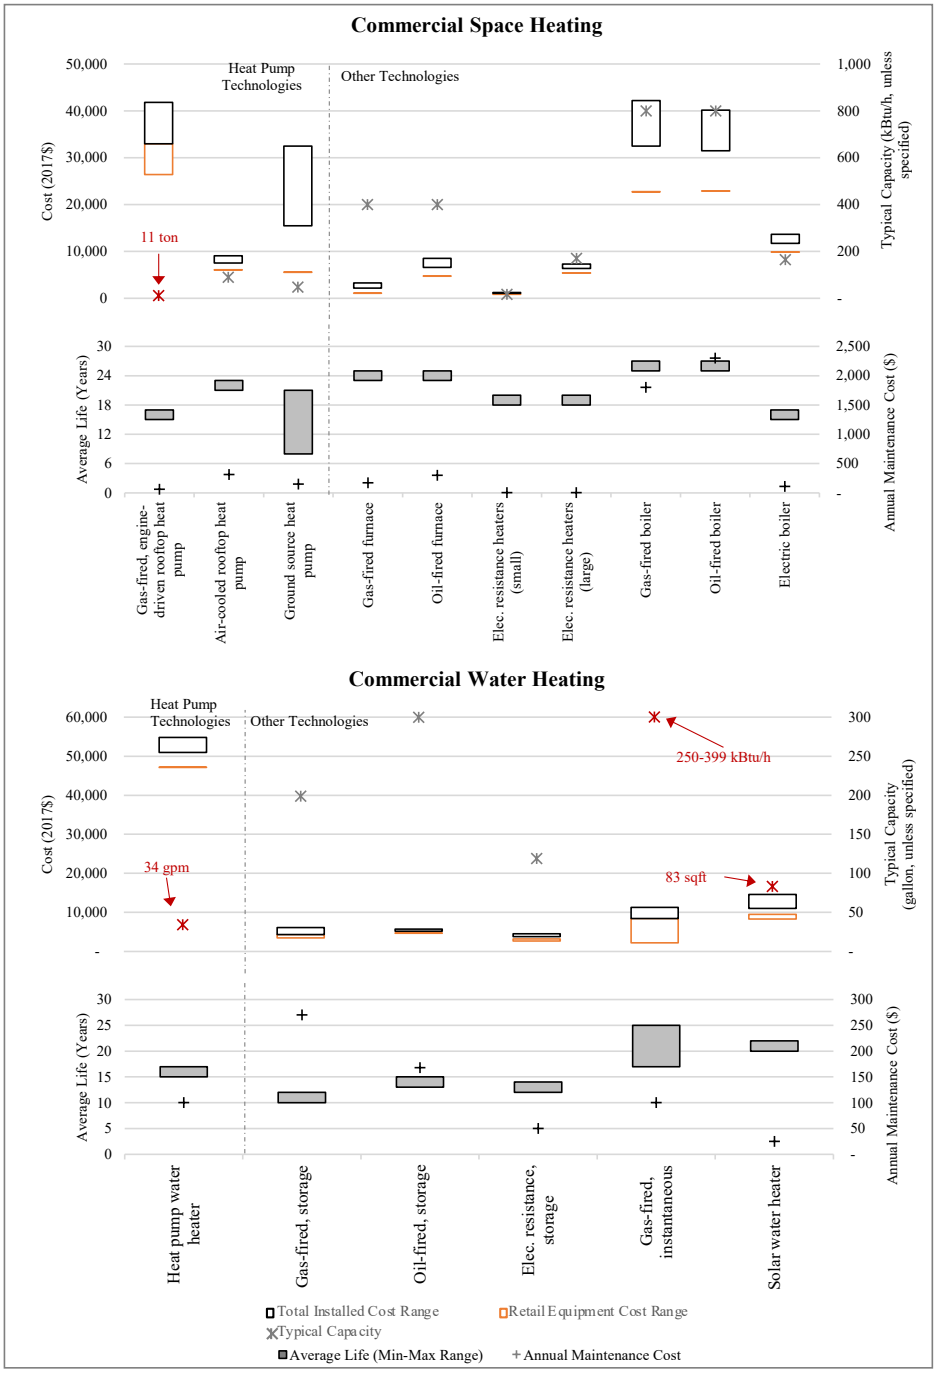

Figure 7 Comparison of heat pump technologies to other technologies: total installed costs with typical capacities and maintenance cost with average life for commercial space heating (top) and water heating (bottom) [6].

The lower plots in each section of the two figures show the min-max ranges of average life (plotted along the primary vertical axis) and average annual maintenance cost (plotted along the secondary vertical axis) for each technology type. Heat pump technologies have average life comparable to other competing technologies and are on the lower maintenance cost regime.

2.3. Financial incentives

HPs have grown in popularity over the past few decades and are now well known to the general public. This increase in awareness was supported by utility and state incentive programs that encouraged deployment of the technologies. Several federal and state-level financial incentives and utility programs for consumers and businesses are available that support HP technologies. Figure 8 shows the total currently active financial incentives and regulatory policies in the United States listed under the Database of State Incentives for Renewables & Efficiency (DSIRE) [7] for HPs including GSHPs. As shown, a large number of rebate and loan programs sponsored by states and utilities exist. Other common mechanisms include tax incentives and tax credits, financing, and grant programs.

Specific to HP technologies, GSHPs qualify for renewable energy tax incentives, whereas no explicit policies or incentives exist for fuel-driven HPs. Numerous appliance and home efficiency programs are in place, which do not specify a technology but support any system, equipment, or appliance that meets the minimum efficiency level (including HP systems). In addition, a few entities provide financial incentives for installers for business development [8].

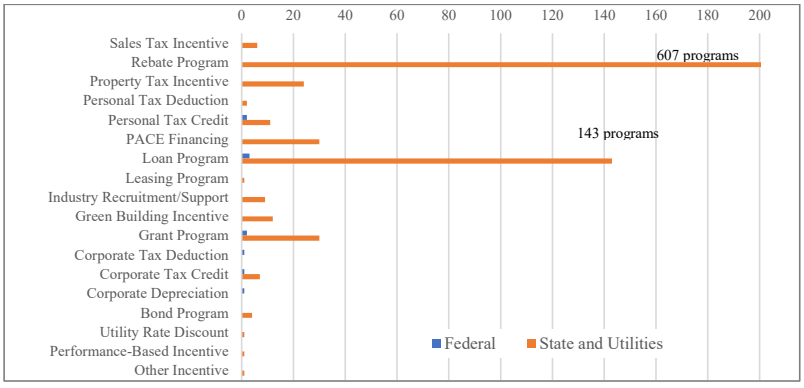

Figure 8 Financial incentives

2.4. Regulatory policy

Figure 9 shows the currently active regulatory policies listed under DSIRE [7] for HP technologies, most of which are enforced by states. On the federal level, the US Department of Energy (DOE) continues to push for elimination of lower efficiency products by implementing more stringent minimum performance regulations, legislation, and standards such as the “Energy Policy Act of 2005 (EPAct 2005)” and the “Energy Independence and Security Act of 2007” (EISA 2007). ENERGY STAR is a voluntary program managed by the US Environmental Protection Agency (EPA) and DOE to promote the eco-friendly industry and cost saving through energy-efficient products. Table 1 summarizes the status of minimum energy performance standards for different HP technologies. The minimum energy performance standards for each technology are provided in the Appendix.

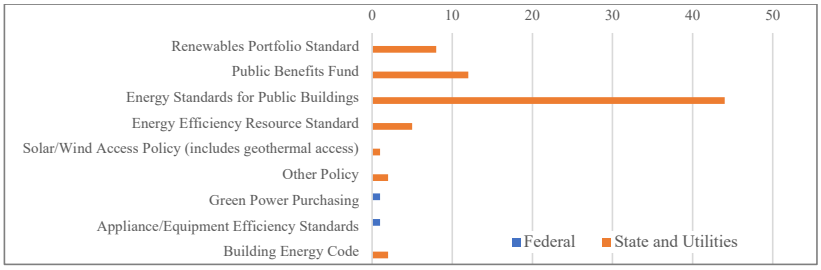

Figure 9 Regulatory policies

Table 1. Status of Minimum Energy Performance Standards for Different HP Technologies [9], [10]

HP Technology		Federal Standard	ENERGY STAR Criteria
Residential	ASHP	Current standards (for central systems) took effect in 2015. See Table A-1	More stringent requirements. See Table A-1
	GSHP	14.1 EER, 3.2 COPh; Current standards (for WSHP[a]) took effect in 2015	See Table A-2
	Air source absorption heat pump	Currently, not covered by NAECA[b]; CEC[c] Title 24 specifies cooling efficiency requirements	
	Heat pump water heater	See Table A-3	See Table A-3
Commercial	Gas-fired, engine-driven rooftop heat pump	Currently, none	
	Air-cooled rooftop heat pump (large ASHPs)	Amended standards in terms of IEER took effect in 2018. More stringent standards will take effect in 2023. See Table A-4	See Table A-4
	GSHP	14.1 EER, 3.2 COPh; Current standards (for WSHP) took effect in 2015	None; Criteria for GSHP apply only to residential applications
	HPWH	Currently, none	Under revision; the public final draft specifies 3.0 COPh

[a]WSHP = Water Source Heat Pump.
[b]NAECA = National Appliance Energy Conservation Act.
[c]CEC = California Energy Commission.

2.5. Technology deployment support

Several trade organizations exist in the United States to promote the deployment of HP technologies with high-quality installations and servicing with industry partners including distributors, vendors, and suppliers. Among these are the Geothermal Exchange Organization [11] and associations in different states, such as Louisiana [12], Minnesota [13], Virginia [14], Colorado, California, and New York [15], and NYSERDA [16]. The California Geothermal Heat Pump Association [17] strives for penetration of the HP into residential and commercial areas while collaborating with the California Energy Commission and the California Public Utility Commission for net zero energy building. There are several regional associations also promoting HP technologies. The Northeast Energy Efficiency Partnerships [18] has programs promoting cold climate ASHPs and HP water heaters (HPWHs) in the northeastern region of the United States. The Northwest Energy Efficiency Alliance has an active program promoting HPWHs [19]. The Electric Power Research Institute has developed an advanced HP specification featuring smart grid response requirements [20].

2.6. Workforce training and education

Some private companies provide classroom and online training for HVAC technicians on HP installation, operation, maintenance and troubleshooting [21][22]. International Ground Source Heat Pump Association (IGSHPA) runs a certification program for GSHP installers and designers [23]. The North American Technician Excellence organization is the largest in the United States for HVAC&R technician certification [24].

3. Overarching R&D in HP Technologies

3.1. Research infrastructure

Within DOE, R&D of HP technologies is supported by the DOE Building Technology Office's (BTO's) HVAC/WH/Appliances Subprogram. This subprogram engages with hundreds of internal and external partners including national laboratories, universities and institutes, industry, small businesses, building owners and operators, other DOE offices and federal agencies, state and local governments, nonprofits, international organizations, and other entities, as well as other subprograms within BTO, to reduce barriers to greater market adoption of premium efficiency technologies (see Figure 10).

DOE's national laboratories provide unique infrastructural support to R&D of HP technologies including modeling capabilities, test beds and simulation platforms, energy system integration facilities, as well as support to regulatory activities. Organizations such as ASHRAE and the Air-Conditioning, Heating, and Refrigeration Technology Institute (AHRTI) also contract R&D to universities, research institutes, and others in the United States and worldwide.

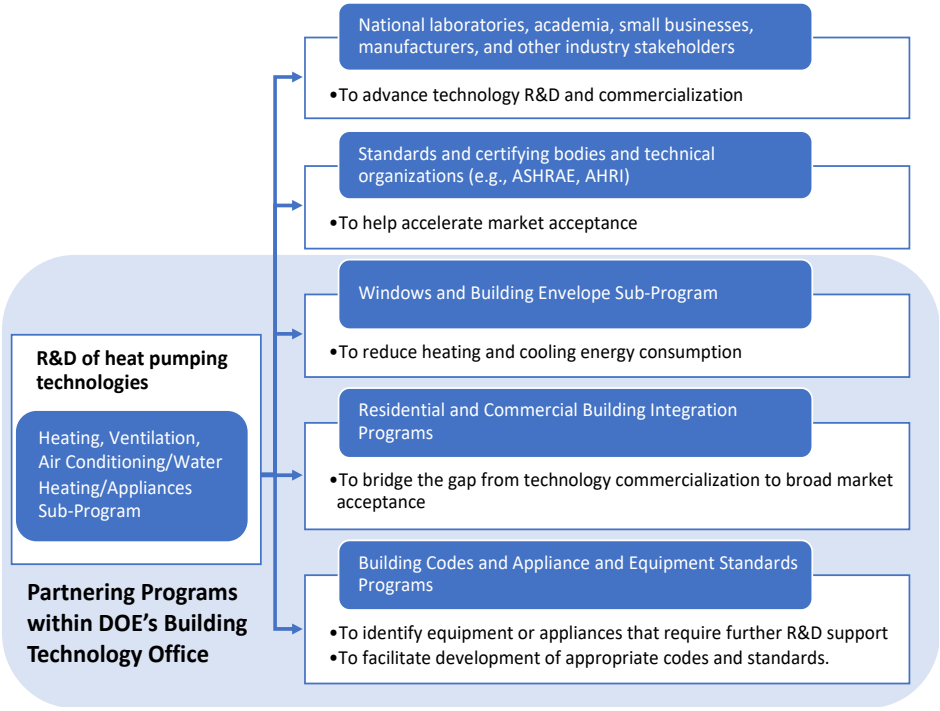

Figure 10 DOE's partners for heat pump R&D [25]

3.2. Research direction

DOE's Multi-Year Program Plan [25] identifies challenges and provides a roadmap for R&D and market simulation. The following are the key challenges for the HP in the R&D, demonstration, and adoption of current and developing HVAC and WH technologies:

- High cost and lack of sustained performance/reliability of high-efficiency systems compared with conventional systems.
- Unrealized design potential of the systems when built out of generic components. Opportunity exists for improved energy and nonenergy performance of many current systems via tailor-made components with advanced materials and designs, though at a higher cost.

- Increasing emphasis on advancing development of nontraditional and advanced vapor compression cycle technologies. Reducing the global environmental impacts of building HVAC&R and WH equipment and systems with advanced technology is extremely challenging.
- High manufacturing costs or lack of manufacturing methods for new components or technologies.

3.3. Research topics

Since 2017, the DOE focus for building energy efficiency R&D, including HPs and HP-related systems, has been increasingly toward advancement of technologies at lower technology readiness levels (TRLs) [25]. So there has been activity on nontraditional cooling and refrigeration technologies (magnetocaloric, elastocaloric, thermoelectric, etc.) and advanced compression technologies (e.g., electrochemical compression). R&D also continues on alternative lower global-warming potential (GWP) refrigerants as well as the low (or zero) GWP alternative technologies. Some work continues in collaboration with manufacturers on maximizing the efficiency of HPWH using lower-GWP refrigerants (moderate to higher TRLs).

The following specific research objectives/topics related to HP technology are being pursued by DOE [25]:

1. Develop and introduce next-generation, transformative technologies for the future such as nontraditional cooling cycles and advanced vapor compression system and component (compressors, heat exchangers, etc.) technologies.
2. Reduce barriers to greater market adoption of premium-efficiency technologies in the near term by refining and reducing the cost of available technologies, including HP technologies for space conditioning and WH.
3. Pursue system-oriented solutions to optimize whole-building energy use. R&D priorities include developing integrated systems that combine end uses, such as energy cascading, as in integrated HP technologies (including ASHPs, GSHPs, and multifunction natural gas–driven HPs).
4. Explore new or different next-generation components to find the best possible cost-effective combinations that have the potential to fully replace or be integrated with conventional technologies, often across end uses.
5. Advance regional solutions to improve the performance of HPs in cold and hot-humid climates (e.g., cold climate heat pump research).
6. Develop advanced vapor compression systems with low- or zero-GWP.
7. Develop HPWH technologies (e.g., electric HPWH with low-GWP; Absorption HPWH; non vapor compression HPWH units, low-GWP solutions).

4. Summary and Outlook

The US HP market has shown steady growth since 2010 following the 2006–2007 housing market collapse. HP shipments have been growing at a faster pace over the past several years relative to competing space heating technologies. The use of ASHPs in cold climates is becoming more feasible through promising R&D and market developments. Current R&D emphases are primarily on advancing development of (1) nontraditional cooling/refrigeration cycles and (2) alternative or advanced compression cycle technologies but also on (3) lower GWP refrigerant alternatives to cope with environmental concerns. Governmental actions, along with public and private-sector incentive programs, promote deploying more efficient HP systems. The future of HP technologies will be highly influenced by the stringent minimum efficiency standards, R&D for advancing nontraditional technologies and alternative lower GWP refrigerants, and tax credits and incentive programs.

Acknowledgments

This research was supported by the DOE Office of Energy Efficiency and Renewable Energy, Building Technologies Office. The authors would like to thank the following individuals and organizations for information and statistical data used in this work: Xudong Wang of AHRI, Xiaobing Liu of ORNL, Jerry Groff of Groff Associates. This manuscript has been authored by UT-Battelle, LLC, under contract DE-AC05-00OR22725 with the US Department of Energy (DOE). The US government retains and the publisher, by accepting the article for publication, acknowledges that the US government retains a nonexclusive, paid-up, irrevocable, worldwide license to publish or reproduce the published form of this manuscript, or allow others to do so, for US government purposes. DOE will provide public access to these results of federally sponsored

research in accordance with the DOE Public Access Plan (http://energy.gov/downloads/doe-public-access-plan).

Appendix

Table A-1. Standard for Residential Air-Source Heat Pump [6]

Residential ASHP Product Class	Current Federal Minimum Efficiency Standards			Current ENERGY STAR Criteria		
	Min.SEER	Min.HSPF	Max. Off Mode Power (W)	Min.SEER	Min.EER	Min.HSPF
Split-System	14	8.2	33	15	12.5	8.5
Single-Package	14	8	33	15	12	8.2
Small-Duct, High Velocity	12	7.2	30	-	-	-
Space-Constrained	12	7.4	33	-	-	-

Note:

- Units for SEER, HSPF and EER are in Btu/Wh (divide by 3.412 to get equivalent dimensionless values).
- For split-system air conditioners (cooling only), the minimum SEER increased to 14 in southern climate regions, while the 13 SEER standard established in 2006 remained effective in the north. Whereas, for split-system ASHPs, the minimum SEER increased to 14 and the minimum HSPF increased to 8.2 in all climate regions.

Table A-2. ENERGY STAR Criteria for Water-to-air Ground Source Heat Pumps

Type	Heating COP	Cooling EER
Closed Loop	3.6	17.1
Open Loop	4.1	21.1
Direct Expansion	3.6	16

Table A-3. Federal Standard and ENERGY STAR Criteria for Residential Electric Storage and Heat Pump Water Heater

Volume Range	Draw Pattern	Federal Standard[1]	Federal minimum UEF for typical sizes	ENERGY STAR
≥ 20 gal and ≤ 55 gal	Very Small	UEF=0.8808-(0.0008*Gal)	No models on the market	2.0
	Low	UEF=0.9254-(0.0003*Gal)	0.91 for a 27-gallon water heater	2.0
	Medium	UEF=0.9307-(0.0002*Gal)	0.92 for a 36-gallon water heater	2.0
	High	UEF=0.9349-(0.0001*Gal)	0.93 for a 45-gallon water heater	2.0
> 55 gal and ≤ 120 gal	Very Small	UEF=1.9236-(0.0011*Gal)	No models on the market	2.2
	Low	UEF=2.0440-(0.0011*Gal)	No models on the market	2.2
	Medium	UEF=2.1171-(0.0011*Gal)	2.03 for a 77-gallon water heater	2.2
	High	UEF=2.2418-(0.0011*Gal)	2.15 for a 82-gallon water heater	2.2

Notes:

- Standards for residential electric storage WH also apply to integrated HPWH.
- Federal standards that came into effect in April 2015 effectively mandate heat pump technology for electric storage water heaters with storage volume > 55 gallons. Thus, the standards for the >55-gallon range and all ENERGY STAR levels are only achievable through heat pump technology.

Table A-4. Federal Standard and ENERGY STAR Criteria for Commercial Air-cooled Packaged Rooftop Heat Pump (large ASHPs) [6]

Cooling Capacity (kBtu/h)	Heating Type	Federal Standard (1/1/2010~)		ENERGY STAR version 2.2 (1/1/2011~)		
		Min. EER	Min. COP at 47°F	Min. EER	Min. IEER	Min. COP at 47°F
Small (≥ 65 and < 135)	Electric resistance or none	11.0	3.3	11.3	11.4	3.35
	Any other type	10.8	3.3	-	-	-
Large (≥ 135 and < 240)	Electric resistance or none	10.6	3.2	10.9	11.0	3.25
	Any other type	10.4	3.2	-	-	-

Note:

- This values in this table are for air-cooled commercial packaged rooftop heat pumps. There are different standards for many other types of commercial heat pumps.
- In 2018, the DOE-regulated metric switched from EER to IEER, and the minimum IEER for ASHPs with electric resistance or no heating system and any other type (e.g., heat pump) are set at 12.2 and 12.0, respectively, for small capacity systems and 11.6 and 11.4 for large capacity systems. They are effective until 2022.

Experimental Research on Air-source Heat Pump Using Heat Pipes as Heat Radiator

Xu Shuxue, Shao Yueyue, Wang Yueyue, Ma Guoyuan*

Beijing University of Technology , Chaoyang district Pingleyuan No 100, Beijing, 100124, China

Abstract

In this study, a concept of air-source heat pump using heat pipes as heat radiator system (ASHPP) for room heating was proposed. The heat pipes radiator was developed to replace the heating terminal equipment used in traditional heat pump plants. All the heat radiators were connected in series. A tested room with artificial load was constructed and an experimental apparatus of ASHPP system was developed. Temperature distribution of each heat radiator has been experimentally investigated. The variations of system heating performance under the condition of different indoor air temperature and outdoor air temperature were researched. The purpose of this study is to provide technique reference for developing new heat pump room heating system.

Keywords: Heat pump;Heat pipe;Compressor;Heating;

1. Introduction

As an efficient technology for energy conservation, air source heat pumps have been widely used in industry and daily life, and are mainly applied for heating water or air. Particularly for household appliances, a heat pump can use water or refrigerant-cooled chillers for cooling in summer and heating in winter. It has the advantages of a high performance coefficient for water-cooled chillers in summer and the ability to function as a heat pump in winter (Willem H et al, 2017 [1] ; Østergaard et al, 2016 [2] ; Chai Qinhu et al,2002 [4]).

Winter heating is of significant concern in northern China, where the requirements for heating quality and thermal comfort have increased. A large amount of energy is consumed in the winter heating period in most of the northern regions of China, and inefficient heating will result in severe environmental pollution. In recent years, the “coal to electricity” program has been applied on a large scale. More than 2 million air source heat pumps were installed in more than 1 million family homes. In some rural areas that cannot be reached by district heating, air source heat pumps are the technology promoted by the government.

The main type of heat pump used in the China “Jing Jin Ji” area is the water loop air source heat pump, and a schematic diagram of the typical form of this common heat pump type is shown in Fig. 1. As shown in Fig. 1, the system consists of an outdoor unit, water pump, water expansion tank, water tank, and indoor radiator. however, they have some disadvantages, including a complex structure and high failure rate, as well as high electrical energy consumption, especially the leak-proof and anti-freeze of the waterway has always caused troubles to heat pump users. (Li Suhua et al, 2014 [5]). In a recent study (Xu et al, 2018 [3]), a new air source heat pump system was proposed. In that system, heat pipes were used as the heat radiator, and a compressor drove the heat pipes to release heat to the room. Based on this research, in order to meet the actual distribution of heating space, a “heat pump with multi-split heat pipe heat radiators” (ASHPP) was proposed for room heating. The heat pipe heat radiators were connected in series, and 9 groups of heat pipe heat radiators were used. At present, there are also many studies at home and abroad for systems that

combine heat pipes and heat pumps. Chen Hongbing et al, 2016 [6] built a heat pipe solar PV/T heat pump system. The test results showed that the average daily power efficiency of the heat pipe mode was 25.7% higher than that of a single photovoltaic power generation system. QU Peipei et al, 2018 [7] established a new dual-evaporator heat pump and separate heat pipe coupling system to investigate the influence of factors such as outdoor temperature and solar radiation intensity on performance parameters under three operating modes.

In this paper, a prototype of the proposed ASHPP heating system was built and an experimental study was performed to analyze the temperature distribution of each radiator. The variation of the heating performance of the system with indoor air temperature and outdoor air temperature were studied. The goal of this research was further improving the energy efficiency level of traditional domestic heat pumps, and developing a new domestic heating technical means.

2. Circulation theory

The ASHPP system is shown in Fig. 1. It consists of a compressor, multiple condensers coupled with heat pipe heat radiators, consists of a compressor, multiple condensers coupled with heat pipe heat radiators, a throttling device, an evaporator, and connecting tubes. The heat pump system operates in servers with the vapour compression circulation. The liquid refrigerant is evaporated in the evaporator and the vapour is absorbed into the compressor. With power consumption in the compressor, the vaporised refrigerant is transformed into a supersaturated vapour at higher temperature/pressure. As shown in Fig. 1, the refrigerant flows out of the compressor through 9 groups of condensers and heat pipes, which combine to function as a heat exchanger. Each piece of equipment releases its embodied thermal energy into a single room, leading to an increase in the in-room air temperature.

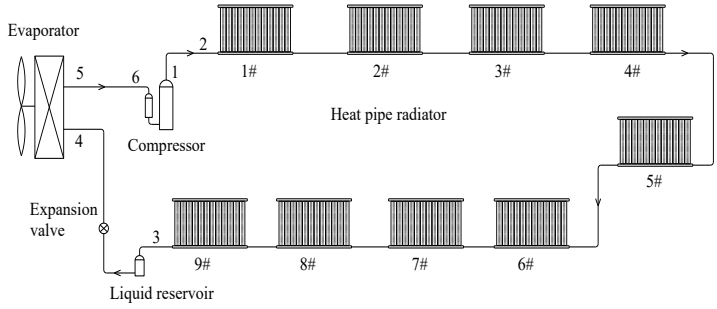

Figure 1: ASHPP system

3. Experimental Study

The heating performance of ASHPP system was mainly affected by indoor and outdoor temperatures. This article built a system and tested it in different indoor and outdoor temperatures. The experimental device mainly included a compressor, finned tube heat exchangers, axial flow fans, etc. The specific models and parameters of the compressor are shown in Table 1.

Table 1 Specific models and parameters of compressors

Model	Frequency	Voltage	LRA I-Block	I-Open max	Volume	Speed
ZW34KSE-PFS-582	50 Hz	220VAC	75.2A	19.75A	8.0 m^3/h	2900/min

The ASHPP system was placed in air enthalpy-type psychrometric rooms, as shown in Fig. 2. A total of 9 indoor units were connected to the outdoor unit in series, and pressure sensors were installed at the inlet and inside each indoor unit. The temperature of both the indoor and outdoor chambers can be controlled from -10 ℃ to 50 ℃.

In the experimental system, the air-side inlet and outlet temperature and humidity could be measured with a temperature transducer (Pt100) and humidity transducer. A hermetic-type compressor with a nominal capacity of 2100 W designed for R410A was installed. Refrigerant pressures in the heat pump and heat pipes were measured using pressure transducers with an uncertainty of ±0.5%. Temperatures were measured using Pt100 temperature transducers with an uncertainty of ±0.15 °C. A mass flow meter was installed to measure the mass flow rate of the refrigerant through the condenser. The power input to the compressor was measured using a power meter with an uncertainty of ±0.5%.

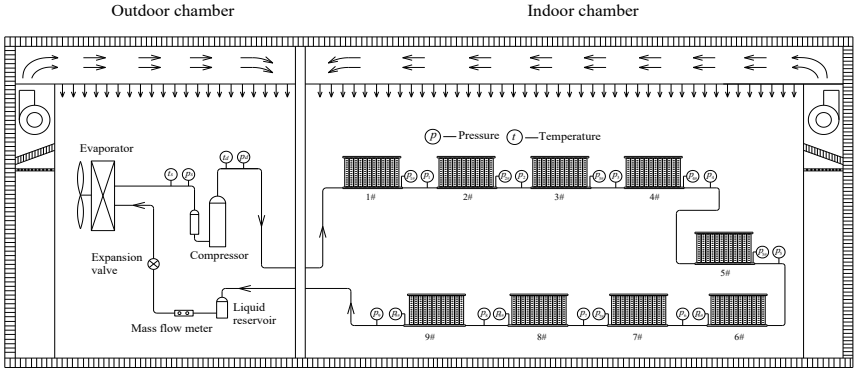

Figure 2: Schematic diagram of the prototype test system

4. Results and discussion

4.1. Radiator surface temperature distribution

Figure 3 shows that, with the exception of the first heat pipe, the surface temperatures of the heat pipes are approximately consistent with each other. For example, the surface temperature of heat pipe 2 is 50 ℃, while it is 49 ℃ at the final heat pipe (#9) when the outdoor temperature t_o=-10 ℃. The surface temperature of first heat pipe (#1), is approximately 18–25 ℃ higher than the other heat pipes. This was because the high-temperature compressor discharge vapor first entered in the first heat pipe (#1), exothermic heat of the first heat pipe contained some sensible heat, so the temperature was high. The surface temperature of heat pipe 2-9 was similar, the final heat pipe (#9) was slightly lower. This indicated that the number of end heat pipe radiators in series matched with the heat pump well, and the refrigerant was fully condensed. Figure 3 also shows that the difference in surface temperature between the first heat pipe and the other heat pipes varies. The lower the outdoor temperature, the larger this surface temperature difference will be. The reason for this is that when the outdoor temperature is lower, the compressor discharge temperature is higher, and the first heat pipe will receive the highest temperature refrigerant from the compressor discharge ports; thus, the surface temperature difference between the first heat pipe and the other heat pipes is increased.

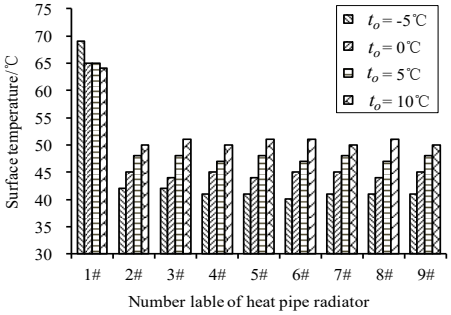

Figure 3: Surface temperature of ASHPP system

4.2. Heating performance of the ASHPP system

According to the experimental results, the heating performance of the system is analyzed. The unit heating capacity formulas are calculated as follows:

$$Q = m(h_1 - h_2) \tag{1}$$

In the formula:
Q——Heating capacity, kW;
m——Mass ratio of refrigerant to mixed liquid in mixed liquid of refrigerant and lubricating oil, kg/s;
h_1——Specific enthalpy of refrigerant at the inlet of heat exchanger, kJ/kg;
h_2——Specific enthalpy of refrigerant at the outlet of heat exchanger, kJ/kg;

The system power consumption was analyzed with the power data recorded by the power meter when the system reached at a stable operating state under a given working condition. The COP was calculated by the power meter and the heating value was calculated by the enthalpy difference during the system reaches at a stable operating state:

$$Q = m(h_2 - h_3) \tag{2}$$

According to calculation, the variation in heating performance with different refrigerants is shown in Fig. 4. Four different refrigerants (R134a, R410A, R32, and R718) were considered, with outdoor temperatures of -10 ℃, -5 ℃, and 0 ℃; the indoor temperature was 20 ℃. Figure 5 indicates that the selection of refrigerant g has an effect on the heating capacity and heating COP of the system. R32 and R410A yield the highest heating capacity and heating COP. Among the four types of refrigerants, the heating COP value with R32 is approximately 1.3%–2.2% higher than that with R134a. For example, the heating COP value of R32 can reach 2.8 for an outdoor temperature of -10 ℃ and indoor temperature of 20 ℃. R718 can also be used as a heat pipe working fluid for room heating, but its heating COP is relatively low, about 8% less than that of R410A.

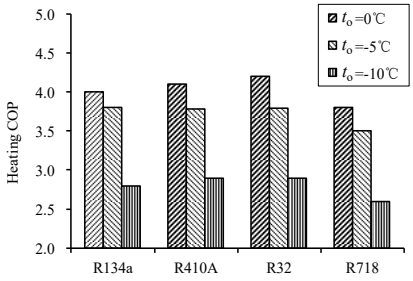

Figure 4: Heating COP for different refrigerant

5. Conclusion

An air-source heat pump with multi-split heat pipe heat radiators (ASHPP) system for room heating was proposed. Heat pipe radiators were connected in series and driven by a compressor and condenser. A test room with an artificial load was constructed, and an experimental ASHPP system was developed. The pressure and temperature distribution were investigated experimentally. Variations in the system heating performance with different numbers of heat pipes were investigated, and the most important conclusions of this study are as follows:

1) Except for the first heat pipe, the surfaces of the other heat pipes were approximately consistent with each other. The surface temperature of the first heat pipe was about 18–25 ℃ higher than that of the other heat pipes.

2) R32 and R410A yield the highest heating capacity and heating COP. Among the four types of refrigerants tested, the heating COP value of R32 was about 1.3%–2.2% higher than that of R134a. R718 can

also be used as the heat pipe working fluid for room heating, but its heating COP was relatively small, about 8% less than that of R410A.

3) When the ASHPP system was run with an outdoor temperature of -10 ℃ and indoor temperature of 20 ℃, the heating COP can reach 2.8.

Abstract

Ammonia is widely used as a refrigerant in air conditioning, food preservation and for fuel storage purposes. Ammonia is an attractive candidate for electrochemical compression (ECC). Electrochemical compressors can be an ideal replacement for mechanical compressors because of noiseless operation, higher efficiencies at lower voltages and the ability to operate without the use of Global Warming Potential (GWP) working fluids. This paper explores the electrochemical compression of ammonia with hydrogen as a carrier gas, using fuel cell type hardware. A perfluorosulfonic acid (PFSA) membrane allows the transfer of ammonia, using hydrogen as a carrier gas, by the conduction of NH_4^+ ions from anode to cathode. The ECC performance was evaluated using electrochemical methods using a single cell at STP. The effects of back-diffusion in the compression process are highlighted and suggestions to improve the ECC of ammonia-hydrogen blends are proposed.

Keywords: Ammonia; Hydrogen; Electrochemical compression; Nernst voltage; Diffusion; Compression Ratio

1. Introduction

Global energy demand is rising rapidly as we face the depletion of conventional sources of energy. There is a need to look for sustainable alternatives to traditional mechanical energy conversion devices such as heat pumps that account for a large and growing portion of the global demand for energy. The developments in fuel cell technology to generate electricity in a clean and environment-friendly manner has placed hydrogen as an important energy vector to meet both stationery and automobile power generation applications. Ammonia is a rich source of hydrogen and could also play a significant role as an energy vector in a hydrogen economy. Moreover, ammonia itself is widely used as a refrigerant in large scale industrial heat pump applications particularly in applications involving the food chain. Electrochemical compression of ammonia therefore can be used for conveying ammonia when used as a bulk energy vector but could also be an alternative to mechanical compressors for heat pump applications.

Electrochemical compression is superior to mechanical compression as it offers the potential to compress a working fluid at higher efficiency, noiseless operation, usage of green refrigerants, and greater reliability due to a lack of moving parts.

The first validation of the concept of an electrochemical compressor based on hydrogen was done by Sedlak et al. [1], who applied a potential difference to transfer protons across a proton exchange membrane and

* Corresponding author. Tel.: +1-302-218-4279.
E-mail address: Bamdad.bahar@xergyinc.com

achieved higher pressures. Rohland et al. [2] and Strobel et al. [3] carried the idea forward to electrochemically transfer and purify hydrogen. All these studies were only focused on hydrogen compression until 2009, when the general idea of using electrochemical compression for heat pump applications was pioneered by Bahar et al. [4]. Bahar et al. [5] then proposed the use of ammonia in electrochemical compressors (ECC) using hydrogen as the carrier gas by engaging perfluorosulfonic acid (PFSA) membranes to electrochemically compress ammonia under a potential difference. An overall system analysis was favorably reported by Tao et al. [6] in 2017.

Ammonia is a well-established contaminant for PFSA membranes in fuel cell applications and is actively scrubbed out of reformed hydrogen gas streams used for fuel cells. Our challenge in this project was to understand and then develop transportation mechanisms for ammonium ions in ion-exchange membranes.

The hardware of an ECC is similar to that of a fuel cell and consists of a membrane-electrode-assembly (MEA) sandwiched between two graphite plates with flow fields for gas distribution, held together by end plates on either side. The entire assembly is held together by eight bolts, all maintained at a same torque (Figure 1).

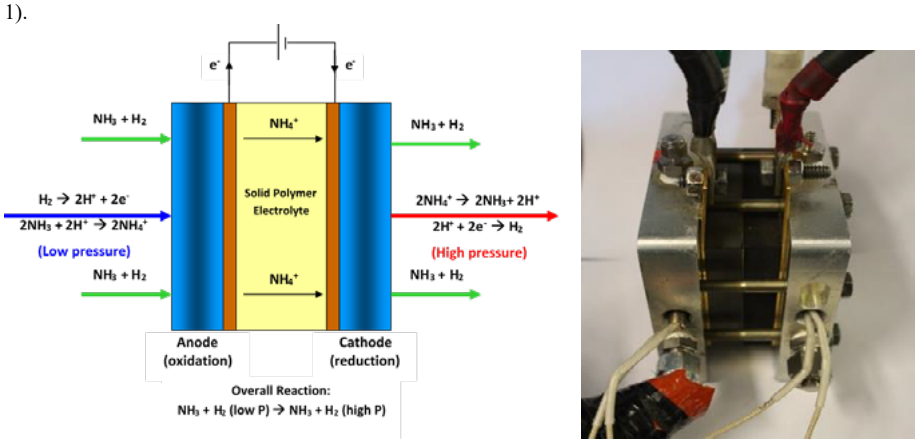

Fig. 1. Schematic of an electrochemical ammonia compressor (left); ECC hardware (right)

A mixture of ammonia and hydrogen gases is fed to the anode, where, by applying a DC voltage, hydrogen gets oxidized to protons (H^+), which combine with ammonia to form ammonium ions ($NH_4{}^+$), as in Equations 1 and 2.

$$H_2 \rightarrow 2H^+ + 2e^- \tag{1}$$

$$2NH_3 + 2H^+ \rightarrow 2NH_4{}^+ \tag{2}$$

The ammonium ions get transferred across the membrane to the cathode. Two electrons are required for this reaction to take place, as per Equation 1. The ammonium ions are reduced at the cathode to regenerate ammonia and hydrogen gases at a higher pressure, as shown in Equations 3 and 4.

$$2NH_4{}^+ \rightarrow 2NH_3 + 2H^+ \tag{3}$$

$$2H^+ + 2e^- \rightarrow H_2 \tag{4}$$

The overall electrochemical reaction can be written as:

$$2NH_3 + H_2\,(low\ pressure) \rightarrow 2NH_3 + H_2\,(high\ pressure) \tag{5}$$

The production of protons facilitates the formation of ammonium ions which is the species conducted by the PFSA membrane. The membrane needs to be functionalized by soaking in aqueous ammonia solution overnight. In this paper, the use of ammonia as a working fluid in an electrochemical compressor (ECC) is

reviewed. The performance of the ECC is presented in the form of output pressures reached within the phase conversion pressure limits of gaseous ammonia at room temperature; cathode pressures and current densities are also plotted for all voltages tested.

The membrane used for experiments was a sulfonated tetrafluoroethylene-based fluoropolymer-copolymer membrane, 50 µm thick. The platinum (Pt) catalyst loading on the electrodes was 0.3 mg/cm^2. The membranes were functionalized for ion exchange from H^+ to $NH_4{}^+$ by soaking in ammonia solution overnight, after which, they were thoroughly rinsed with deionized water and dried gently using paper towels. The membrane surface has residual ammonia and does not readily stick to the electrodes, so the membrane and electrodes were stacked together inside the ECC and assembled by tightening the bolts. The ECC was assembled with 25 cm^2 hardware.

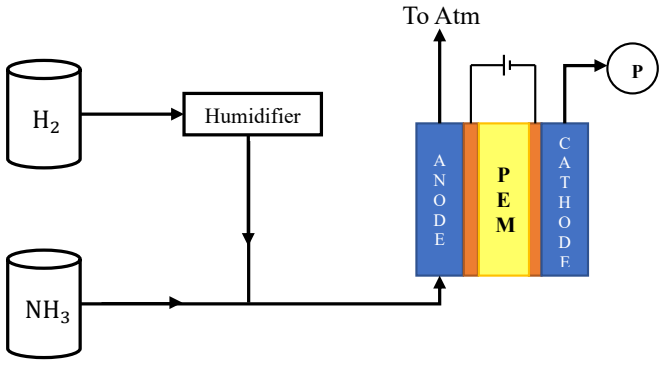

Fig. 2. Experimental setup of the electrochemical ammonia compressor

The ECC was tested at room temperature (22°C) and pressure (1 atm). The PFSA membranes used for experiments only function when properly hydrated [7, 8]. Hence, it is important to maintain adequate humidity in the system. The inlet gas stream at the anode consisted of a 50-50 mixture of fully hydrated hydrogen (100% RH at a flow rate of 100 cm^3/min) and dry ammonia (0% RH at a flow rate of 100 cm^3/min), resulting in an overall humidity around 50%, whereas, the cathode port terminated with a pressure transducer. A schematic of the experimental setup is shown in Figure 2. The ammonia inlet stream was kept dry as ammonia reacts with water to form ammonium hydroxide, which can precipitate inside the humidifier chamber. The anode outlet was open to the environment, hence the anode pressure was fixed at 1 atm. The ECC cell was tested using the fuel cell test station (FCTS) from Arbin Instruments. The experiments were performed at four different operating voltages: 0.025, 0.05, 0.075 and 0.1 V.

2. Results and Discussion

Before preparing the MEA, the membranes were soaked in ammonia solution, which makes them alkaline in nature implying that the contribution of H^+ to the generated current can be neglected, which is also evident by the almost zero current when the ECC was tested with only hydrogen at the anode. Also, the total amount of ammonia and hydrogen gases generated at the cathode can be expressed in terms of total current I:

$$\dot{n}_{H_2} = \frac{I}{2F} \tag{6}$$

$$\dot{n}_{NH_3} = \frac{I}{F} \tag{7}$$

where $\dot{n}_{H2}$ is the mol/s of hydrogen transferred across the membrane according to Faraday's law [9], $\dot{n}_{NH3}$ is the mol/s of ammonia transferred, and F is Faraday's constant.

The applied cell voltage E_{cell} is the sum of the Nernst potential, the activation overpotential, and ohmic (IR), mass transport and back diffusion losses [10]:

$$E_{cell} = E_{Nernst} + \Delta E_{Activation} + \Delta E_{Ohmic} + \Delta E_{Transport} + \Delta E_{Back\ Diffusion} \tag{8}$$

The activation overpotential $\Delta E_{Activation}$ is a sum of the overpotentials at the anode and the cathode. The ohmic losses ΔE_{Ohmic} arise mainly due to the membrane resistance and contact resistance between difference components of the ECC. At high current densities, mass transport losses denoted by $\Delta E_{Transport}$ could become significant due to the inability to maintain adequate reactant gas supply to the anode catalytic sites; however this loss term is not expected to be significant in the case of ammonia compression due to the small operating currents. $\Delta E_{Back\ Diffusion}$ represents losses due to back diffusion of ammonia and hydrogen from the pressurized cathode to the anode through the membrane. All of these losses cause the required voltage to exceed the Nernst voltage for a given compression ratio. The Nernst potential E_{Nernst} defined by the Nernst equation, Equation 9, depends logarithmically on the pressure ratio between the cathode (high) and anode (low). The total pressure at the anode and cathode can be expressed in terms of the partial pressures of hydrogen and ammonia.

$$E_{Nernst} = \frac{RT}{F} ln\left\{\left(\frac{P_{H_2,out}}{P_{H_2,in}}\right)^{\frac{1}{2}}\left(\frac{P_{NH_3,out}}{P_{NH_3,in}}\right)\right\} \tag{9}$$

where R is the universal gas constant, and T is the cell temperature in K.

The ECC performance at different operating voltages is presented in Figure 3. For each applied voltage, the current density (red curve) is the highest at the start of the operation and declines rapidly at first before gradually reaching an equilibrium value after a few hours. Concurrently, the cathode pressure (blue curve) rises rapidly at the start and eventually plateaus to an equilibrium value. Both the initial and equilibrium current densities increase with the applied voltage as shown in Figure 3. Similarly, the equilibrium pressures also increase with the applied voltage. The fact that the current is non-zero although the cathode pressure has equilibrated indicates that back-diffusion is occurring.

The backward diffusive flux $(\dot{n}_b)$ as given by Fick's law is directly proportional to the difference in the concentration of individual species (ΔC) across the membrane and inversely proportional to the membrane thickness (d):

$$\dot{n}_{b,NH_3} = \mathcal{D}_{NH_3} A \frac{\Delta C_{NH_3}}{d}, \quad \dot{n}_{b,H_2} = \mathcal{D}_{NH_3} A \frac{\Delta C_{H_2}}{d} \tag{10}$$

where $\dot{n}_{b,NH_3}$ and $\dot{n}_{b,H_2}$ are the backward diffusive fluxes for ammonia and hydrogen, respectively. $\mathcal{D}_{NH_3}$ and $\mathcal{D}_{NH_3}$ are the diffusivities of ammonia and hydrogen, respectively, in the membrane. The concentration of ammonia and hydrogen at either face of the membrane is directly related to their partial pressures through Henry's law. Henry's constant (H) depends on the type of membrane and the gas in contact with the membrane [10].

$$C = HP \tag{11}$$

Combining Equations 10 and 11, we can express the diffusive fluxes as a function of cathode and anode pressures as:

$$\dot{n}_{b,NH_3} = (\mathcal{D}H)_{NH_3} A \frac{(P_c - P_a)_{NH_3}}{d} \tag{12}$$

$$\dot{n}_{b,H_2} = (\mathcal{D}H)_{H_2} A \frac{(P_c - P_a)_{H_2}}{d} \tag{13}$$

where $\mathcal{D}H$ is the permeability constant and depends on the nature of the gas and membrane. Denoting $\dot{n}_n$ as the net molar flow rate to the cathode (= forward flux – back diffusive flux), and assuming that both ammonia and hydrogen follow the ideal gas law, we can write:

$$(\dot{n}_n)_{NH_3} = \dot{n}_{f,NH_3} - \dot{n}_{b,NH_3} = \frac{\dot{P}_{c,NH_3} V_c}{RT} \tag{14}$$

$$(\dot{n}_n)_{H_2} = \dot{n}_{f,H_2} - \dot{n}_{b,H_2} = \frac{\dot{P}_{c,H_2} V_c}{RT} \tag{15}$$

where $\dot{P}_c$ is the rate of cathode pressure rise (Pa/s), and V_c is the pressurized volume on the cathode side (m^3). Substituting the expressions for forward and backward fluxes in Equations (14) and (15), the compression equations can be written as:

$$\text{Ammonia: } \frac{I}{F} - (\mathcal{D}H)_{NH_3} A \frac{\left(P_{NH_3,c} - P_{NH_3,a}\right)}{d} = \frac{\dot{P}_{NH_3,c} V_c}{RT} \tag{16}$$

$$\text{Hydrogen: } \frac{I}{2F} - (\mathcal{D}H)_{H_2} A \frac{\left(P_{H_2,c}(t) - P_{H_2,a}\right)}{d} = \frac{\dot{P}_{H_2,c} V_c}{RT} \tag{17}$$

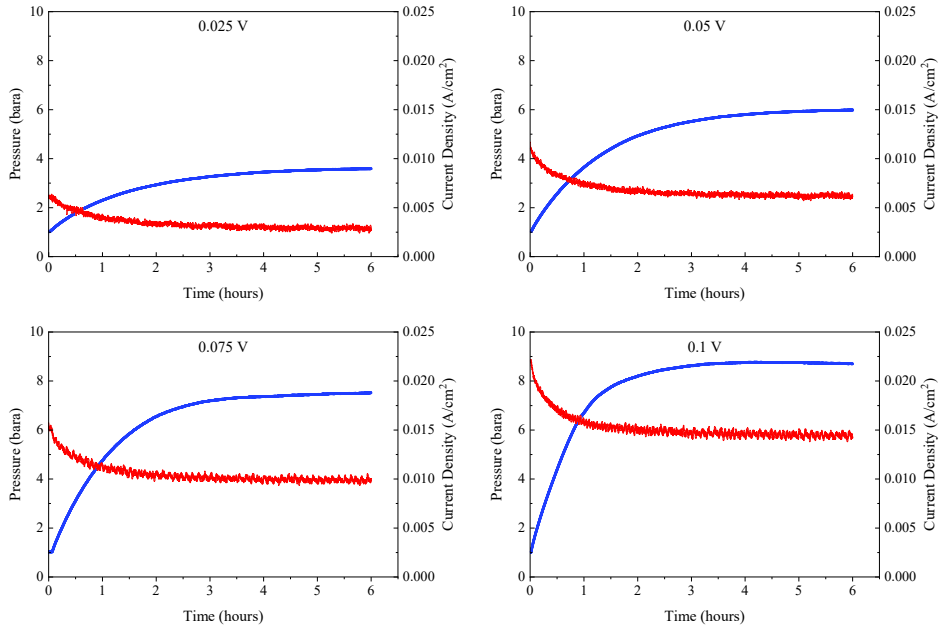

Fig. 3. Pressure (blue) and current density (red) vs. time for Nafion 212 at different applied voltages

Since ammonium is a much bulkier ion than a proton, the current density observed in this case is much less than in the case of a pure hydrogen compressor [7].

When the pressure reaches its equilibrium value, $\dot{P}_c = 0$, in an ideal scenario without back-diffusion, the equilibrium current would also reduce to zero. However, in reality, the forward flux equals the backward flux at steady state, and hence, there is an equilibrium current which maintains the cathode at equilibrium pressure $\left(P_{c,eq}\right)$given by Equations (18) and (19).

$$\frac{I_{eq}}{F} = \frac{(\mathcal{D}H)_{NH_3} A \left(P_{c,eq} - P_a\right)_{NH_3}}{d} \tag{18}$$

$$\frac{I_{eq}}{2F} = \frac{(\mathcal{D}H)_{H_2} A \left(P_{c,eq} - P_a\right)_{H_2}}{d} \tag{19}$$

As the pressure builds at the cathode, with the anode still at atmospheric pressure, it creates a pressure difference across the membrane, which in turn forces ammonia to permeate back through the membrane to the anode by back-diffusion. This poses a barrier in achieving higher pressures. The back-diffusion losses increase

as the pressure difference across the membrane increases, hence lowering the ECC efficiency at higher pressures.

The composition of the ammonia-hydrogen gas mixture at the cathode side was measured using the Nesslerization method at two different stages of compression – (i) cathode open and (ii) cathode closed. The cathode outlet stream containing the ammonia-hydrogen mixture was passed into a graduated cylinder (250 mL) which was completely filled with and held inverted in a 1250 mL beaker containing Nessler's reagent. Ammonia in the outlet stream immediately and completely reacts with Nessler's reagent to change its color from pale yellow to yellowish-brown [11,12], which was analyzed using a spectrophotometer (Vernier SpectroVis Plus). The hydrogen in the mixture is inert with respect to Nessler's reagent and was collected in the graduated cylinder using the downward displacement method.

First, the quantification of the cathode outlet stream was carried out when the cathode was open to the atmosphere. At this stage, both anode and cathode were maintained at the same pressure $(P_a = P_c)$ and hence, back-diffusion losses were zero. In this case, the ratio of ammonia to hydrogen measured was 2, which is also the stoichiometric ratio of NH_3 and H_2 at the cathode as per Equations 1-4.

Next, the cathode outlet was closed and ECC was allowed to pressurize. After the pressure attained equilibrium, the quantification of the cathode outlet stream was carried out by slowly opening the outlet valve and passing the constituents to the Nessler's reagent solution. The ammonia-hydrogen ratio obtained in this case is plotted along with the results from the cathode open case for all four operating voltages in Figure 4.

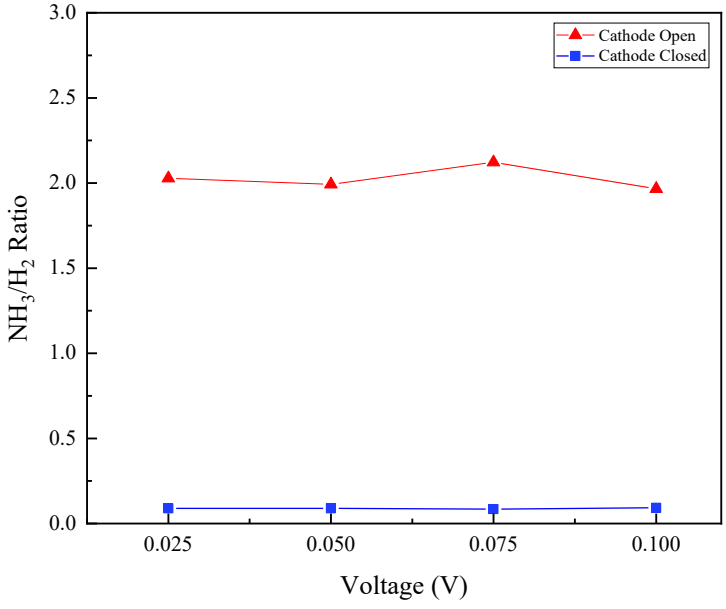

Figure 4. $NH_3{:}H_2$ volumetric ratios for 'cathode open' and 'cathode closed' cases for the four voltages tested

The $NH_3{:}H_2$ for cathode open case was measured to be 2. However, the ratio obtained in the 'cathode closed' case is only about 0.085. This means that the cathode chamber is predominantly composed of hydrogen in the 'cathode closed' case. Thus, one can conclude ammonia diffuses back to the anode at a significantly faster rate than hydrogen.

Furthermore, separate depressurization experiments were carried out to evaluate the permeability coefficients of both hydrogen and ammonia through the Nafion membrane. The cathode was initially pressurized by directly connecting it to the respective gas cylinders. The applied voltage was set to zero and the cathode was allowed to depressurize. The gas diffusing back from cathode to anode was detected by the formation of gas bubbles when the anode outlet tube was immersed in oil.

The rates of depressurization can be determined by setting $I = 0$, $P_{NH_3,a} = 0$, and $P_{H_2,a} = 0$ in Equations (16) and (17), which gives exponential expressions for the rates of depressurization:

$$P_{NH_3,c}(t) = P_{NH_3,c,i}\exp\left(-\frac{(\mathcal{D}H)_{NH_3}ART}{dV_c}t\right) \quad (20)$$

$$P_{H_2,c}(t) = P_{H_2,c,i}\exp\left(-\frac{(\mathcal{D}H)_{H_2}ART}{dV_c}t\right) \quad (21)$$

where $P_{NH_3,c,i}$ and $P_{H_2,c,i}$ are the initial cathode pressures of ammonia and hydrogen, respectively, at the start of depressurization.

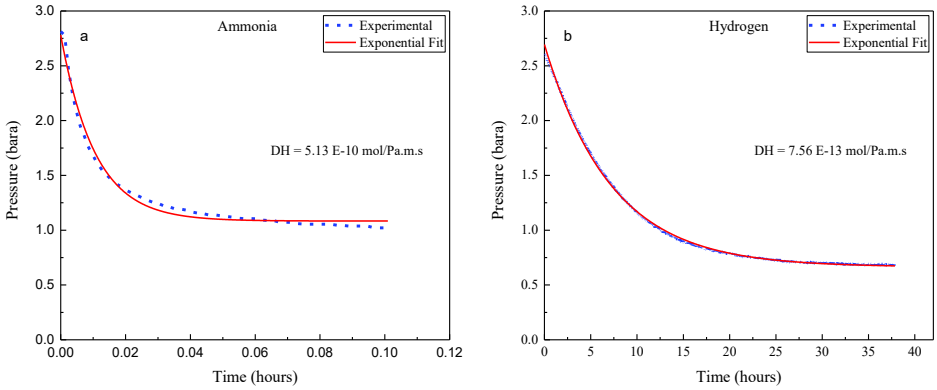

Figure 5. Cathode depressurization profiles for (a) ammonia, and (b) hydrogen

Figure 5 shows the measured depressurization curves (blue) obtained for both ammonia and hydrogen. The exponential curve fits (red) closely match the experimental curves for both gases as shown in Figure 5. Using the curve fits and substituting the known values of $\boldsymbol{A}, \boldsymbol{R}, \boldsymbol{T}, \boldsymbol{d}$, and $\boldsymbol{V_c}$, into Equations (20) and (21), the values of the two permeability coefficients are obtained as:

$$(\mathcal{D}H)_{NH_3} = 5.13\,E-10\ \mathrm{molPa^{-1}m^{-1}s^{-1}}$$

$$(\mathcal{D}H)_{H_2} = 7.56\,E-13\ \mathrm{molPa^{-1}m^{-1}s^{-1}}$$

The permeability coefficients obtained here are similar to the values found for Nafion membranes for ammonia ($\sim 9E-10\ \mathrm{molPa^{-1}m^{-1}s^{-1}}$) in Refs. [12-14] and hydrogen ($\sim 3.5\,E-14\ \mathrm{molPa^{-1}m^{-1}s^{-1}}$) in Refs. [15–17]. Figure 5 shows that when $(\mathcal{D}H)_{NH_3} \gg (\mathcal{D}H)_{H_2}$, then the cathode chamber is mostly composed of hydrogen and ammonia is only present in trace quantities. The Nafion membrane functionalized in ammonia solution is highly permeable to molecular ammonia and hence, it is very difficult to pressurize ammonia using an ECC with the given set of materials and conditions. Nafion being a PFSA membrane, requires moisture to function properly. However, higher hydration levels also exacerbate back-diffusion. Therefore, a better candidate for ammonia compression could be a membrane that can operate at low humidity levels. Also, membrane chemistry could be optimized to enhance the conduction of ammonium ions while mitigating the diffusion of molecular ammonia. A thicker membrane could also reduce the rate of back-diffusion and improve the working process of compression.

3. Conclusion

This work discusses the advantages of an electrochemical ammonia compressor over a conventional mechanical compressor. Electrochemical compression hardware was used for the ECC of an ammonia-hydrogen blend; hydrogen was used as the carrier gas, which facilitates the generation of ammonium ions. The ECC was operated at various voltages using a single cell setup. When the cathode outlet is open, the amount of ammonia produced at the cathode is twice that of hydrogen. When the cathode is closed, the pressure rises rapidly and eventually plateaus to an equilibrium value. Similarly, the current is maximum at the start of the compression and drops to attain an equilibrium value. The quantification of cathode constituents during

equilibrium resulted in an ammonia:hydrogen ratio to be around 0.085, which is much smaller than the ideal value of 2. Separately conducted depressurization experiments for ammonia and hydrogen showed that the permeability coefficient of ammonia is about three orders of magnitude larger than that of hydrogen. This implies that ammonia back-diffuses much faster than hydrogen and hence, hydrogen contributes almost the entire cathode pressure. Successful ECC of ammonia would require an alternate membrane formulation that allows the forward transfer of ammonium ions while simultaneously reducing the back diffusion of molecular ammonia.

Abstract

Ionic membranes are widely used in the electrochemical applications such as electrolysis and fuel cells. Recent advances in these membranes have led to new markets for ionic membranes, that can provide high water permeability in heating, ventilation, and air conditioning (HVAC) applications. These materials can be useful in many applications to help provide more efficient building technologies and higher indoor air quality through devices such as ionic liquid heat pumps (ILHPs), ionic liquid desiccants (ILDs), and energy recovery ventilators (ERVs) and water-based evaporators (WBEs). Water transmission mechanisms behind the water transport is not well understood, since different functional membranes provide transmission in different ways. Water transportation can be a function of ionomer structure via the building blocks of the backbone, or from the functional groups on the side chains or from subtle features in membrane design and composition. In this work, we studied the permeation properties of different advanced ionic membranes. Membranes that show high water selectivity, and permeances exceeding $4x10^5$ g/(day*m^2*Pa) are presented. Principal mechanisms driving the water transmission such as sorption, diffusion, and pervaporation (permeation/evaporation) are described and identified for different classes of membranes. High performance membranes are identified for optimum applications for different HVAC systems.

1. Introduction

The number of air conditioning units employed globally will increase from approximately 1.2 billion units to at least 4.5 billion by 2050. Developing countries will see a fivefold increase in demand over the same period. This increased demand will place a massive new burden on electricity grids that are already straining under current demand. When combined with the atmospheric impact of the refrigerants utilized by air conditioners, the energy consumption associated with mechanical cooling represents one of the largest end-use risks to our climate. Hence heating and cooling for buildings is accounts for a good portion of the resource demand in the developed world. Sustainable and high efficiency technology for heating and cooling applications is critical global need.

Water transporting membranes can be useful in many HVAC applications that reduce the total energy load for buildings. In one application, this is done by reducing the relative humidity in the air to be treated (and reduction in latent heat requirements in HVAC systems). Ionic liquids, as the name implies, are ionic salts that remain liquid under normal operating conditions. These fluids are mainly useful for their desiccation properties as concentrated ionic liquids (ILD's), as they can adsorb or desorb water vapor to help control the relative humidity of the air in its container. With membranes, they are mainly utilized in flat sheet or shell and tube contactors that utilize fluid flows of air and desiccant in crossflow patterns. These systems can dehumidify gas streams with high efficiency. Additionally, these contactors can be paired with a heat pump system to

E-mail address: bamdad.bahar@xergyinc.com

regenerate the desiccant so that the system can be operated in a loop. In Energy recover ventilator (ERV) applications, an assembly of membranes allows exchange of heat between a cool and warm airstream (incoming and outgoing streams required to make up fresh air in buildings). In yet another application, membranes are used to enable heated water from heat pump systems to evaporate. Membranes in all these applications allow water vapor to transport from one side to the other. Interestingly, these classes of membranes are also being used to control humidity in vegetable trays in refrigerators. There are many other critical applications like for example sea water desalination membranes where water transmitting membranes have utility. Thus, the transport rate of water in membranes is clearly a critical issue in the performance of these systems. This paper provides basic insight into water transmission across functional (non-porous) membranes.

Figure 1 & 2. Applications for Advanced Ionic Membranes

It should be noted that there are two classes of membranes used for these applications, porous and non-porous membranes. Porous membranes are typically microporous structures with 'open' pores which allow for gas flow across the membranes; while non-porous membranes typically involve impervious polymer films that do not allow any bulk (gas) flow across them. There are significant differences in how these two classes of membranes perform. Micro-porous membranes generally offer higher water transmission rates, but also allow bulk flow (i.e. contaminants) to also cross the membranes. Impervious (non-porous) membranes offer much higher selectivity, however with some reduction in water transmission rates. This paper only reviews impervious non-porous membranes, which are targeted at applications that require no, or low cross contamination; and usually very long operating life. These applications include ERV's where contamination of incoming air into a building is a critical issue, and in ILD's where salt carryover, and salt crystallization in micro-porous membranes is also a critical issue in operation.

Polymeric, non-porous reinforced membranes made from (ionically) functionalized polymer materials that transmit water were originally developed as solid polymer electrolytes for electrochemical applications [1]. These materials were originally developed as solid polymer electrolytes for electrochemical applications. These materials typically have ionically conductive groups embedded in the repeating unit of the polymer. These functional groups aid in the transport of water through the membrane.

Water mass transfer mechanisms are reviewed, different transport mechanisms are discussed, and performance data is provided for reference.

2. Water Transmission Mechanisms

Water transmission mechanisms behind the water transport is not well understood, since different functional membranes provide transmission in different ways. Water transportation can be a function of

ionomer structure via the building blocks of the backbone, or from the functional groups on the side chains or from subtle features in membrane design and composition.

2.1. Electro-Osmotic Drag

When a voltage is applied across the polymer electrolyte membrane, water is mainly transported inside the membrane by electroosmotic drag. Fig. 3 is a schematic of the water transport in a fuel cell membrane. The two main water transport processes in the membrane are electro-osmotic drag and back diffusion. Electro-osmotic drag refers to the phenomenon of water molecules being dragged by the current-carrier protons from the anode to the cathode. The electro-osmotic coefficient is the transport number of water molecules that are carried with each proton moved from the anode to the cathode. The electro-osmotic coefficient mainly depends on the temperature and water content.

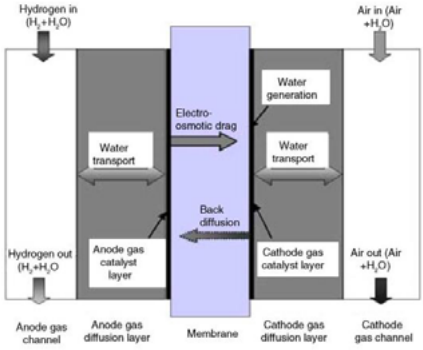

Figure 3: Schematic of water transport in a proton exchange membrane (PEM) fuel cell

2.2. Solution-Diffusion Theory

Solution-diffusion is the generally accepted mechanism of mass transport through non-porous membranes, which was first proposed by Graham [1] based on his extensive research on gas permeation through homogeneous membranes. It is held that gas permeation through a homogeneous membrane consists of three fundamental processes: (1) solution of gas molecules in the upstream surface of the membrane. (2) Diffusion of the dissolved species across the membrane matrix. (3) Desorption of the dissolved species in the downstream face of the membrane. These three fundamental processes also govern the mass transport across pervaporation membranes [2]. A schematic of the solution-diffusion theory is as shown in Fig. 4.

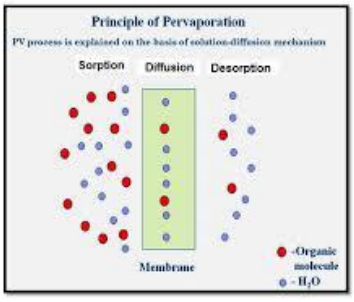

Fig. 4. Schematic of Solution-Diffusion in Pervaporation

It is to be noted that the solution-diffusion theory is only valid for governing permeation through non-swollen membranes. If membranes are swollen or plasticized by transporting species, the interactions between polymer chains tend to be diminished, and the membrane matrix will therefore experience an increase in the free volume. Hence, to reflect the permeation the solution-diffusion must be modified to account for the increase in the free volume. In the next section we discuss the results obtained from ASTM E96 and MDM testing.

2.3. Pervaporation

Pervaporation (permeative evaporation) is a mass transport phenomenon present in dense non-porous membranes. Pervaporation occurs in a gas-liquid separation system that is separated by the membrane, as the liquid contacts the membrane surface it permeates and undergoes a liquid to vapor phase change to end up in the gas stream. This can be done in reverse to remove a gas vapor to the liquid phase, as would be done in an ILD system. There are two main models that are used to describe the transport process: Free Volume and Diffusion; the latter being the more common. However, both models are important to understand and may describe the systems better in cases discussed below.

The free volume model describes a system where vapor passes through a membrane from a high concentration feed to a low concentration permeate stream. This low concentration can be established by using a vacuum line or a condenser, but the driving force is established by the difference in partial pressures between the two feeds. The mass flux is established through corresponding adsorption-desorption processes on the corresponding faces of the membrane. This flux can be established by using a condenser downstream on the permeate side, and it can be increased by adding a heater to the feed stream. These units would create the pervaporation process in the combination of the adsorption and corresponding desorption of the liquid within the membrane, and the evaporation of the liquid from the surface of the membrane with partial pressure differential. This model for membrane flow is more useful in porous materials such fiberglass or expanded polytetrafluoroethylene membranes like those commonly used in air conditioners [3], [4].

For non-porous membranes the model must include a mechanism for the diffusion of the pervaporate through the solid structure of the polymer. The solution-diffusion is defined by Fick's laws of diffusion. Fick's first law defines the flux of the system to be proportional to the concentration gradient of the fluid. This law is represented mathematically as Equation 1, where J is the flux of the system, D is the diffusion coefficient, φ is the concentration of the molecule to be dissolved, and x is the one-dimensional distance. This law describes the molecular movement of molecules from areas of high concentration to low. Fick's second law describes the diffusion dependence of the concentration gradient with respect to time. This law is derived from the first law's interaction with the law of mass conversation. The equation can be written as Equation 2. This is useful for non-steady state systems such as the air conditioning cycle. The diffusion coefficient will change based on the conditions of the system. The predominant variables are temperature, viscosity, and density. For polymer systems the diffusion coefficient can also be dependent on the primary on the concentration of the molecule within the membrane itself. This permeate in polymer is known as swelling and can have both positive and negative effects on the pervaporate and mechanical performance of the membrane [5]. Additionally, this can make real systems significantly more complicated as the change in concentration can create a change in membrane thickness [1], [3-5], [6].

$$J = -D\frac{d\varphi}{dx} \tag{1}$$

$$\frac{\partial\varphi}{\partial t} = D\frac{\partial^2\varphi}{\partial x^2} \tag{2}$$

The driving force for transport of different components is provided by a chemical potential difference between the liquid feed/retentate and vapor permeate at each side of the membrane. The retentate is the remainder of the feed leaving the membrane feed chamber, which is not permeated through the membrane. The chemical potential can be expressed in terms of fugacity, given by Raoult's law for a liquid and by Dalton's law for (an ideal) gas. During operation, due to removal of the vapor-phase permeate, the actual fugacity of the vapor is lower than anticipated on basis of the collected (condensed) permeate.

For many systems, ionically functionalized polymers are proving to be the most exciting developments. These systems are made from standard polymer backbones that could be functionalized with sidechains capped with an ionic group. These chains can be of varying length and the caps are of strong acids or bases. The most well-known of these is perfluorosulfonic acid (PFSA), which consists of a backbone of polytetrafluoroethylene with an end capped with a sulfonic acid group. This ionomer is both temperature and chemically stable. Other ionomers are functionalized with trimethylammonium, pyridine, or imidazole groups as well. The ionic groups significantly aid these materials in their water transport properties due to their hydrophilic nature. However, research in recent years indicates that the ionic groups form ionic channels formed my areas of clustered functional groups. These channels form ordered pathways for the water to more easily transfer from one surface

of the membrane to the other that are more thermodynamically favorable than the simpler diffusion seen a homopolymer with a hydrophilic backbone. These micro- or nanostructures can be aided with the addition of a surfactant or a scavenger [2], [7], [8].

Pervaporation was mainly studied and used for organic solvent dehydration. Several hydrophilic and hydrophobic membranes have been used for this application. However, hydrophobic membranes work for these purposes by selectively allowing organic compound to pass through while rejecting water and they cannot be used for HVAC applications since the membranes need to permit water movement at high flux rates. There are several available commercial polymer membranes such as polyurethanes (PU), polyvinyl alcohol (PVA), polyimides (PI), Sulfonic Acid functionalized polymer (Perfluoro and Polystyrene i.e. PFSA's and PSSA's) and polyacrylonitrile (PAN) [9].

Water transport in PFSA membranes has been studied extensively in relation to their use in electrochemical devices (such as fuel cells and electrolysis applications). In PFSA's water transport proceeds through a combination of diffusion through void spaces in the membrane, along with protons through the pores in the membrane due to electro-osmotic drag and hydraulic permeation due to pressure gradient [10]. Sulfonated styrene/ethylene – butylene/styrene (S-SEBS) triblock polymer is another low-cost proton conducting material. The sulfonic acid functional group is connected to the backbone via a fluorocarbon sidechain in PFSAs and via a benzene ring in S-SEBS [11]. The hydrophilic and hydrophobic regions in both these materials show microphase separation as seen in Figure 5, forming narrow channels through which proton and water transport takes place. In the left of Figure 5, the hydrophobic sulfonated "heads" form the outer ring of the channel with the hydrophilic fluorocarbon "tails" inside of the electron transport channels. To the right, the fluorocarbon tails face outwards, creating a proton channel within the ring.

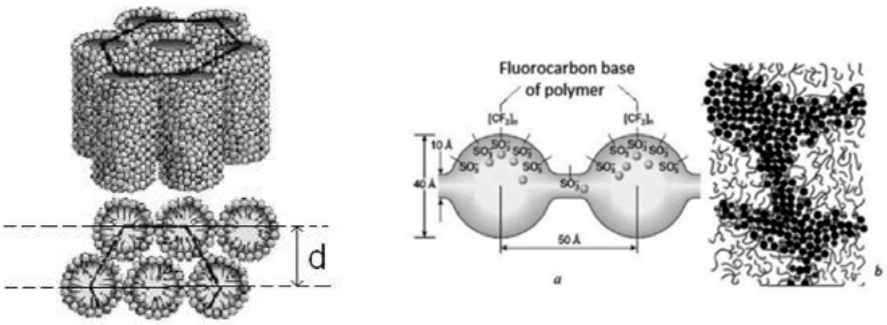

Fig. 5. (Left) Packing structure of PFSA channels; (Right) Microphase separation and channels in PFSA

2.4. Composite Membranes

High Performance Ionomers for water transport require water adsorption in order to function. However, water channels in the Ionomer make the polymer structure weak (gel like). High water content increases the water transmission rate but decreases the mechanical strength. The ideal membrane system is thin (shortest transport path), strong (durable and easily installed), and utilizes highest functionality polymer (i.e. highest water adsorption). In order to address the competing requirements of high-water transmission (i.e. thinness) and mechanical strength, membranes are typically made by reinforcing the functional polymer with a mechanically strong structural element – i.e. composited.

Therefore, composite membranes consist of at least two structural elements made from different materials, as shown in Figure 2. A single-layer composite membrane consists of a thin, selective layer atop a microporous support. The support provides mechanical strength, whereas the water transmission is performed by the thin top-layer. A multi-layer composite membrane can consist of a porous support and many layers of different materials, each performing a specific function. Thin-film composite membranes are typical for pervaporation applications.

The selective layer can be applied by lamination, solution coating, interfacial polymerization, or plasma polymerization methods. Compared to integrally-skinned asymmetric membranes, composite membranes offer several significant advantages: (i) independent selection of materials from which the separating layer and the porous support are formed, (ii) independent preparation of the separating layer and the porous support membrane, thereby making it possible to optimize each structural element, and (iii) very expensive membrane materials (>1000 $/lb) can be used because only a very small amount of polymer is required for the formation of the thin separation layer (~1 g polymer/m^2 of membrane for a 1-µm-thick selective layer).

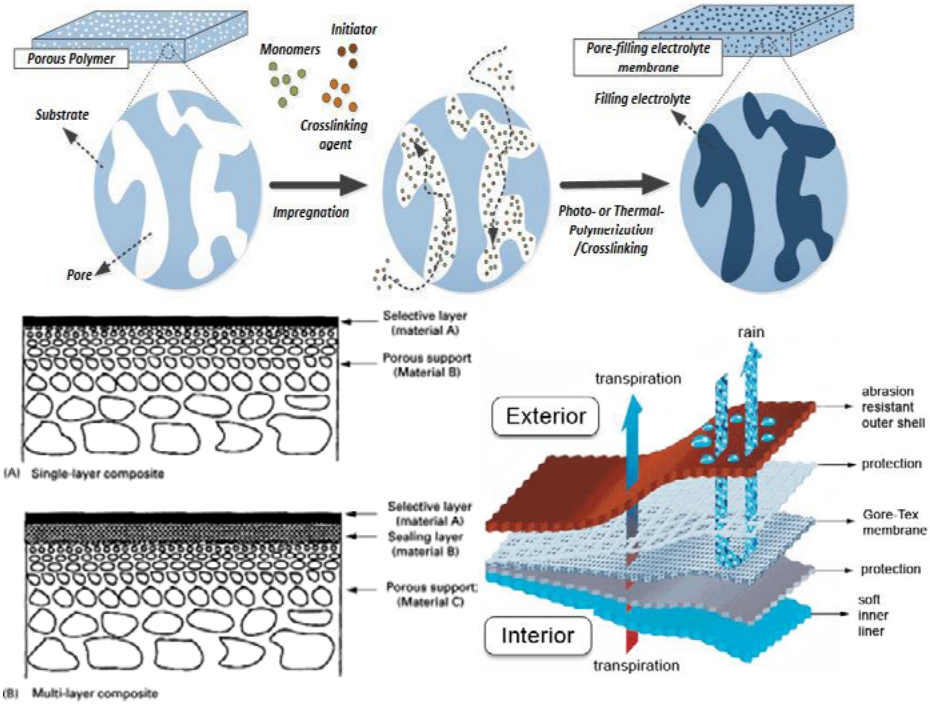

Figure 6: (Top & bottom left) Graphics showing functional polymer combined with porous reinforcement to form a reinforced non-porous composite membrane; (bottom right) composite structures in clothing industry

Composite structures are very common in the clothing industry. Beyond ionic polymers, other polymers that provide water transmission can be found in fabric outerwear. For example, the simplest sort of rain wear is a two-layer sandwich. The outer layer is typically nylon or polyester and provides strength. The inner one is polyurethane (PU), and provides water resistance, at the cost of breathability. Polyether Block Amide are also now increasingly used for footwear applications. This schematic (Figure 6, bottom) describes a composite structure developed by W.L. Gore and Associates for the fabrics industry.

3. Experiment & Results

3.1. Description of Test Conditions

Reinforced and unreinforced membranes were tested using a modified method based on ASTM E96 standards developed to determine the moisture vapor transmission rate (MVTR) of highly permeable materials [12]. The test consists of a cup filled with saturated NaCl solution and sealed with ePTFE (expanded Polytetrafluoroethylene). A layer of ePTFE is attached to a support and set to float in a freshwater bath. The membrane to be tested is placed on the ePTFE film and the saltwater cup is inverted on it. The saturated NaCl solution in the cup acts as a desiccant and provides a driving force for the movement of water from the tub to the cup. The cup is weighed after 10 minutes and the increase in weight represents water transport through the

membrane. The average moisture vapor transfer rate was calculated from this weight change and was then normalized by the area of the membrane and the pressure differential across the membrane. The room and bath temperatures were controlled at 20˚C. The saturated NaCl solution provides a RH of 75%. At 20˚C, the saturation vapor pressure is 2.33 kPa and the pressure differential, the driving force of the mass transfer, is 0.5825 kPa.

Table 1. Different reinforcements and their properties

Support	Construction	Thickness (μm)	Porosity
R1	ePE	5	60%
R2	ePTFE	3	80%
R3	ePTFE	10	80%

As seen in Table 1, two different reinforcement constructions were investigated: expanded polyethylene (ePE) and expanded polytetrafluorethylene (ePTFE). The expanded polytetrafluorethylene support was tested at two different thicknesses. As seen in Table 2, these reinforcements were coupled with three different ionomers to make a reinforced membrane: two cationic ionomers, a long perfluorosulfonic acid (PFSA) (ionomer A) and a garment membrane (ionomer B); and an anion exchange ionomer (ionomer C). In addition to reinforced ionomers, unreinforced membranes were made using ionomers B and C.

Table 2. Membrane permeabilities

MVTR Test Index	Ionomer	Reinforcement	Thickness (um)	Permeance (g/m^2*day*kPa)
1	A	R3	25	$2.51x10^5$
2	B	R1	10	$4.67x10^5$
3	C	R2	5	$2.15x10^5$
4	B	-	25	$6.90x10^5$
5	C	-	15	$6.82x10^5$

3.2. Results & Analysis

As seen in Figure 7, membranes without reinforcement outperformed membranes with reinforcement, due to the increased channel distance and the hydrophobicity of the reinforcement. Of the unreinforced membranes, the garment membrane shows the greatest potential for further research. It outperformed the PFSA and AEM, despite being a thicker membrane. The potential of the water vapor transmission of ionomer B becomes even more apparent when the permeance was normalized to the thickness (Figure 7b). While these unreinforced membranes had sufficient mechanical strength for the 0.5824 kPa driving pressure differential, in an HVAC application the driving pressure can easily exceed 5 kPa, and even 100 kPa, depending on the design of the system. These high pressures will increase the crossover and possibly even burst the unreinforced membrane. Furthermore, because the unreinforced membranes gain their mechanical stability from their thickness, they tend to be significantly more expensive, requiring more ionomer resin than a reinforced membrane.

Of the reinforced membranes, sample 2, the garment membrane supported by ePE, performed the best. This is particularly significant as ePE was not the thinnest membrane and exhibited the lowest porosity, both key factors in water transport through porous membranes. However, by imbibing the material with garment ionomer, the material outperforms thinner membranes with higher porosity.

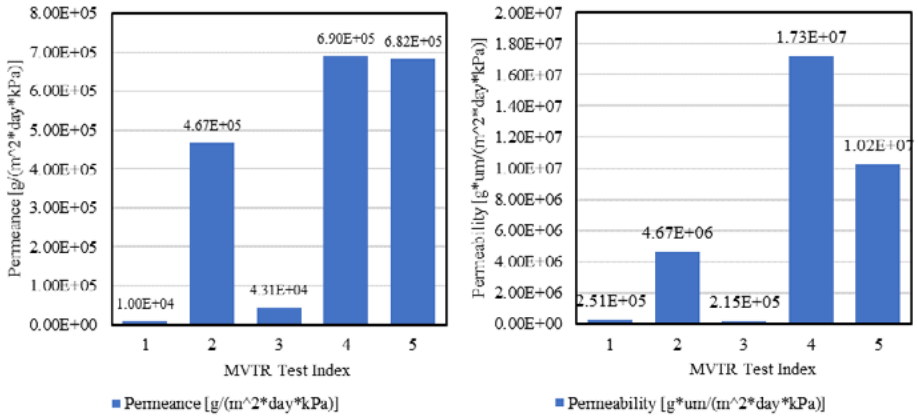

Fig. 7. Comparison of permeance of different membranes (left) and comparison of permeability (permeance normalized to membrane thickness) (right)

Conclusions

The HVAC industry has been relatively slow to adopt the use of water transmission membranes for its applications. Until relatively recently, most ERV modules for example, used paper media as the interfacial layer between incoming and outgoing air streams. In ILD systems, porous structures that allow for bulk flow across them are also very common.

These results confirm that thinner non-porous membrane layer does exhibit the highest water permeation rate – consistent with theoretical expectations. While transmission rates (normalized for thickness) are generally lower in the 'bulk polymers' compared to porous membranes, by reducing the thickness of the polymer layer you can more than compensate for the rate reduction, and obtain water transmission rates (permeability) that are comparable – or indeed better than porous membranes. While at the same time, also take advantage of the greater selectivity (i.e. reduction in cross stream contamination). This remains true for both polymers and all supports. Also, crucially, the thinnest (highest performance) membrane is also the lowest cost system.

This outcome is disruptive and transformational, because it enables entry into many historically 'cost' sensitive applications – where impervious membranes have always been an attractive but also prohibitively expensive engineering option.

To move this membrane technology to the market, larger scale application testing must be performed. In the theoretical application to a subtropical monsoon climate similar to that of New Delhi, the average daily latent cooling load of a 90 m^2 apartment is about $2.67x10^4$ kJ or about 11 kg of water per day. Assuming the same pressure drop through the air conditioner would provide a similar driving pressure as in the MVTR testing (0.5825 kPa), the air conditioner would require about 4 m^2 of the best performing reinforced membrane or about 2.8 m^2 of the unreinforced membrane. Further research into the design of such a system can be made to determine and improve the driving pressure differential. This research would also help to determine the coefficient of performance of the system – which is directly related to the fan speed and driving pressure differential.

This is especially true for reinforced (composite) membranes since very thin non-reinforced membranes are simply too weak for engineering integration. Typically, a decrease in thickness corresponds to a decrease in mechanical properties. By combining a reinforcement with the functional polymer, a new class of high-water transmission membrane is now available to the HVAC industry.

4. Nomenclature

Table 2. Acronyms and abbreviations, defined

Term	Definition	Term	Definition

ePE	Expanded polyethylene	PFSA	Perfluorosulfonic acid
ePTFE	Expanded polytetrafluoroethylene	PI	Polyimides
ERV	Energy recovery ventilator	PSSA	Polystyrenesulfonic acid
HVAC	Heating, ventilation and air conditioning	PU	Polyurethanes
ILD	Ionic liquid desiccant	PVA	Polyvinyl alcohol
ILHP	Ionic liquid desiccant	S-SEBS	Sulfonated styrene/ethylene-butylene/styrene
MVTR	Moisture vapor transmission	WBE	Water-based evaporator
PAN	Polyacrylonitrile

Abstract

Chlorine and Fluorine containing refrigerant based heat pumps currently consumes over 2,000 Trillion-Watt hours per year of electric power [1]. Current refrigerants used in these devices have climate harming "Global Warming Potentials" (GWP) that are thousands of times higher than that of CO_2 gas. This paper explores a novel heat pump technology based on solid-state (metal hydride based) refrigerant employing hydrogen compression. This paper provides performance data for solid state refrigerant heat pumps for air conditioning (AC) and Ultra Low Temperature (ULT) freezer systems. Operational data, lessons learnt, and optimal practices needed to deploy these systems are reviewed. Key components in the system are analyzed, including the metal hydride heat exchangers, (electrochemical and other) Hydrogen compressors, and system controls.

1. Introduction to Solid-State refrigerant (Metal-Hydrogen Sorption Systems)

A refrigerant is a substance used in a heat pump or refrigeration cycle that typically undergoes phase transition with favorable thermodynamic properties that enables heat absorption or rejection upon phase transition. Chlorine and Fluorine containing refrigerant based heat pumps currently consumes over 2000 Trillion-Watt hours per year of electric power [1]. Current refrigerants used in these devices have climate harming "Global Warming Potentials" (GWP) that are thousands of times higher than that of CO_2 gas. Therefore, alternatives to current refrigerants are critically needed to address the shortcomings of current refrigerants.

Solid state refrigerants hold the potential to provide a highly efficient, low cost, recyclable, environmentally friendly alternative to traditional refrigerants. Metal hydrides (MH) are a class of solid-state refrigerants. Metal hydrides are metallic compounds, in which one or more hydrogen centers have nucleophilic, reducing, or basic properties. For heat pumps, we utilize the reversible heat-driven reaction of a hydride-forming metal/alloy, or intermetallic compound (IMC) with hydrogen gas. Hydrogen changes phase from a gas to a solid metal alloy with very favorable thermodynamic properties.

$$M(s) + xH_2(S) \rightleftharpoons MH_x(s) + Q \quad (1)$$

In Eq.1, M is a metal or alloy (e.g., vanadium (V) or a body-centred cubic (BCC) solid solution based upon it), or an IMC (typically with linear (AB_2) or trigonal bipyramidal (AB_5) molecular geometries); (s) and (g) relate to solid and gas phases, respectively, and Q is the reaction enthalpy. The overall process performance is strongly dependent on the intrinsic features of metal hydride reaction including its thermodynamic and kinetic

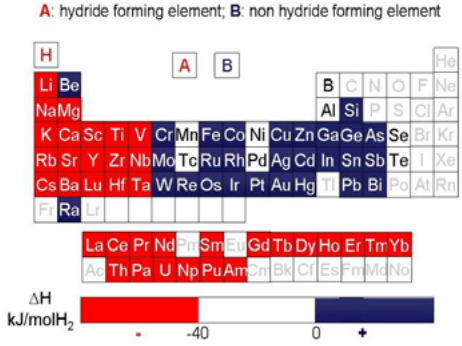
characteristics, as well as composition, structure and morphology of the solid phases (M, MH_x) involved in the process. These features are mainly related to fundamental aspects of hydride materials.

Equilibrium of the metal-hydrogen reaction is characterized by an interrelation between hydrogen pressure (P), concentration of hydrogen in the solid phase (C) and temperature (T). PCT diagrams can be generated to characterize specific hydride-forming materials. These provide the thermodynamics of its interaction with gaseous hydrogen. At low hydrogen concentrations ($0 \leq C < a$) hydrogen atoms form an interstitial solid solution in the matrix per Henry–Sieverts law. When the value of C exceeds concentration of the saturated solid solution, precipitation of the hydride (β-phase with hydrogen concentration) occurs. The system then exhibits a first order phase transition at a constant hydrogen pressure, $P = P_P$ ($a \leq C \leq b$). This pressure is called the plateau pressure (P_P) in the metal–hydrogen systems. The process is almost exactly (100%) reversible, with slight differences as the concentration changes. This is termed hysteresis and is a source of efficiency loss (<5%).

Depending on the type and composition of the hydride-forming material, the equilibrium hydrogen pressures vary in a very broad range, from below 1 bar to exceeding 1 kbar at room temperature. Most of the lower pressure compression alloys (P_H < 200 bar at T_H < 150 °C) belong to the AB_5-type intermetallic compounds while significantly higher, >1 kbar, hydrogen pressures can be generated using AB_2-type compounds. Current prototype systems have been built using a wide variety of commercial AB_5 compounds, although in the future, the high thermal exchange capacity of AB_2 could lead to smaller heat exchangers.



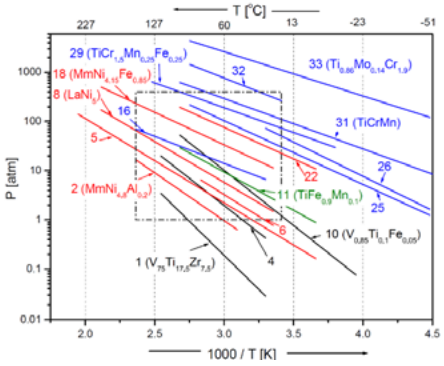


Fig. 1. Hydride and non-hydride forming elements in the periodic system of elements [2].

Proper hydride selection is critical to designing useful metal hydride heat exchangers. Figure 2 (right) provides equilibrium characteristics of the interaction of hydride-forming alloys suitable for Hydrogen. The data is sorted in the ascending order for desorption plateau pressure. Figure 2 (left) provides Van't Hoff plots for selected hydride-forming alloys suitable for hydrogen.

Fig. 2. Van't Hoff plot and enthalpy and entropy of formation of hydride complex for selected sorbent refrigerants (SRs) [2]

Hydrogen compression is critical for a metal hydride refrigerant based heat pump cycle. Hydrogen can be compressed using mechanically driven, electrochemically driven or metal hydride (heat driven) compressors. For durable performance, hydride systems must remain dry and hydrogen gas streams must be pure and free of contaminants. Much like other refrigerant systems, the type of compression employed must be mated with the specific type of hydride selected and the overall requirements of a specific heat pump application. One of the first modern metal hydride heat pumps (MHHPs) was built in 2014 (Figure 3). Hydrogen compression ratio (P_H/P_L) for hydrides can vary in the range 10–50.

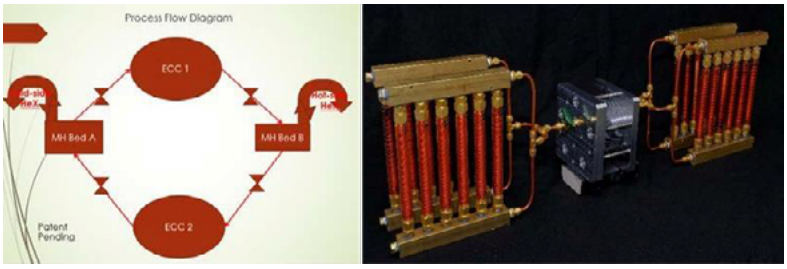

Fig. 3. (a) A schematic for a potential ECC-based MHHP. (b) Picture of prototype ECC-based MHHP

Initial development of the electrochemical compressor-based metal hydride system was conducted with commercially available hydride cylinders with heat exchanger capability. Two designs differing in the placement of the heat exchanger coil and the aspect ratio of the units were tested: exterior-wrapped tubes brazed to the high aspect-ratio hydride containing cylinder (Figure 4a), and a coiled tube placed inside a lower aspect ratio hydride cylinder (Figure 4b). Both designs showed significant deficiencies in heat exchange capability.

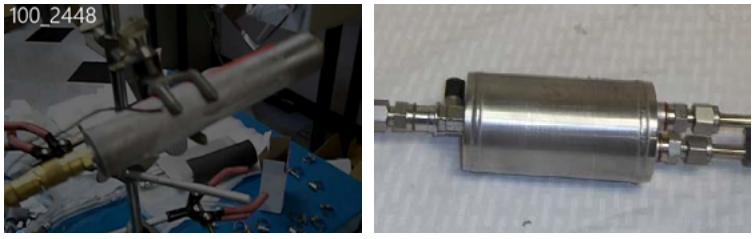

Fig. 4. Hydride cylinders with heat exchanger capability (a) high aspect-ratio hydride with potential for exterior wrap-around coil and (b) (b) a coiled tube placed inside a lower aspect ratio hydride cylinder.

Figure 5 shows results for COP vs operating voltage. While low voltages (<0.1 V) provide the greatest benefit to COP, low voltage systems have a lower current and H_2 flow and thus require larger, more expensive systems to maintain a constant temperature. Conversely, faster heating can be achieved with smaller systems by operating at higher voltages represented (>0.2 V).

Fig. 6. Working pressure and surface per internal volume of various diameters of metal hydride tubing

As seen in Figure 6, microtube heat exchangers provide practical benefits including: the ability to hold very high pressures within tubes, flexible tubes which can be coiled, and highly configurable tube patterns which allow precise thermal performance. Furthermore, microtubes take advantage of fundamental design principles as decreasing the diameter increases the surface area per unit volume. As the convective heat transfer rate (Q) is proportional to the surface area, per Equation 2, small diameter tubes increase the heat transfer rate as well.

$$Q = Time \times h \times External\ Surface\ Area \times \left(T_{surface} - T_{external}\right) \quad (2)$$

In most heat exchangers, the technical design limitation to tube diameter is pressure drop. However, the small molecular size and high velocity of hydrogen enables it to travel through very small diameter tubes with very little pressure loss. Microtubes tubes have allowed for over a 10X decrease in sorption time. In lab testing (Figure 7), 100% of the MHHX hydrogen capacity is absorbed in under 40 seconds, compared to 1600 seconds with the previous generation of MHHX.

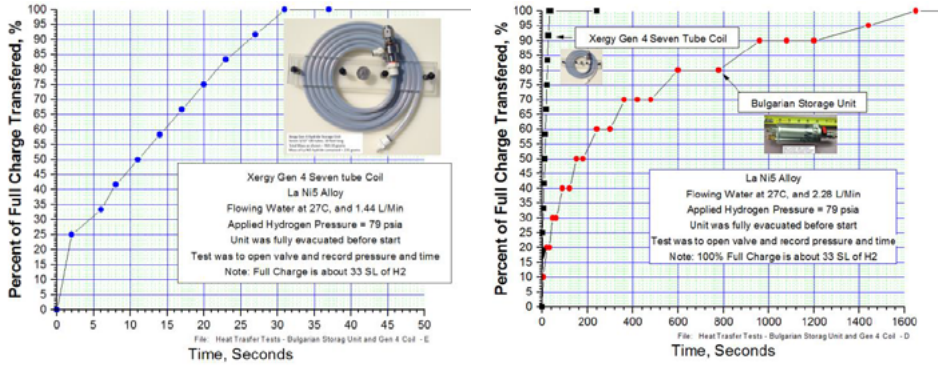

Fig. 7. Comparison of mass flow rate of hydrogen into metal hydride microtubes (left) and into a typical tank-type metal hydride cannister (right).

2. Environmental and Commercial Analysis of Room Air Conditioners Employing Metal Hydride Solid-State Refrigerant Technology

2.1. Introduction

Air conditioning solutions utilizing heat exchangers with metal hydride refrigerant show a very strong potential to provide a novel cooling solution with low energy consumption and zero GWP. Like a vapor compression air conditioner, a MHHX uses a compressor to generate its cooling power, however the cooling is generated via ionic sorption of hydrogen gas rather than through the incumbent vapor-compression refrigeration. The compression can be provided by a typical mechanical compressor or an electrochemical compressor (ECC) – like a proton exchange membrane (PEM) ECC or a nickel hydrogen (Ni-H) ECC. While a mechanical compressor's efficiency is thermodynamically limited to the Carnot cycle, an electrochemical compressor is electrochemically limited by the materials in the system.

The refrigeration efficiency of a metal hydride heat pump (MHHP) system using a PEM ECC, Ni-H ECC, or mechanical compression was explored. The energy use and economic viability of the systems was explored for the current technology with a target payback period of 3 years on the premium over an incumbent room air conditioner (RAC). As the energy use of such a system is very dependent on the climate conditions, this analysis uses climate data for a 90 m^2 apartment in New Delhi, India, a climate reflective of the median cooling requirements of the emerging middle class. The benchmark unit operates with a seasonal COP of 3.5 and a GWP of 17601 [3].

2.2. System Overview

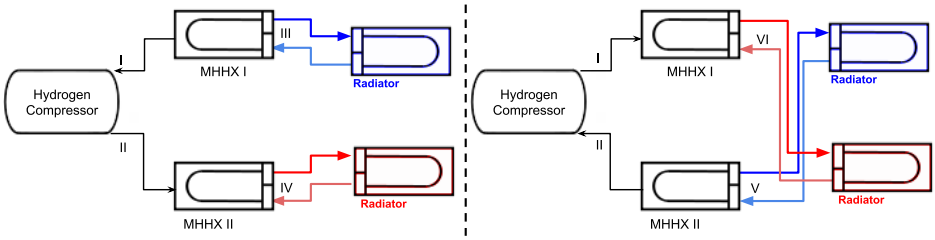

Fig. 8. MHHP RAC system half-cycles with H_2 flows (I, II) and heat transfer fluid flows (III-VI). Left: First half-cycle; Right: Second half-cycle.

Regardless of the hydrogen compressor in the system, a MHHP RAC system functions the same. During the first half of a cycle (Figure 8, left), high pressure hydrogen flows out of the compressor (II) and adsorbs onto MHHX II, while low pressure hydrogen is desorbed from MHHX I and flows into the compressor (I). The coil under low pressure adsorbs heat from the cooling fluid (III) to generate cooling power on the cold radiator, while the coil under high pressure releases heat in the waste heat exchange fluid (IV) to the hot radiator. During the second half of a cycle (Figure 8, right), the hydrogen flow is reversed. High pressure hydrogen flows out of the compressor (I) into MHHX I and low-pressure hydrogen flows out of the MHHX II and into the compressor (I). MHHX II now generates the cooling power (V) for the cold radiator and MHHX II (VI) now rejects waste heat to the hot radiator.

2.3. Benchtop Prototype PEM-ECC-MHHP System

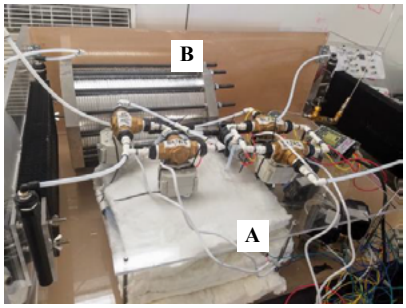

Fig. 9. Benchtop prototype air conditioner with a pair of MHHX in insulation (A) and PEM-ECC (B).

A benchtop prototype AC (Figure 9) was designed and built using 250 W PEM ECC and MHHX technology as a proof of concept. The initial run of the system (Figure 10) showed that the average temperature drop across a MHHP under low pressure is about 3.56 C and provided a 174 W cooling load (of the expected 250 W). After "breaking-in" the PEM ECC, a process that takes about 50 minutes, the PEM ECC performed as expected for about 20 minutes, until the humidifier ran out of water and the performance of the system dropped. During the time that the PEM ECC performed as expected, its average power consumption was 163 W. Although the COP of this run (~1) is less than that of the incumbent technology, the benchtop prototype provided a standard system design for the RAC systems.

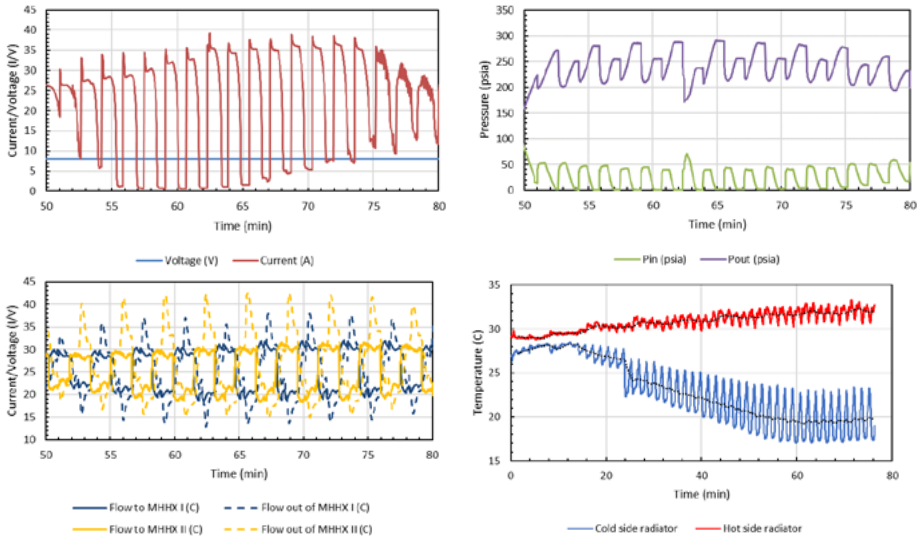

Fig. 10. (Clockwise, from top left) Compressor power, compressor pressure, and MHHX performance of benchtop prototype after first run start-up procedure, heat pump temperature throughout a run of the prototype

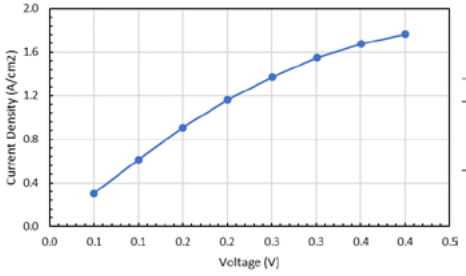
This analysis identified the first key engineering challenge in designing a MHHP RAC – reducing the required hydrogen flow rate. Substituting the R-2006, an AB_5 metal hydride, with R-2042, a Vanadium-BCC metal hydride, increased the hydrogen to sorption enthalpy ratio by 1.4, decreasing the required hydrogen flow by about 28%. The required hydrogen flow was further reduced by increasing the cycle time from 2 minutes to 4 minutes – reducing the required hydrogen flow by 50% but increasing the required metal hydride mass by a factor of 2.

With these modifications, the 250 W system was scaled up to a residential RAC system. An analysis of the cooling requirements of a New Delhi apartment showed that a MHHP system would require 2.5 kW of sensible cooling power to maintain a comfortable room temperature. Both PEM ECC-MHHP RAC and Ni-H ECC-MHHP systems were designed with an ILD subsystem to meet these conditions.



2.4. Overview of 2.5 kW MHHX Subsystem for Residential RAC

Regardless of the type of compressor used, every system has the same fundamental 2.5 kW MHHX subsystem design. The system requires 4 MHHX coils using R-2042X solid state refrigerant. Two coils make up each metal hydride heat exchanger (i.e. MHHX I and MHHX II seen in Figure 1) to provide a constant output of sensible cooling. The total subsystem material cost of the metal hydride heat exchangers is about $22.10, although this is largely due to the cost of the heat exchangers – the R-2042X solid state refrigerant would only cost an estimated $4.00. The refrigerant required for a comparable conventional air conditioner, using R-410A is about 6 lbs. Estimating from its cost on business-to-business (B2B) ecommerce sites, R-410A costs about $1.25 per pound, the total cost of conventional refrigerant is $7.50.

2.5. Residential RAC PEM-ECC-MHHP

A residential room air conditioner (RAC) with a metal hydride heat pump using a proton exchange membrane electrochemical compressor (PEM-ECC-MHHP) was designed to meet the cooling requirements of a typical New Delhi apartment. Given the modifications outlined in the previous section, the design requirements (Figure 11) of the ECC were calculated.

The key design variable in a PEM electrochemical compressor is the voltage applied to each cell. Changing the voltage applied to a cell changes the current density of the cell as dictated by the polarization curve, as seen in Figure 11. As the ECC requires a total 6,150 amps, the voltage determines both the number of cells the ECC requires as well as its power consumption and coefficient of performance.

Parameter	Requirement
Hydrogen Flow Rate (SLM)	42.9
Total Amperage (A)	6,150
Active Area (cm^2)	150

Fig.11. Polarization Curve of selected 25.4 μm PEM and design requirements of PEM-ECC for a 2.5 kW MHHP

As seen in Figure 14, the optimal COP design of the system is about 6.67. This system would require 57 cells with a voltage and current density of 0.12 V and 0.73 A/cm^2. With the current technology, the bill of materials (BOM) of the system totals to about $490.

The PEM-ECC was, again, identified as the cost critical component, equal to 62% of the total BOM. To achieve the target payback period of 3 years, the system must be improved. The membrane component of the system showed the strongest potential for improvement. The current density of a membrane can be improved at a given voltage by decreasing the thickness of the membrane. A general analysis of current membranes shows that at any given voltage the current density improves with the thickness by about 0.7-0.8 (A/cm2)/μm. As seen in Figure 12, the system requires about a 1.86X improvement to its current density to achieve a payback period of 3 years. This system would require membranes about 10μm thick and would operate at a voltage of 0.12 V with a current density of 1.36 A/cm2. The BOM of this system would be about $343. The system would have a 1.83X decrease in energy consumption and a 2.3X decrease on overall climate impact from the benchmark technology [3].

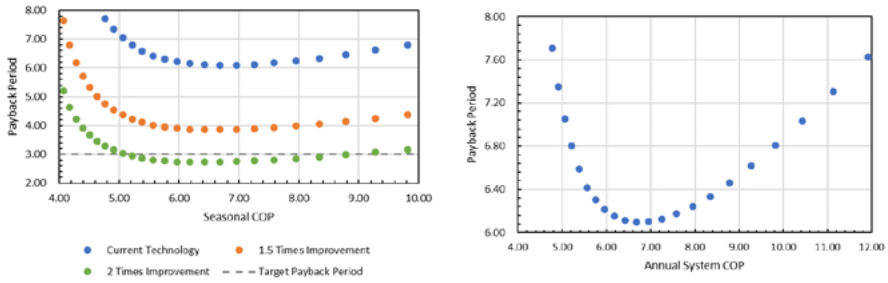


Fig. 12. Required improvement to current density of PEM ECC to achieve target payback period of 3 years (left) and payback period analysis of current PEM ECC to find optimum design COP (right)

2.6. Residential RAC Ni-H-ECC-MHHP

A Nickle Metal Hydride Electrochemical Compressor has the same design requirements as the PEM ECC. However, because the Ni-H ECC functions in a "batch" mode, compressing a batch of hydrogen to the appropriate pressure and then discharging it, two Ni-H ECC subsystems would be required to provide a continuous flow of hydrogen to the metal hydride coils. Like the PEM ECC, the key Ni-H ECC design variable is the cell voltage. However, for a Ni-H ECC, the relation between the cell voltage and the current density is considerably more linear and was assumed to be linear for the purpose of this investigation.

As seen in Figure 13, the optimum COP of the system is 5.25, achieving a payback period of 2.6 years. The given a 3-year restraint on the payback period the maximum COP of the system is 7.7. A system designed for a COP of 7.7 would require 0.044 volts per cell, resulting in a current density of 0.11 A/cm^2. The BOM of this system would be about $374 when produced at 100,000 units/year. This system would have a 2.21X reduction in power consumption from the benchmark unit and a 2.76X decrease in overall climate impact.

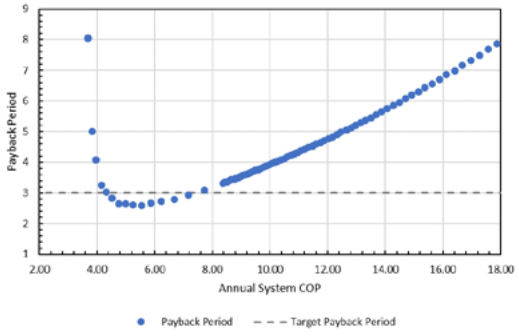

Fig. 13. Payback period analysis of Ni-H ECC to find Optimum Design COP

2.7. Residential RAC Using Rotary Compression MHHP with Integrated ILD System

While electrochemical compressors have the potential to greatly increase the COP of a MHHP RAC, conventional RAC rotary and scroll compressors can also provide the required hydrogen flow. A rotary mechanical compressor designed for a 6000 BTU/hr., R-22 RAC was substituted for the PEM-ECC in the R-2008 benchtop prototype. This mechanical compressor provided a hydrogen flow rate of 30 SLPM-H2 – 5X the required hydrogen flow for the 250 W unit. Therefore, the RAC providing 2.5 kW of sensible cooling would require 8,600 BTU/hr. mechanical compressor to provide ~42.9 SLPM-H2.

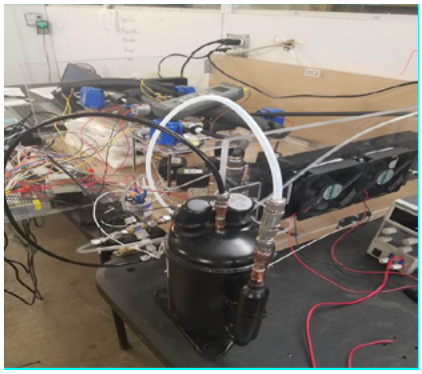

Fig. 14. Benchtop RAC prototype (250 W, R-2008) using a rotary compressor designed for a 6000 BTU/hr. (1758 W) RAC using R-22

An analysis of the compressors rotary and scroll compressor products product found that the average COP of these compressors, when using R-22 is 3.17 [4]. The average COP of these compressors in a R-2042 MHHP subsystem would be 4.52, with a power consumption of 550 W. While these systems were not designed nor optimized for hydrogen flow, they still show strong potential for a high efficiency cooling solution. The MHHX component costs of the RAC is comparable to the non-compressor components of a conventional RAC. Therefore, a RAC utilizing a conventional compressor shows strong potential for an early, low cost MHHP-RAC.

2.8. Comparative Cost Analysis

With the current technology, the Ni-H ECC was found to be a much more effective system than the PEM ECC. The main cost difference between the Ni-H ECC and PEM ECC is the cost of the electrochemical cells. As seen in Table 1, although the Ni-H ECC requires considerably more cells, the cost per cell is far lower. This is largely due to the decreased material cost of the Ni-H bipolar plates and electrode. The Ni-H uses 1% platinum carbon rather than the more costly pure platinum coating of the PEM cells. The PEM plates are over 10x thicker than the Ni-H plates, requiring much more material.

Table 1. Cost Comparison between the Ni-H ECC (0.068 V, 0.17 A/cm2) and PEM ECC (0.125 V, 0.761 A/cm2) Designed for a Minimum Payback Period Using Current Technology

Component	Ni-H Cost per Cell	PEM Cost per Cell
Electrode	$0.323	$2.833
Metal Support	$0.029	$0.05
Gasket & Sealing	$0.098	$0.756
Bipolar Plate	$0.049	$2.00
Total Cost per Cell	**$0.0490**	**$0.5639**

3. ULT Freezer Application

A ULT freezer is freezer that operates between -40 and -86°C. Modern ULT freezers typically use up to 20 times the energy footprint of household fridges. One approach to building these units involves employing hydrofluorocarbon R-508B. Alternatively, Dichlorodifluoromethane (R-12) and Chlorodifluoromethane (R-22) are also used for this application as a refrigerant, although recently their use has been banned under the

Montreal Protocol. These units are used for many sensitive applications (such as storage of medical samples) and operate 24-7 consuming significant energy; and operate with very poor efficiency (COP < 0.5).

One feature of solid-state refrigerant heat pump systems is their ability to provide significantly higher efficiencies at ultra-low temperatures. Changes of temperatures of almost -100°C are being demonstrated (Figure 15) with very small diameter tubing possessing extremely high surface areas per unit mass and unit volume.

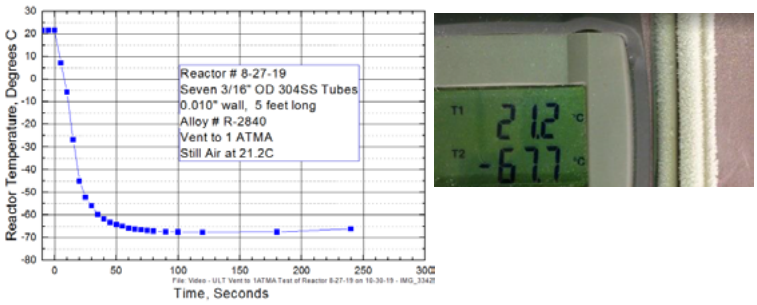

Fig. 15. Reactor temperature of ultra-low temperature (ULT) prototype run (left) and prototype reactor showing frost on surface (right)

An additional advantage of metal hydride air conditioners, refrigerators and ULT freezers is their ability to run on low grade thermal energy (such a solar thermal or geothermal energy). Even heat source temperatures as low as 70°C can be used for any application because the metal hydride alloys can be "staged" to produce any pressure needed to operate the metal hydride device.

Figure 16 below demonstrates this unique ability where only 70°C hot water can be used to compress Hydrogen gas from 21 psia up to over 5000 psig using only five stages of metal hydride alloys. This is possible because each hydride alloy will generate a threefold pressure rise (via the 70°C heat) during its compression stage, thus increasing the hydrogen outlet pressure to over three times the inlet pressure coming into the hydride stage. Each following hydride "stage" has been alloyed engineered to accept the "high pressure" hydrogen gas exiting the previous hydride stage as it's "low pressure' inlet hydrogen. Additionally, multi-staged metal hydrides can be applied beyond heat pump applications to high pressure hydrogen gas generation.

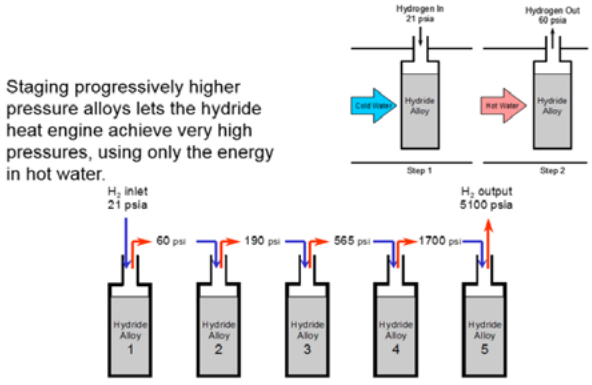

Fig. 16. Low-cost solar thermal energy can be used as the energy source to power (top right); Multi-staged MH Alloys to produce cooling, gas liquefaction and high-pressure hydrogen gas generation.

4. Conclusions & Further Applications

The comparably low cost of solid-state refrigerant per ton of cooling, as well as the removal of materials with global warming potential, is very promising for its use to reduce the carbon footprint of residential air

conditioners. Metal hydride technology utilizes the exceptional heat transfer ability of metal hydride alloys - housed in very small diameter tubes - to create extremely large external surface areas per unit volume, mass and cost. This new heat transfer technology is a new technology platform that represents a paradigm shift in the reduction of energy use, and the cost of, many of our cooling, heating and power generation products, and will greatly speed up our transition to a solar energy economy.

5. Nomenclature

Table 2. Acronyms and abbreviations, defined

Term	Definition	Term	Definition
AB2	Linear molecular geometry	MHHX	Metal hydride heat exchanger
AB5	Trigonal bipyramidal geometry	Mm	Mischmetal
B2B	Business-to-business	Ni-H	Nickel-hydrogen
BCC	Body-centered cubic	PCT	Pressure-concentration-temperature
BOM	Bill of materials	PEM	Proton exchange membrane
COP	Coefficient of performance	P_H	Pressure (high)
ECC	Electrochemical compressor	P_L	Pressure (low)
GWP	Global-warming potential	P_P	Pressure (plateau)
IMC	Intermetallic compound	RAC	Room air-conditioner
MH	Metal hydride	SR	Sorbent refrigerant
MHHP	Metal hydride heat pump (a system containing 2+ MHHX)	ULT	Ultra-low temperature

6. Appendix I: Proposed Nomenclature for Sorbent Refrigerants

6.1. Appendix I.A: Nomenclature for Metal Hydride Solid State Refrigerants

Below is the proposed nomenclature for metal hydride based, solid state refrigerants (the R-2000 series refrigerants). The R-2100 to R-2300 series refrigerants are Vanadium-BCC metal hydrides. The R-2400 to R-2600 series refrigerants are AB5-type intermetallics. The R-2700 series refrigerants are TiFe based, AB-type intermetallics. The R-2800 to R-2900 series refrigerants are AB2-type intermetallics. The R-20XX series refrigerants have been left as a place holder for miscellaneous, novel, and proprietary metal hydride refrigerants.

Abstract

Metal hydrides present an alternative heat pump approach to efficiently achieving extreme temperatures, without high GWP refrigerants. These materials work by complexing with hydrogen in order to generate incredible thermal lifts; an alloy of TiCrMn, complexes hydrogen at 90°C and exhausts at approximately -60°C, for example. A drawback of this class of materials is that greater temperature lifts require higher pressure hydrogen. This paper analyzes four methods of producing pressurized hydrogen: two electrochemical systems, one system employing metal hydride compression, and one using conventional mechanical compression. Electrochemical compression makes use of ion selective electrolytes that provide pressurized hydrogen when a potential gradient is applied. Metal hydride compressors operate by reversing the principle behind the metal hydride heat exchangers used in these heat pumps – i.e. releasing hydrogen at pressure when the metal hydride is heated. Mechanical compressors use various designs to move a mass of gas and shrink the volume it occupies, thereby compressing the gas. This paper provides operational data for these four different compression strategies. Heat pump cycles employing these systems are analyzed for critical performance parameters.

1. Background

1.1. Metal Hydride Heat Pump

Metal hydride heat pumps (MHHP) operate using pair(s) of metal hydride heat exchangers (MHHX) to generate heating and cooling. Any compression technology that pumps hydrogen can be utilized to adsorb and desorb hydrogen from the MHHX. Adsorption of hydrogen on to the metal hydride is an exothermic reaction that produces heat, and desorption of hydrogen from the metal hydride is an endothermic reaction and pulls heat from the surroundings.

During the first half of a cycle, high pressure hydrogen flows out of the compressor (I) and adsorbs onto the metal hydride of MHHX A, while low pressure hydrogen is desorbed from the metal hydride of MHHX B and flows into the compressor (II). The coil under low pressure pulls heat from the cooling liquid (III) to generate cooling power on the cold radiator (C), while the coil under high pressure releases heat in the waste heat liquid (IV) to the hot radiator (D). During the second half of a cycle, the hydrogen flow is reversed. High pressure hydrogen flows out of the compressor (II) and MHHX B and low-pressure hydrogen flows out of the MHHX A and into the compressor (I). MHHX A now generates the cooling power (V) for the cold radiator (C) and MHHX B (VI) now rejects waste heat to the hot radiator (D).

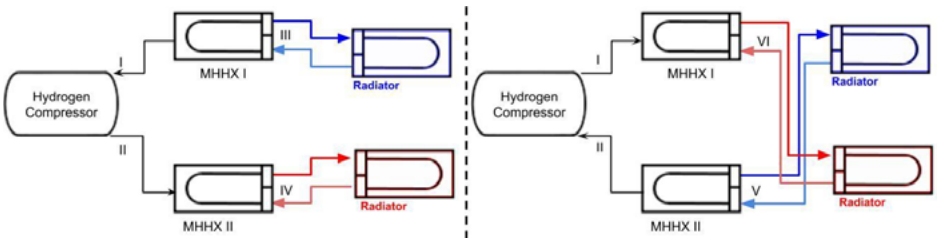

Fig. 1. MHHP configuration and flows during first half-cycle (top) and second half-cycle (bottom)

Different forms of compression were analyzed assuming a room air conditioner (RAC) with a capacity of 2.5 kW of cooling. To improve the economics of the MHHP from the benchtop testing the cycle time was doubled (decreasing the hydrogen flow rate and increasing the mass of the MHHX), and a different metal hydride was selected with a greater heat of formation. This allows for smaller compressors, the most cost critical component in the system. Based on the selected metal hydride, the cycle time, and cooling capacity, the estimated hydrogen flow rate for all systems was 43 SLM.

1.2. Proton Exchange Membrane (PEM) Based Electrochemical Compression

Proton exchange membrane (PEM) electrochemical compression (ECC) is a method of hydrogen compression that is a derivative of fuel cell technology. It is a solid-state compression technology that offers the benefits of no moving parts, no noise, and high efficiencies. Pressure lifts are generated by transporting hydrogen in its ionic form as protons.

A PEM, depicted in Figure 2, is sandwiched on either side by a catalyst and a gas diffusion layer. A voltage is applied to the membrane electrode assembly (MEA) to drive the hydrogen compression reaction. Hydrogen contacts the catalyst/membrane interface at the anode of the system and reacts to form protons and electrons. The protons transport across the membrane, as the membrane is ion-selective and allows cations to transport across. The protons recombine with the electrons at the catalyst/membrane interface of the cathode to form hydrogen. The method of applying a potential to the MEA allows for high pressure hydrogen to be generated from a low-pressure hydrogen feed.

The overall standard potential for the system is 0.00 V, however this assumes an ideal case with no pressure differential and perfectly balanced half cells. The overpotential, or additional energy, that must be applied due to the pressure differential is given below.

$$V = \frac{RT}{2F} * ln\left(\frac{P_{cathode}}{P_{anode}}\right);\ Anode: H_2 \rightarrow 2H^+ + 2e^-, E° = 0.00\ V;$$
$$Cathode: 2H^+ + 2e^- \rightarrow H_2, E° = 0.00\ V;\ Overall: H_{2,low} \rightarrow H_{2,high},\ E°_{total} = 0.00\ V$$

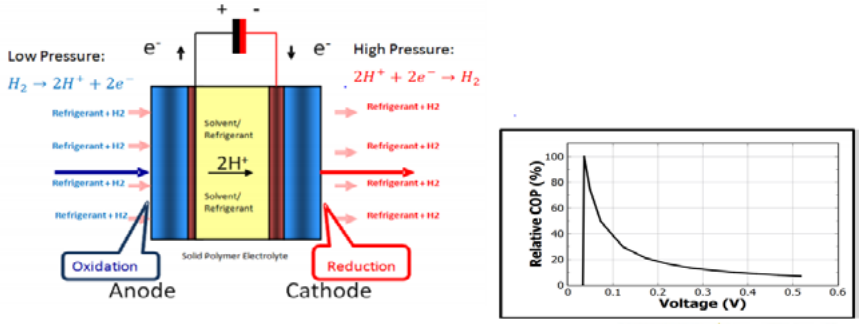

Fig. 2. Proton exchange membrane electrochemical compressor proton flow diagram (left) and COP curve (right)

When operating the cell at low pressure differentials the voltage required is very close to 0.00 V, i.e. the system efficiency is very high. However, some heat pump applications require pressure ratios of >10x, decreasing the overall efficiency of the PEM ECC. From Figure, the COP of an ECC system exponentially increases at cell voltages <0.1 V. In order to make PEM ECC-MHHP systems viable, the current density (proportional to the hydrogen flow per unit area) must be increased at low voltages.

The development of PEM ECCs has been focused on decreasing the weight and volume and increasing the current density, to improve the economic viability and the energy efficiency of the system. Additionally, combined PEM ECC-MHHP systems have been successfully run for initial analysis.

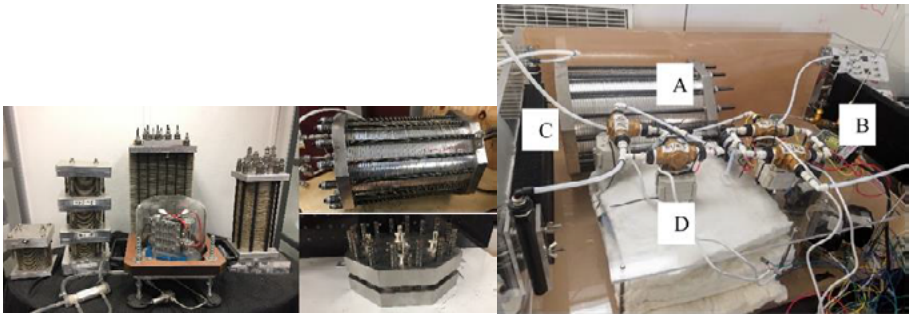

Fig. 3. Left: A selection of PEM-ECCs; Right: Proof-of-concept 250 W PEM ECC-MHHX

A benchtop prototype AC unit was designed and built using a nominal 250 W MHHX as a proof of concept. The main system components are (a) PEM ECC, (b) cold-side radiator, (c) hot-side radiator, (d) pair of MHHX, heat exchange fluid line (the white plastic tubing in Figure 3), and hydrogen line (the metal piping). The heat exchange fluid line is designed to transfer the heating and cooling from the MHHXs to the appropriate radiators. The cold side radiator cools down the space, while the hot side radiator dumps heat to the ambient air. The hydrogen line has valving to change which MHHX is feeding to the inlet and outlet based on the cycle.

During testing the outlet pressure of the compressor ranged from 13.8-20.7 bar (200-300 psia), and the inlet ranged from 3.44 (50 psia) to near vacuum. The average temperature drop across a MHHX under low pressure was about 3.56°C, providing a cooling load of 174 W (of the expected 250 W). After “breaking-in” the PEM ECC, a process that took about 50 minutes, the PEM ECC performed as expected for about 20 minutes, until the humidifier ran out of water and the performance of the system dropped. During the time that the PEM ECC performed as expected, its average power consumption was 163 W. Although the COP of this run, ~1, is less than that of the incumbent technology, the benchtop prototype provided a standard system design for the RAC systems, and there are many variables to optimize to improve system efficiency. The system run also provided a basis for hydrogen compression analysis of the other compressors.

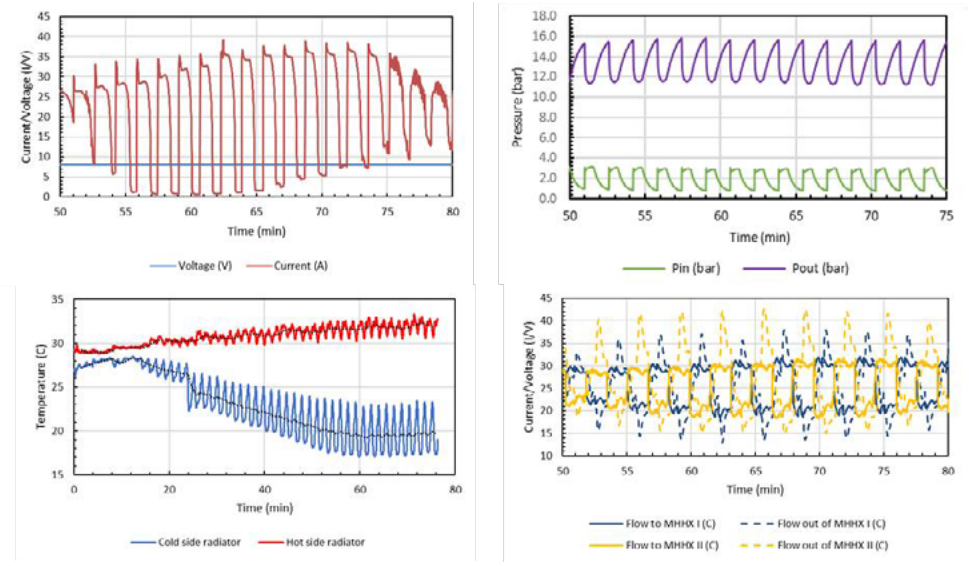

Fig. 4. (Clockwise from top left) Power consumption; ECC pressure differential; MHHXs' temperature; and Cooling during proof-of-concept runs

Based on current testing data, utilizing 25.4 µm membranes would require a total number of 57 cells with an active area of 150 cm^2 to meet a 3-year payback period (on a premium over a conventional, mini-split ductless RAC) for a 2.5 kW air conditioner, operating at 0.12 V per cell and 0.71 A/cm^2. The estimated total power consumption for the compressor is 730 W with a system cost of $380. The weight, dimensions, and volume of the PEM ECC are 149.7 kg, 25.4 cm x 25.4 cm x 29 cm, and 18.7 L (330 lbs, 10"x10"x11.4", and 1,140 in^2), respectively. Future improvements with the membrane and bipolar plate are required to improve the economics of the system. Extrapolating from the information in Figure 5, with a decrease in thickness to about 10 µm, 0.12 V could provide 1.36 A/cm^2 (capturing 75% of the improved ionic conductivity). The number of cells decreases to 30, with an estimated energy consumption of 730 W and costing $230. The weight, dimensions, and volume decrease to 65.8 kg, 25.4 cm x 25.4 cm x 12.7 cm, and 8.20 L (145 lbs, 10"x10"x5", and 500 in^3). Further improvements can be made to the system overall to reduce the voltage at the required current level, which would lead to improvements in COP.

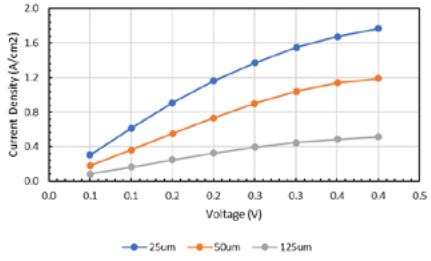

Fig. 5. Potential of improvement to PEM ECC due to membrane thickness

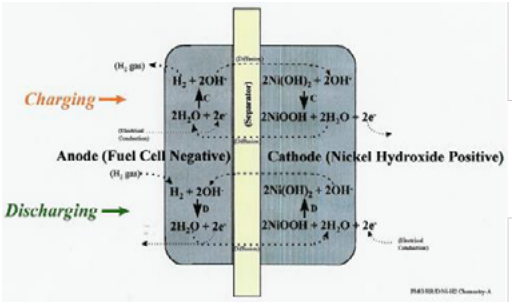

1.3. Alkaline Electrochemical Compression

The anionic electrochemical compression technology analyzed for use in a MHHP is based on well-established nickel hydrogen (Ni-H) battery technology. Going from a cationic to anionic systems greatly reduces the cost of the system. The expensive metal plates in the cationic systems, stainless steel and titanium,

can be replaced with cheaper metals like nickel, and the expensive platinum group metals (PGM) can either be replaced entirely with non-PGM catalysts, or reduced in quantity.

The battery technology is used in reverse, where power is put in to compress hydrogen instead of hydrogen expanding to produce power. While the energy density is only about one third as that of a lithium battery, the Ni-H battery has a long life, with cells capable of operating for 15 years at 80% depth of discharge (DOD) in satellite applications [1]. The cells can be designed to operate up to 82.74 bar (1200 psi), so this technology is applicable to MHHPs [2].

The nickel-hydrogen battery combines the positive nickel electrode of a nickel-cadmium battery with the negative electrode of a fuel cell. During charging, water is reduced at the anode to form hydroxyl ions and hydrogen gas. The hydroxyl ions transport through the alkaline electrolyte, typically KOH, and oxidize the nickel hydroxide ($Ni(OH)_2$) to form nickel oxyhydroxide (NiOOH). During discharging the reverse reactions occur, where the NiOOH is reduced back to $Ni(OH)_2$ and hydrogen gas is oxidized to reform water. There are three main architectures for designing a Ni-H battery: individual pressure vessel, common pressure vessel, and bipolar design. For this application we analyzed the bipolar plate design, with a positive electrode made up of porous nickel structure, which is packed with the nickel hydroxide, and a negative electrode like that of a fuel cell, which contains a platinum group metal catalyst with a gas diffusion layer.

$$Negative: H_2O + e^- \leftrightarrow \frac{1}{2}H_2 + OH^-$$
$$Positive: Ni(OH)_2 + OH^- \leftrightarrow NiOOH + H_2O + e^-$$
$$Overall: Ni(OH)_2 \leftrightarrow NiOOH + \frac{1}{2}H_2$$

Fig. 6. Alkaline exchange membrane electrochemical compressor electron flow diagram (left) and equations on electrodes (right)

In our proposed system a pair of Ni-H batteries work in tandem, i.e. one is charging while the other one is discharging. This allows for one to provide compressed hydrogen gas to the adsorbing MHHX, while the other is pulling hydrogen gas from the desorbing MHHX. The discharging battery provides most of the electrical power for the charging battery through a step-up converter, and the net difference is provided by an external source. The pair cycles back and forth like the MHHXs, and the discharging battery becomes the charging battery. Therefore, the power consumption of the system is the external voltage at the operational current of the battery providing high pressure hydrogen.

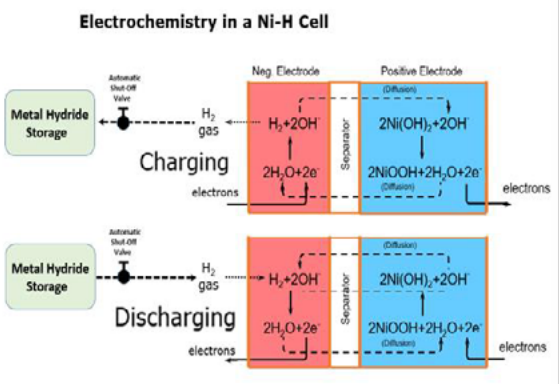

Fig. 7. Electrochemistry in a Ni-H cell (left) and prototype AEM ECC (right)

To meet the demands of a 2.5 kW air conditioner and achieve a payback period of 3 years, each battery will comprise of 228 cells at an active area of 490 cm^2. The discharging battery will operate at a voltage of about 1.25 V/cell at 11 mA/cm^2, and the charging battery will operate at 1.206 V/cell at 11 mA/cm^2, such that the input voltage is 0.044 V/cell. The input power to the system would be 540W with a system cost of $270. The weight, dimensions, and volume of the Ni-H battery system are 40.8 kg, 61 cm x 30.5 cm x 11.43 cm, and 21.23 L (90lbs, 24”x12”x4.5”, and 1,296 in^3), respectively.

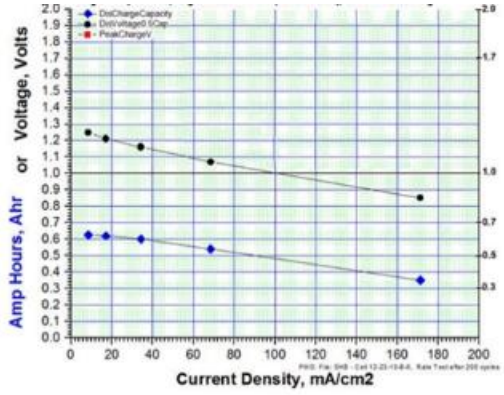

Fig. 8. Performance of NiMH compressor with respect to current density

1.4. Metal Hydride Compression

Metal hydrides (MH) are metallic compounds or alloys that adsorb and desorb hydrogen based on the temperature and hydrogen pressure conditions experienced by the MH. Based on the characteristics of the MH, it will adsorb a certain mass of low-pressure hydrogen at a specific low temperature. Once saturated with hydrogen the hydride is then heated causing the plateau pressure of the hydride to increase (as it is temperature dependent). This increase in plateau pressure causes the hydrogen to desorb from the hydride, allowing for compression of hydrogen gas by the metal hydride compressor (MHC) The temperature of the hydride and the mass of the hydride determines the flow rate, and the output pressure is controlled by the final temperature and the heating rate. Once the hydrogen is completely desorbed the hydride is cooled and then refilled with low pressure hydrogen to start the cycle over again. Figure 9 shows the basic cycle in action.

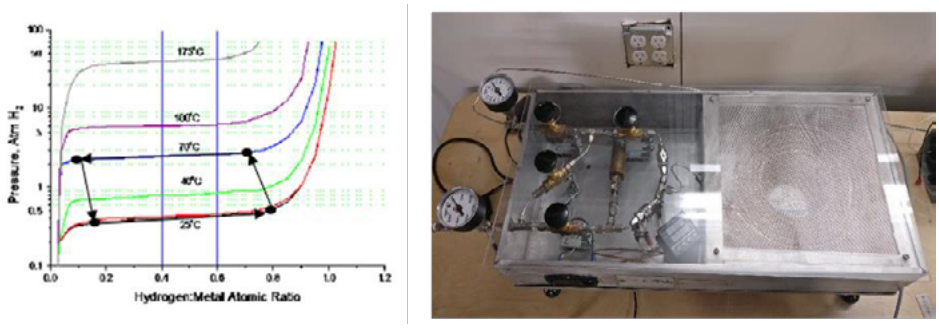

Fig. 9. Metal hydrogen compressor pressure cycle (left) and example compressor (right)

In our proposed system a series of MHCs work in tandem, i.e. some will be adsorbing hydrogen while the others will be desorbing hydrogen. The MHCs that is desorbing hydrogen is heated using a nichrome resistive heating wire, and the MHCs that is adsorbing is cooled down by a fan.

To meet the demands of a 2.5 kW air conditioner, the MHC system will comprise of 20 MHC coils of 1.524 m (5 ft) in length, with 10 producing hydrogen at any time. To achieve the desired pressure and hydrogen output each will need to be heated to 200°C, resulting in a power consumption of ~500 W per coil, or 5000W total. The coils cooling down will be running on a fan system that draws an average 70 W, for a total system power draw of 5500W, at a system cost of $456. The weight, dimensions, and volume of the MHC system are 22.7 kg, 30.5 cm x 61 cm x 25.4 cm (50lbs, 12”x24”x10”, and 2880 in^3), respectively.

1.5. Mechanical Compression

The final method of compression analyzed for the MHHP was a standard mechanical compressor that is already mass manufactured. The type of mechanical compressor selected for testing was an R-22 compressor for a vapor compression (VC) heat pump with a rated cooling capacity of 6,330 kJ/hr (6,000 BTU/hr). This type of compressor is a scroll compressor, with two interleaving scrolls to pump, compress or pressurize fluids such as liquids and gases. Often, one of the scrolls is fixed, while the other orbits eccentrically without rotating, thereby trapping and pumping or compressing pockets of fluid between the scrolls. Another method for producing the compression motion is co-rotating the scrolls, in synchronous motion, but with offset centers of rotation. The relative motion is the same as if one were orbiting.

Fig. 10. R-22 compressor (left) and MHHP employing the same (right)

Connecting the compressor to a hydrogen tank provided a flow rate of ~30 SLPM of hydrogen at a current of 2.4 A and a voltage of 110 VAC. When only connected to a tank the compressor was able to achieve a 12.4 bar (180 psi) maximum from atmospheric pressure. Once it was turned off, a large internal leak caused the sharp increases of the inlet pressure of Figure 11. The compressor was also hooked up to imitate the pressure swings of the MHHP and maintain the 13.8 bar (200 psi) necessary to provide heating and cooling from the MHHXs.

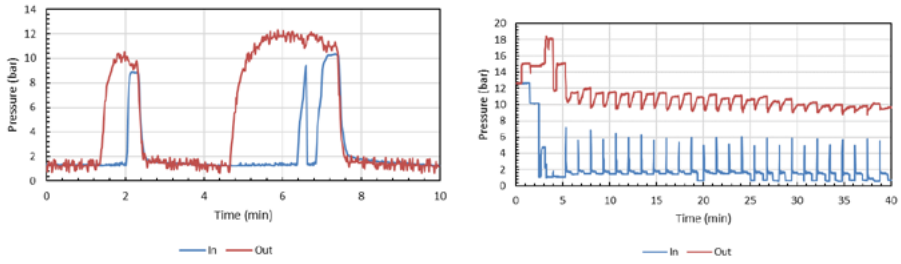

Fig. 11. Compressor when connected to a tank (left) and compressor imitating pressure swings of MHHP (right)

Because the 2.5 kW cooling system requires ~43 SLM of hydrogen and the 6330.4 kJ/hr (6,000 BTU/hr) compressor provided 30 SLM, a compressor sized for ~9074 kJ/hr (8,600 BTU/hr) should provide the requisite flow rate. The power consumption for a mechanical compressor in a MHHP system was estimated from the power consumption of rotary scroll compressors that met or exceeded (by less than 1055 kJ/hr (1000 BTU/hr)) the cooling load requirement. Assuming the power consumption is linear to the output cooling load, the power consumption of the compressors was proportionally decreased by the amount their cooling load exceeded 9073.5 kJ/hr (8600 BTU/hr). The average COP of typical systems employing R-22 is 3.17 [3]. With an average power consumption of 550 W, the average COP of employing a mechanical compressor in the MHHP is 4.52, with a system cost estimated in the range of $50-100. The weight, dimensions, and volume of the Ni-H battery system are 15.4 kg, 22.9 cm x 15.24 cm x 22.9 cm, and 7.96 L (34 lbs, 9”x6”x9”, and 486 in^3), respectively. While these systems were not designed nor optimized for hydrogen flow, they still show strong potential for a high efficiency cooling solution. The MHHX component costs of the RAC is comparable to the non-compressor components of a conventional RAC. Therefore, a RAC utilizing a conventional compressor shows strong potential for an early, low cost MHHX-RAC.

2. Conclusion

Experimental and theoretical data shows that hydrogen compression systems coupled with MHHP technology provides a realistic alternative to standard freon based heat pump systems.

From performance data and techno-economic analysis it is evident that PEM Compressors are highly efficient for low to medium pressure application but require more initial cost. At higher pressures the cost increases even further, limiting the technology to low temperature lift applications. Ni-H compressors provide a better electrochemical alternative with lower cost and higher efficiency than PEM for low to medium pressure application. This is a relatively low TRL technology for hydrogen compression, but with more development, this technology can overcome PEM compressor technology. MHC is the most expensive and least efficient of all the technologies. However, it does allow for much higher-pressure applications. One such application is in extreme temperature systems, such as ultra-low temperature freezers. Because the temperature drop is to -85°C, MHHXs designed for this application require very high pressures (>2000 psi). Mechanical compression of hydrogen offers the most near-term solution to implementation of a MHHP but will not see the advancements that the electrochemical systems will see, in terms of cost reduction and improvements in power consumption, with future development in the electrochemical compression technology.

The Table 1, below, provides a comparison of different hydrogen compression technologies.

Table 1. Summary of hydrogen compression technologies

Compression Technology	System Cost ($)	System Power Consumption (W)	Weight (lb)	Volume (in^3)
PEM ECC	380	730	330	1140
Ni-H	270	540	90	1296
MHC	456	5500	70	2880
Mechanical	50-100	550	34	486

3. Nomenclature

Table 2. Acronyms and abbreviations, defined

Term	Definition	Term	Definition
AEM	Anion Exchange Membrane	MHHP	Metal Hydride Heat Pump
COP	Coefficient of Performance (Wh/Wh)	MHHX	Metal Hydride Heat Exchanger
DOD	Depth of Discharge	PEM	Proton Exchange Membrane
ECC	Electrochemical Compressor	PGM	Platinum Group Metal
MEA	Membrane Electrode Assembly	RAC	Room Air-Conditioner
MH	Metal Hydride	SLM	Standard-Liter per Minute (0°C, 1 bar)
MHC	Metal Hydride Compressor	VC	Vapor Compression

Abstract

If two-phase flow occurs in the Variable Refrigerant Flow (VRF) system air conditioner, the distribution characteristic may be changed, and uneven distribution problem will occur. In addition, changing the orientation of the refrigerant distributor from horizontal to vertical in order to reduce the installation space, this uneven distribution becomes even worse. In this study, computational fluid dynamics (CFD) simulation is used to calculate uneven distribution of two-phase flow in a vertically installed distributor and to analyze the factors affecting the uneven distribution by analyzing the internal flow. CFD results are validated by the previous experimental results. Due to the momentum difference, liquid phase flows toward the end of the header and the gas phase flows near the inlet. Uneven distribution is exacerbated as the void fraction increased. The geometry of the header is modified to improve the non-uniform distribution and the result are compared with the existing data.

Keywords: computational fluid dynamics (CFD), distribution, two-phase

1. Introduction

Variable Refrigerant Flow (VRF) system is an air conditioning system that supplies refrigerant to several indoor units using one outdoor unit. VRF system has high efficiency because it can control the cooling and heating depending on thermal loads of each indoor space. Due to its convenience and efficiency, demand is increasing in commercial and residential buildings. VRF system supplies the refrigerant to each indoor unit by using a refrigerant distributor, and the refrigerant distributor can also be connected to other refrigerant distributors. As the height of a building increases, the height difference criteria of the refrigerant distributor also increase. In a vertical pipe connecting the distributor, the refrigerant flowing in the liquid state can be vaporized into a two-phase state due to the static pressure loss caused by the height difference. When a two-phase flow is supplied to the refrigerant distributor, unlike the distribution tendency of a single phase flow, uneven distribution occurs. In addition, in order to reduce the installation space, there is a demand to change the direction of the refrigerant distributor from horizontal to vertical. If the refrigerant is distributed to each indoor unit through a vertically installed distributor, the uneven distribution can be worse than the horizontal installation. If uneven distribution occurs inside the refrigerant distributor for the influence of such supply conditions, some of the indoor units do not receive sufficient refrigerant mass flow rates to meet their thermal demand. Then, the outdoor unit will have additional operation to supply the required mass flow rate in the indoor space, and it will be a negative impact on the energy efficiency of the system. Therefore, it is necessary to investigate the distribution characteristics when the two-phase flow is supplied to the vertically installed refrigerant distributor.

The refrigerant distributor is a manifold shape. The flow distribution problem in the manifold shape has been mainly dealt with in the research of parallel-flow heat exchangers. Many researchers [1-6] have conducted experimental and numerical studies on the flow distribution in parallel-flow heat exchangers. Dario et al. [1] reviewed the study of two-phase flow distribution in parallel channels and summarized the factors that influence the two-phase flow distribution. The factors affecting the distribution are divided into geometrical

factors, fluid properties, and operating conditions. Kim et al. [2] experimentally investigated the two-phase flow distribution of R-134a in a downward flow mini-channel heat exchanger varying the operating conditions (mass flux, quality), geometrical factor (inlet position) and compared with the data conducted with R-410A. Vist and Pettersen [3] experimentally investigated the two-phase distribution varying geometrical factors (header diameter, flow direction) and operating conditions (mass flow rate, quality, heat load). Lee and Lee [4] experimentally investigated the two-phase distribution tendency varying the geometrical factor (intrusion depth) and operating conditions (mass flux, quality). Zhou et al. [5] numerically investigated the flow distribution in a central-type parallel heat exchanger. Flow distribution by changing the geometrical factor (dividing and combining header ratio, header and tube diameter ratio) was mainly considered. Said et al. [6] numerically investigated reducing mal-distribution at heat exchanger by installing orifice and nozzle between header and branch tubes.

In the previous study, many researchers conducted experimental and numerical study on flow distribution in heat exchangers. As a result, geometric factors and flow conditions affected the flow distribution in the manifold. In the case of experimental study, however, there are limitations in the analysis of the internal flow characteristic of header by installing the measurement device inside the distributor. In the numerical study, the flow characteristic in the header by the change of geometrical factor was performed by 3-D simulation, but the analysis was mainly dealt with in single phase flow.

In this study, computational fluid dynamics (CFD) simulation is conducted to investigate the two-phase flow distribution characteristics in a vertically installed distributor used in the VRF system. The distributor shape is modeled by simulating the refrigerant distributor used in the VRF system, and the two-phase flow distribution is calculated by changing the inlet tube position and void fraction. Two-phase flow inside the header are analyzed through quantitative values such as the void fraction of the cross-section and the superficial velocity. Based on the analysis, the geometry of the distributor is modified to improve the flow distribution. Then distribution characteristics of the modified distributor are compared with those of the existing distributor.

2. Numerical Method

2.1. Geometry

The VRF system consists of three pipes, two of them are gas pipe and the other is a liquid pipe. The two-phase flow due to height difference occur in the liquid pipe of refrigerant distributor. The modelling of refrigerant distributor is shown in Fig. 1. The header is installed vertically, and the shape of the header is a double pipe through which a circular tube passes in the center. Then four circular branch tubes for supplying the refrigerant to each indoor unit are installed having the 3mm of intrusion depth. The number of each branch tube is named from channel #1 to channel #4 according to the installed location from the top to the bottom. The direction of inlet tube is horizontal and is perpendicular to the installation direction of the branch tube. The position of the inlet tube varies depending on the analysis conditions.

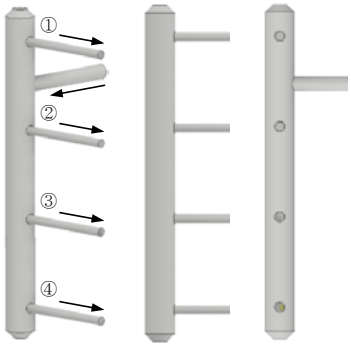

Fig. 1. Modelling of Refrigerant Distributor

2.2. Governing Equation

Transient analysis is conducted to calculate two-phase flow distribution in the distributor modelled in chapter 2.1. The commercial CFD code STAR-CCM+ is used for the numerical computations. A second order upwind scheme is used to discretize the velocity convective term and SIMPLE (Semi-Implicit Method for Pressure-Linked Equations) algorithm is adopted for the velocity-pressure coupling in STAR-CCM+

The flow pattern of two-phase flow inside the header was bubbly flow [7]. Therefore, Eulerian-Eulerian model is adopted to solve the governing equation. In Eulerian-Eulerian approach, each phase is treated mathematically inter-penetrating continua and mixed in each control volume. Then, governing equations are solved for each phase. Assuming adiabatic and incompressible flow, continuity and momentum equation of each phase is given as follows:

$$\frac{\partial}{\partial t}(\rho_k \alpha_k) + \frac{\partial}{\partial x_i}(\rho_k \alpha_k U_{i,k}) = 0 \tag{1}$$

$$\frac{\partial}{\partial t}(\rho_k \alpha_k U_{i,k}) + \frac{\partial}{\partial x_j}(\rho_k \alpha_k U_{i,k} U_{j,k}) = -\alpha_k \frac{\partial p}{\partial x_i} + \alpha_k \rho_k g_i + \frac{\partial}{\partial x_j} \mu \alpha_k \left[\left(\frac{\partial U_j}{\partial x_i} + \frac{\partial U_i}{\partial x_j} \right) - \frac{2}{3} \frac{\partial U_j}{\partial x_j} \delta_{ij} \right] + M_{i,k} \tag{2}$$

where α_k and $M_{i,k}$ represent the volume fraction of phase k and interfacial momentum transfer. In this study, Inlet tube, manifold, branch tubes have different flow directions each other. To model the momentum transfer of interface, dispersed phases are assumed spherical particle and only the drag force is considered in this study. Drag is interfacial force that disturbs the flow of bubbles by the surrounding liquid. For drag coefficient C_D, Schiller and Naumann drag coefficient [8] is chosen. Drag force and drag coefficient are given as follows:

$$F_d = \frac{3}{4} \frac{C_D}{d_b} \alpha \rho_c |U_r| U_r \tag{3}$$

$$C_D = \begin{cases} \frac{24}{Re_d}\left(1 + 0.15 Re_d^{0.687}\right) & 0 < Re_D \le 1000 \\ 0.44 & Re_D > 1000 \end{cases} \tag{4}$$

Where Re_d and ρ_c represent the Reynolds number of dispersed phase and density of continuous phase. To calculate turbulence, RANS model is used, which is calculated by dividing the average component and the variation component. Since the Eulerian-Eulerian model is used, the turbulence model of each phase is also calculated separately. In the case of continuous phase, the Realizable K-epsilon model is used, which modify the standard k-e model to calculate the Reynolds stress [9]. The equations for turbulence kinetic energy k and turbulence dissipation rate ε are as follows:

$$\frac{\partial \alpha_c \mathrm{k_c}}{\partial \mathrm{t}} + \frac{\partial (\alpha_c \mathrm{k_c} U_{i,c})}{\partial x_j} = \frac{1}{\rho_c} \frac{\partial}{\partial x_j} \left[\alpha_c \left(\mu_c + \frac{\mu_{T,c}}{\sigma_k} \right) \frac{\partial \mathrm{k_c}}{\partial x_j} \right] + \alpha_c \frac{\mu_{T,c}}{\rho_c} \left(\frac{\partial \mathrm{U_{i,c}}}{\partial \mathrm{x_j}} + \frac{\partial \mathrm{U_{j,c}}}{\partial \mathrm{x_i}} \right) \frac{\partial \mathrm{U_{i,c}}}{\partial \mathrm{x_j}} - \alpha_c \varepsilon_c \tag{5}$$

$$\frac{\partial \alpha_c \varepsilon_c}{\partial \mathrm{t}} + \frac{\partial (\alpha_c \varepsilon_c U_{i,c})}{\partial x_j} = \frac{1}{\rho_c} \frac{\partial}{\partial x_i} \left[\alpha_c \left(\mu_c + \frac{\mu_{T,c}}{\sigma_\varepsilon} \right) \frac{\partial \varepsilon_c}{\partial x_j} \right] + \alpha_c C_1 \frac{\varepsilon_c}{2} \left(\frac{\partial \mathrm{U_{i,c}}}{\partial \mathrm{x_j}} + \frac{\partial \mathrm{U_{j,c}}}{\partial \mathrm{x_i}} \right) \frac{\partial \mathrm{U_{i,c}}}{\partial \mathrm{x_j}} - \alpha_c C_2 \frac{\varepsilon_c^2}{k_c + \sqrt{(\mu_c/\rho_c)\varepsilon_c}} \tag{6}$$

where α_c represents volume fraction of continuous phase.

Turbulence response model is used to calculate the turbulence of the dispersed phase. The turbulence of dispersed phase is correlated from the turbulence of the continuous phase by using the correlation derived from the response coefficient. In this study, the Issa response coefficient which is a function of void fraction is used [10].

2.3. Grid

To generate the mesh in fluid domain, polyhedral mesh and prism layer mesh are applied. In order to calculate the turbulence, the area identified by the law of wall should be generated in a compact grid and calculated for each area. In this study, the prism layer thickness is generated to satisfy $y^+ < 5$ condition to calculate the turbulence from the viscous sublayer. To determine the base size of polyhedral mesh, grid

independence test is performed by comparing the y-axis velocity distribution in the branch tube and the base size is determined to be 8,200,000 cells.

2.4. Boundary Condition

The working fluid in this study is an air-water mixture. The void fraction is calculated by assuming a slip ratio of 1 when the quality of the refrigerant is varied from 0 to 0.1. The mass flow rate of air and water are determined by using the same void fraction. The wall is assumed an adiabatic wall and no-slip condition. Inlet boundary condition is set to mass flow boundary condition. The mass flow rate of water is $0.26\ \mathrm{kg/s}$, and the mass flow rate of air is varied in the range of $1.16 \times 10^{-4} \sim 9.70 \times 10^{-4}\ \mathrm{kg/s}$ depending on the void fraction. The outlet boundary condition is selected as the pressure boundary condition and set to 0 Pa based on the atmospheric pressure. The inlet boundary conditions used in the analysis are shown in Table 1.

Table 1. Inlet boundary condition of air and water

Material	Volume flow rate [kg/s]
Water	0.26
Air at $\alpha = 0.17$	1.16×10^{-4}
Air at $\alpha = 0.39$	4.43×10^{-4}
Air at $\alpha = 0.53$	9.70×10^{-4}

3. RESULT AND DISCUSSION

3.1. Simulation Results and Validation

CFD simulation is used to calculate the two-phase flow distribution in the header according to the inlet position and the void fraction change. The void fraction has been changed from 0.17 to 0.53 and the inlet position is located at the top or bottom of the header and is called the upper inlet and bottom inlet in each case. The calculated mass flow results show fluctuations, and time-averaged values are used. The mass flow rate distributed to each branch tube is represented by Liquid Fraction which is the ratio of the mass flow rate distributed to each branch tube to the total mass flow rate. The distribution tendency calculated by CFD are compared with the experimental data conducted by Ham [7]. A comparison of results is shown in Fig. 2.

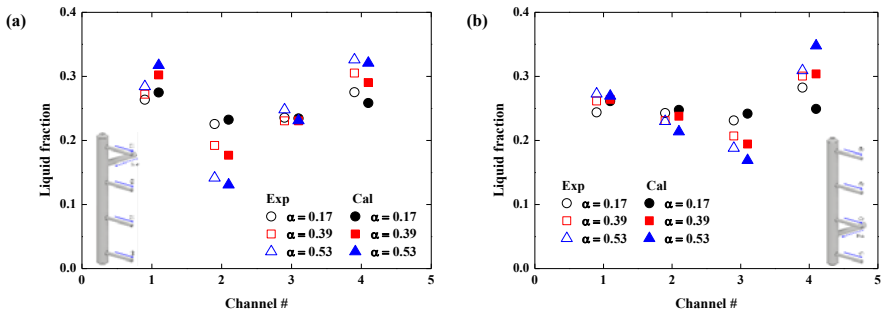

Fig. 2. Validation with The Experimental Data by Ham[7]: (a) Upper Inlet, (b) Bottom Inlet

Fig. 2. (a) shows the distribution tendency at the upper inlet condition. The analysis result shows that the gas fraction tends to be high in channel #2 near the header inlet tube. In contrast, liquid fraction of channel #1 and #4 located at both ends of the header is high and liquid fraction flowing into channel #2 is low. The maximum difference of 3.30%p is observed in the channel #1 when the void fraction is 0.53, and the distribution of CFD follows the experimental results.

The distribution tendency at the bottom inlet conditions is shown in Fig. 2. (b). The analysis result shows that liquid fraction flow into channel #4 at the bottom of the header is high. And liquid fraction liquid fraction

flowing into channel #2, #3 is low due to gas fraction inflow. The liquid fraction shows a maximum difference of 3.85%p at channel #4 when the void fraction is 0.53. Therefore, the bottom inlet case also follows the experimental distribution tendency of liquid phase.

3.2. Effects of inlet position and void fraction

Two-phase flow characteristics according to the void fraction change at each inlet location are analyzed by internal flow. When the two-phase flow develops from the inlet tube, phase separation occurs due to density difference between the liquid phase and the gas phase. As the two-phase flow flows into the header, it collides with the double pipe installed inside the header, and two-phase flow is divided into two branches and flow to the wall of the header. Then the incoming flow creates two vortices. First, since the diameter of the header is larger than that of the inlet tube, vortices and flow separation are generated at the part where the inlet tube and the header are connected. When the flow is passing through the double pipe, like external flow, the second vortices are generated causing separation at the rear end of the double pipe. In the region where the flow separation is generated, the gas phase with small momentum rotates and flows toward the axis direction of header. Fig. 3 shows the cross-sectional contours of volume fraction and velocity vector distribution in the cross-section (yz plane) at the header adjacent to the inlet. In the figure, gas fraction is concentrated in the region close to the inlet tube and in the rear part of the double pipe. As the void fraction increased, the size of the vortex increased.

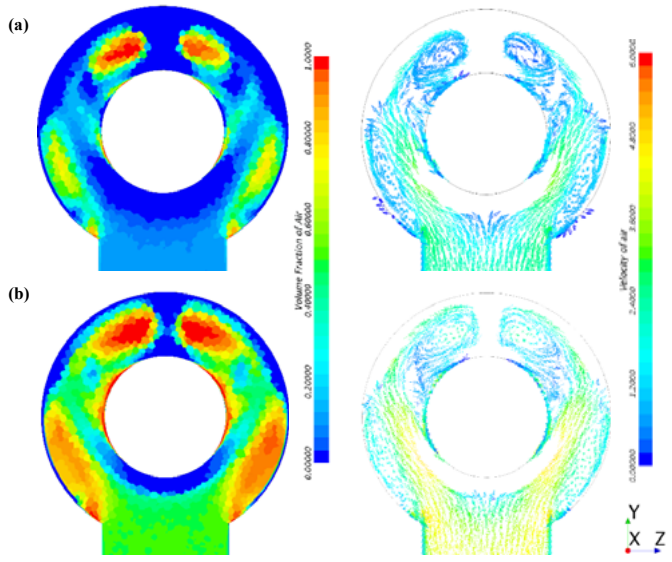

Fig. 3. Cross-Sectional Contours of Void Fraction and Velocity Vector of Header Adjacent to The Inlet: (a) $\alpha = 0.17$, (b) $\alpha = 0.53$

Flow developed at the inlet splits in both directions of the header, while generating a vortex. Volume fraction contours of the header cross-section are shown in Fig. 4.

In the upper inlet case, flows are split two ways that upward direction to channel #1 and downward direction to channel #2, #3, and #4. In each direction, the flow develops while maintaining the vortex and then flows toward the branch tube. Since the liquid phase has a greater momentum than the gas phase, the liquid phase flows toward both ends of the header due to the inertia force. The gas phase tends to flow to the channel located at the center of header. Therefore, the gas phase flowing in the upper part of the inlet cross-section due to phase separation, is directed downward. In the downward section contains channels #2, #3, and #4, due to the momentum difference, the gas phase flows to channels #2 and #3 close to the inlet and the liquid phase flows to channel #4 located at the end of header. The direction of flow and the buoyancy are inconsistent, then the gas phase lose momentum while flowing between channels #2, and #3 and flow back to channels #2.

In the bottom inlet case, the two-phase flow from the inlet generates vortices and develops and is divided into downward direction to channel #4 and the upward direction to channel #1, #2, and #3. The downward

flow to the channel #4 has less gas phase than the upward flow due to the phase separation at the inlet. In addition, because the flow direction is downward, the gas phase flows back to upward due to the buoyancy effect. Therefore, in the case of void fraction 0.17, no gas phase flow to the channel #4, and some gas phase is distributed as the void fraction increased. The upward flow is similar with the downward at upper inlet case. Due to the momentum difference, much of gas phase flow to the channel close to the header. Although little amount of gas phase flows to the channel #4 at the bottom end of header, gas phase flowing upward is distributed more uniform than the upper inlet condition. In order to compare quantitatively to the distribution tendency according to the inlet position, standard deviation of distribution is compared. Table 2 shows the standard deviation of the liquid fraction at upper and bottom inlet case according to the change of void fraction. The distribution tendency of the bottom inlet case is more uniform than the upper inlet case in all void fraction conditions.

Table 2. Standard deviation of liquid fraction according to inlet position

	Upper inlet	Bottom inlet
α=0.17	0.018	0.007
α=0.39	0.050	0.034
α=0.53	0.078	0.067

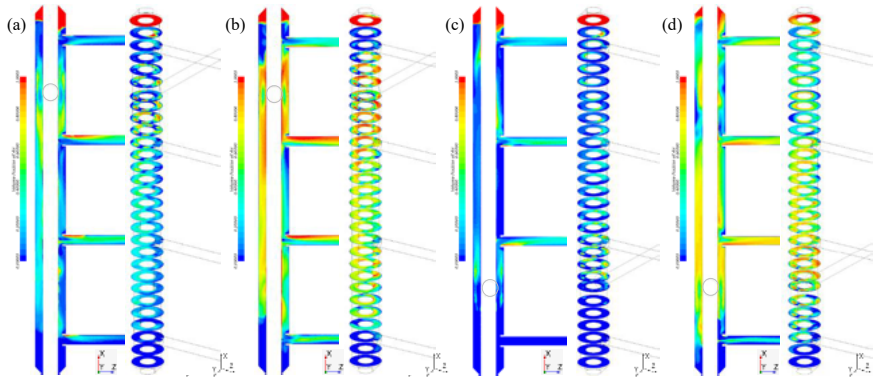

Fig. 4. Contour of Volume Fraction: Upper Inlet (a) $\alpha = 0.17$, (b) $\alpha = 0.53$; Bottom Inlet (c) $\alpha = 0.17$, (d) $\alpha = 0.53$

To compare the velocity of the gas phase and liquid phase and to analyze the change in the magnitude of the momentum in each section, the superficial velocity is compared. The superficial velocity is defined as follows:

$$U_{s,k} = \alpha_k U_k \tag{7}$$

where α_k and U_k represents volume fraction and velocity of the phase k. Fig. 5 is a graph of the axial cross-sectional mean magnitude of superficial velocity inside the header for gas phase and liquid phase at a void fraction of 0.53. The x axis represents the position in the axial direction of the header and the y axis represents the cross-sectional mean superficial velocity. Fig. 5. (a) and (b) are the upper and lower inlet cases, respectively.

The superficial velocity distribution of the liquid phase is the highest at the x=-0.078 m cross-section where the inlet tube is located due to the influence of the mass flow rate from the inlet tube to the header. The liquid flow collides on the rear wall of the header and flows axially in two directions. At the inlet of the header where the liquid flow splits from the wall into bifurcation, creating a vortex, the superficial velocity decreases significantly. As the flow splits in two directions at the inlet of the header, the superficial velocity gradually decreases. Branches are located at the cross-sections at x=0.12 m, 0.04 m, -0.04 m, and -0.12 m, respectively. However, the liquid phase maintains superficial velocity up to channel #1, #4 (x=0.14 m, -0.14 m) at both ends of the header. Comparing the two inlet conditions, the superficial velocity of the liquid phases tended to be the same. But in the bottom inlet case, liquid phase is less distributed to the channel #4 located downwards due to

the influence of gravity. Therefore, the superficial velocity is higher than that of channel #1 in the upper inflow condition.

The gas flow shows different tendency in two cases compared to the liquid phase. Since the phase separation of the gas phase in the inlet tube, most of the gas phase flows in the upper part of the inlet cross-section. In the upper inflow condition, however, most of the gas flowed to downward. Therefore, the highest superficial velocity value is obtained in the cross-section of x=-0.078 m.

However, the bottom inlet case shows the highest superficial velocity at the cross-section of x=-0.07 m rather than x=-0.078 m because the gas phase located at the top of the inlet flows directly to the top of the header. In addition, the upper inlet case is due to the buoyancy, the gas phase flows backward, and most of the flow rate flows into the channel #2. Then the superficial velocity decreases significantly after channel #2 (x=0.04 m). In Fig. 5. (a), the superficial velocity of x=-0.04 m to x=0.04 m is 0.3 m/s. However, the bottom inlet case shows that the superficial velocity decreases relatively uniformly in channels 2 and 3. In Fig. 5. (b), the superficial velocity of the same section is 0.5 m/s, which is relatively high. And in both cases, there is a region filled with gas phase on top of header (x=0.14 m), so the velocity of the liquid phase is zero, but the velocity of the gas phase is not zero.

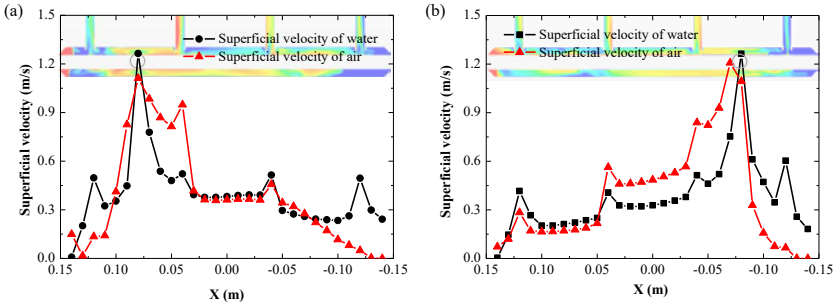

Fig. 5. Cross-Sectional Superficial Velocity Magnitude of Header: (a) Upper Inlet, (b) Bottom Inlet

3.3. Geometry Modification

It is confirmed that uneven distribution occurs when two-phase flow flows into the vertically installed header. Under every condition, most of gas phase flow into the channel #2 and #3, which are close to the header inlet, and most of liquid phase flow into the channel #1 and #4 located at both ends of the header. As the void fraction of the two-phase flow increased, this uneven distribution became more exacerbated.

The factor that most influences the uneven distribution inside the header is the density difference between the two fluids. Due to the difference in the density, phase separation and buoyancy occur, and despite homogeneous flow, the difference in momentum occurs and each phase has a different distribution tendency. The distribution characteristic of two-phase flow is shown in Table 2. The bottom inlet case shows a relatively uniform distribution than upper inlet case because the effect of buoyancy is reduced. Therefore, in this study, the header is modified under the bottom inlet case. In the bottom inlet case, the gas phase mostly flows upward, and the liquid phase is distributed at both ends of the header. To improve distribution, the gas phase flowing through channels # 2 and # 3 must be distributed along with the liquid phase to the end of header. In particular, the # 4 channel has little gas phase due to the buoyancy effect, so it needs to be improved through geometry modification.

Various researchers have tried to improve the distribution by modifying the header design. Webb and Chung [11] attempted to improve the distribution by inserting obstacles such as baffles or weirs inside the header or by inserting inlet tubes. When inserting the obstacle, the incoming two-phase flow created a jet through the obstacle, and each phase were mixed well, then it improved distribution characteristics. However, obstacles depended on the internal geometry of the header. If the part of the geometry changed, the design must be changed accordingly. Mahvi and Garimella [12] and Pistoresi [13] tried to improve the distribution by reducing the cross-section area of the headers instead of inserting obstacles. The header is designed that the cross-section is narrowed from the header inlet to the end, then the mixing of the gas and the liquid phase is improved to have the uniform distribution.

In the case of the header used in this study, since direction of the inlet tube is horizontal and the header is installed vertically and the double pipe is inserted the center of header, the method of reducing the outer diameter of the double pipe header is used. Under the bottom inlet case, it is expected that if the diameter of the header heading toward channel #4 is reduced, the momentum of the gas phase heading to channel #4 is increased, and the liquid fraction of channel #4 is reduced and flow to the upper part of header.

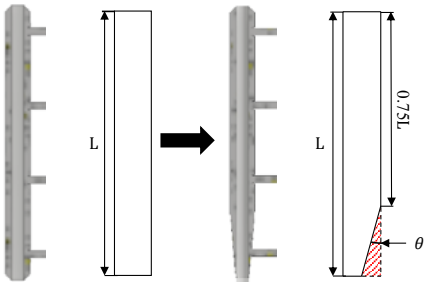

Fig. 6. Schematic of header plane-section modification: (a) Modification Channel #4, (b) Modification Channel #1 and #4

Schematic of the geometry modification of the header is shown in Fig. 6. The diameter of the cross-section from the header inlet to channel #4 is adjusted through the modification angle θ. The modification angle of the header can be converted from 1° to 5°.

The CFD simulation is performed with the void fraction 0.53 condition as a default, which has the largest uneven distribution in the bottom inlet case. The distribution tendency according to the modification angle of the header simulated by CFD is shown in Fig. 7. In the distribution tendency shown in Fig. 7, the distribution is improved as the modification angle increases. Unlike the effect of changing the void fraction, the amount of change in the liquid and gas phases due to the change in modification angle is relatively small. At the bottom of the header, the liquid fraction gradually decreases, but the gas fraction gradually increases. The increasing liquid mass flow rate to the upper side of the header does not change the liquid fraction in channels # 2 and # 3 when the modification angle is changed to 3°. As the angle increases to 5°, the volume fraction change affects to the channel #1, so that the liquid fraction distribution is improved in the upper part of header.

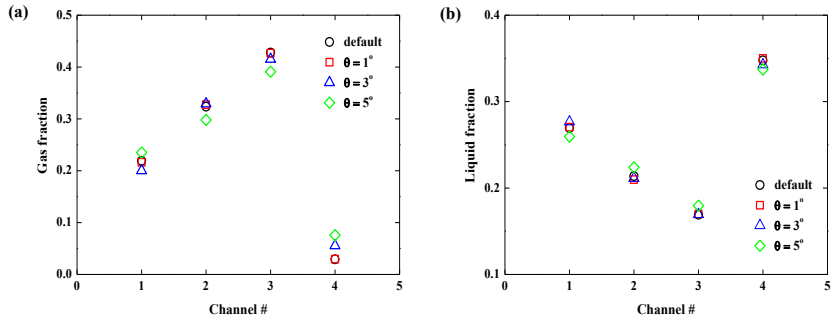

Fig. 7. Effect of header modification angle on flow distribution: (a) Gas Fraction, (b) Liquid Fraction

Table 3. Standard deviation of liquid fraction according to inlet position

Modification angle	Air	Water
Default	0.147	0.067
1°	0.146	0.067
3°	0.136	0.066
5°	0.115	0.058

Table 3 shows standard deviation according to the modification angle. The distribution tendency according to the modification angle is shown through the standard deviation. As the modification angle is increased, the distribution is gradually improved.

4. Conclusion

In this study, the two-phase distribution characteristics of the refrigerant distributor used in the VRF system is investigated by CFD simulation. Internal flow of the header is analyzed by CFD simulation and the factor that affects the uneven distribution of two-phase flow is investigated. The analysis conditions are divided into upper inlet condition and bottom inlet condition according to the header inlet position. For each condition, the flow characteristics in the header are analyzed according to the change of void fraction. Based on the analysis, the geometry of the header is modified to evaluate the two-phase flow distribution characteristics. Some major conclusions are as follows:

- The two-phase flow distribution results simulated by CFD are following the tendency as those measured by the previous experimental study.
- Most of the gas phase flows into the channel close to the inlet tube both the upper inlet and the bottom inlet cases, and the liquid phase flows to the both rear part of the header.
- As the void fraction is increased, uneven distribution is exacerbated.
- When the inlet position is located at the upper part of the header, the buoyancy force acts on the gas phase flowing downward then the gas phase flows counter currently.
- When the inlet is located at the bottom part of the header, a small amount of gas phase is distributed to channel #4, but the overall flow distribution shows less uneven compared to the upper inlet conditions.
- The geometry is modified to narrow the diameter of the headers towards branch 4 to improve the non-uniform distribution.
- As the modification angle is increased, the liquid phase distributed to branch 4 decreases while gas fraction increases.
- Standard deviation results show that the distribution is and improved as the modification angle increased.

Abstract

Membrane Ionic Liquid Desiccant Air Dehumidification (MILDAD) is a promising alternative to conventional dehumidification systems that employ mechanical compressors and refrigerant-based cooling with evaporator and condensing coils. However, its application has been limited due to high manufacturing and installation cost, durability issues, concerns with corrosion due to leakage and salt carry over into the downstream air and onto surfaces. This paper reviews substantial progress made with new systems based on combining advanced ionic membranes that are pressure resistant, thin walled with high water permeability, and non-porous with synthetic organic, non-crystalline ionic liquid desiccants. Alternative design configurations are discussed comparing cross flow shell-and-tube membrane contactors employing ionic membrane tubes through which ionic liquid desiccant air flows. Performance data for MILDAD prototypes is provided. Dehumidification of the incoming supply airstream and regeneration into exhausted building air is demonstrated. The latent effectiveness of the MILDAD system will be discussed along with some future steps to improve performance of the system.

1. Introduction

According to U.S. Energy Information Administration [1], the world's energy consumption grew 54% between 1990 and 2015. Buildings accounted for 20% of the total energy consumption in the world, and 40% in the United States. About 55% of the energy consumed in U.S. buildings is to keep the indoor environment thermally comfortable [2]. Humidity level is one of the important indicators of the quality of the indoor environmental quality (IEQ), which directly affect people's productivity and health. ASHRAE standard 55-2013 and 62.1-2016 request that HVAC system must be able to maintain a humidity ratio of below 0.012, and the relative humidity should be controlled below 65% to keep a good IEQ. Previous studies have observed that water provides a major breeding ground for the growth of bacteria and fungi in buildings, thus, affecting people's health [3][4]. In many regions, air dehumidification is necessary to reduce the moisture level in the indoor environment.

Conventional air dehumidification methods include mechanical cooling and sorption (adsorption with solid desiccant or absorption with liquid desiccant). With mechanical cooling, air is cooled down to its dew point temperature and water vapor in the air is condensed. To provide acceptable air temperature for air-conditioning or ventilation, the cold air usually needs to be warmed (reheat), which wastes energy. Sorption method uses solid or liquid desiccant to absorb water vapor in the air [5]. In a conventional Liquid Desiccant Air Dehumidification (LDAD) system, the liquid desiccant is in direct contact with the wet air to be treated and absorbs water vapor in the wet air. With LDAD, the air temperature and humidity can be independently

*Corresponding author. Tel.: +1 (302)-629-5768. *E-mail address:* bamdad.bahar@xergyinc.com

regulated, and the cooling system can work more energy efficiently with higher evaporating temperature. However, since air flow directly contacts with liquid desiccant in conventional LDAD systems, small solution droplets can be carried over by the air flow and spread into ductwork or the conditioned space. It not only negatively impacts the health of occupants, but also results in corrosion of the air supply ductwork. In addition, dehumidification performance of the liquid desiccant could degrade due to exposure to the pollutants in the ambient environment.

A liquid-to-air membrane energy exchanger can be used to eliminate the carry-out or entrainment of tiny desiccant droplets. The study reported here investigates the new membrane-based ionic liquid desiccant air dehumidification (MILDAD) system by using the aqueous solution of an ionic liquid as the desiccant. The first innovation of the system is using membrane-based mass-heat exchanger to eliminate the carry-over problem of the typical LDAD. The second innovation of the MILDAD is the use of ionic liquid as desiccant. Ionic liquid is synthesized liquid salts which are in the liquid phase when exposed to room temperature and atmospheric pressure. They have high thermal stability, negligible or no vapor pressure, high solubility in water, low or no corrosion to metals, and low driving temperatures to release water vapor (for regeneration). Ionic liquid, therefore, are ideal substitutes for traditional desiccant liquids because they can reduce or eliminate the corrosion and save the liquid desiccant used in the operation. Using ionic liquids has potential to remarkably reduce the operation and maintenance cost, as well as improve system performance.

2. Technology Description

2.1. Membrane Contactors

A MILDAD system uses semi-permeable membranes to separate the liquid desiccant and the air so that the problem of carryover is avoided [6]. A porous membrane is a thin material with pores in it that allow some substances to penetrate through it while preventing others from entering. A non-porous membrane is a thin material that incorporates (typically a polymer) material that transmits water. The driving force between the air and the liquid desiccant is the difference in water vapor pressure on either side of the membrane. There are two main parameters to describe a membrane: water transmission rate and selectivity. The water transmission rate (sometimes referred to as “Permeability”) is the rate at which vapor permeates through a membrane per unit area or per unit driving force; selectivity is the ratio of the permeability coefficient of vapor and the others in the humid air through the membrane [5]. The degree of selectivity is largely based on the membrane properties. There are some technical challenges to using MILDAD, such as biological fouling on the membrane; low moisture permeability, poor strength, and high cost of the membrane [7]. Yang et al. (2015) reported that the uneven distribution of liquid desiccant mainly caused by membrane deflection will significantly reduce performance [8]. In this work, we report data for non-porous i.e. gas impervious membranes [9]. In order to minimize membrane deflection and leakage issues (which is typical of systems incorporating flat sheet membranes) a tubular construct was developed. This also reduces the uneven distribution of desiccant. It should be noted that while porous membranes show higher initial rates of moisture permeability compared to non-porous (i.e. impervious or dense or composite membranes), non-porous membranes provide much better selectivity and eliminate cross-contamination and biological fouling; thus even at a lower permeation rates, they maintain stable performance and exceed the moisture permeation rates of porous membranes over time.

2.2. Ionic Liquid Desiccant

The most frequently used liquid desiccants are lithium chloride, triethylene glycol, and calcium chloride [10]. However, the traditional desiccant liquids have problems of corrosion, high cost and so on. Thus, alternative liquid desiccant is highly desirable. Ionic liquids are salts comprised of organic cations and inorganic anions or organic anions. In this study, the aqueous solution of an ionic liquid [EMIM][OAc] (1-Ethyl-3-methylimiadazolium acetate) is used as the liquid desiccant. It has high thermal stability and with low or no corrosion to metals [11]. Moreover, it does not have any crystallization problem. Fig. 1(a) shows the constant [EMIM][OAc] concentration lines in a psychrometric chart, which indicate the equilibrium conditions for air in contact with an [EMIM][OAc] solution at the specified concentrations. Fig. 1(b) shows the commonly used concentration ranges of various liquid desiccants at 20 ºC for typical air dehumidification operation, which is indicated by the blue band of equilibrium vapor pressure.

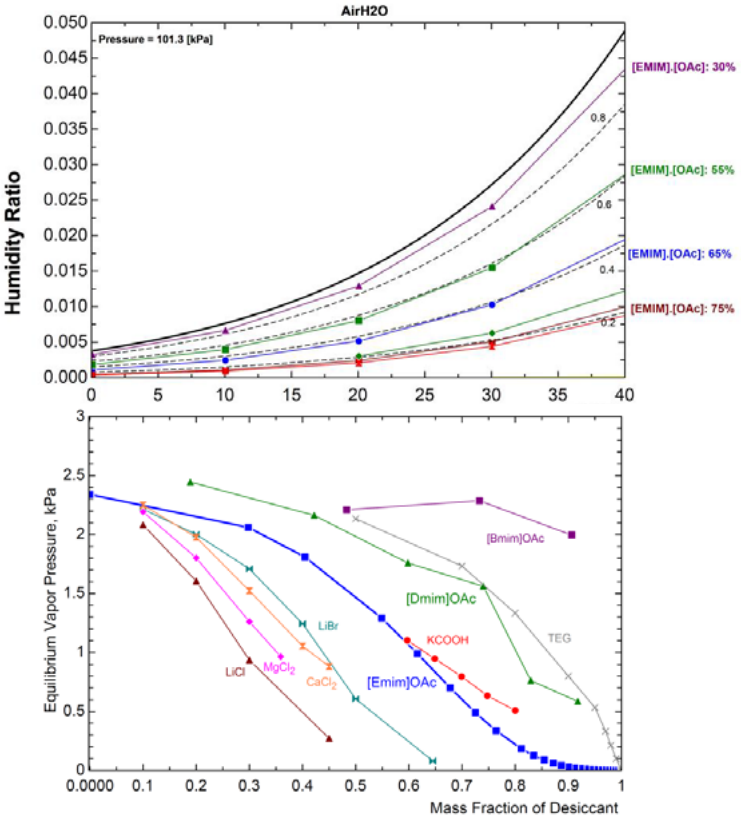

Fig. 1: Properties of [EMIM][OAc] dehumidification capacities at different concentrations (top), (b) commonly used concentration ranges of different desiccants (bottom)

2.3. Membrane-based Liquid Desiccant System

Fig. 2 shows the construction of a counter-flow membrane-based liquid desiccant air dehumidification system. A MILDAD is generally comprised of two supply air streams and two modules—a dehumidifier and a regenerator. A liquid desiccant solution is pumped through the permeate side channels, and an air stream is drawn to the feed side channels at the same time. Because of the difference between the temperature and humidity of the solution stream and air stream, heat and mass are exchanged through the membrane. In this process, the concentration of the solution is reduced by absorbing water vapor. Meanwhile, the solution absorbs heat generated by phase transformation of water vapor and then its temperature rises. The water vapor pressure on the surface of the solution increases with the decrease of the concentration of liquid desiccant and the increase of temperature, and the moisture absorption capacity of the solution decreases. The hot dilute solution is pumped into the regenerator to exchange heat and mass with a hot and dry air stream to evaporate the moisture. After that, the solution becomes concentrated again, and the vapor pressure becomes lower as well. It will be sent to the dehumidification module to keep continuous operation of the MILDAD.

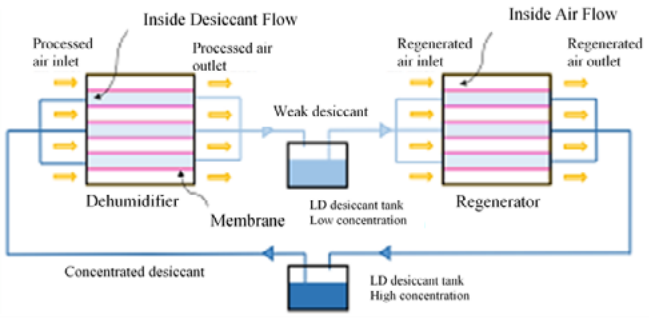

Fig. 2: Schematic diagram of basic procedure of membrane-based liquid desiccant system

3. Design of a Small-Scale Prototype MILDAD

A small-scale prototype MILDAD was developed. It uses a bundle of membrane tubes made with an ionic (nonporous) membrane instead of multiple membrane plates as in the referenced studies. The membrane tubes have better mechanical strength than the membrane plates and thus are expected to work at higher flow rates on both the air and solution sides of the membrane without any leakage. The schematic of the new prototype is shown in Figure 3.

The small-scale MILDAD prototype is shown in Figure 4. It measures 2.5 inches (64 mm) long, 4 inches (102 mm) wide, 4 inches (102 mm) high. It has 26 tubes made with an ionic (nonporous) membrane. The tubes are laid out in a staggered arrangement. Each tube has an outer diameter of 0.13 inch (3.3 mm) and an inner diameter of 1/8 inch (3.2 mm). The distance between two adjacent tubes is 1/4 inch (6.4 mm). The staggered arrangement could provide better convection heat and mass transfer but could also result in a higher air-side pressure drop. The end of each tube is connected to a header containing ILD solution. The ILD solution flows inside the tubes from the top header to the bottom header, while air is drawn through the outer surface of the tubes perpendicularly to the solution flow to exchange heat and water vapor with the ILD solution, forming a crossflow pattern.

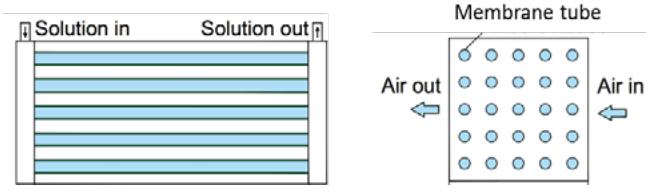

Fig. 3. Concept design of a MILDAD using membrane tubes: a side view (left) and a section view (right).

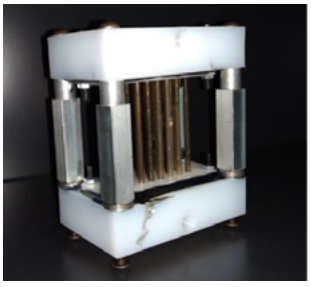

Fig. 4. A small-scale prototype of the MILDAD.

4. Experiments

The performance of both the dehumidification and humidification (regeneration) of the small-scale prototype MILDAD was evaluated under various operating conditions, including inlet air temperature and humidity, air and ILD solution flow rate, and ILD solution temperature.

Several performance metrics are evaluated based on the measured data, including moisture removal rate (m_v), specific vapor transportation rate (J), effective permeance (P), latent cooling (Q), and latent effectiveness (ε_L).

The moisture removal rate (m_V) is the product of the absolute humidity difference (ΔAH) and the mass flow rate of air (m_{air}), which represents the quantity of water vapor removed within a unit time, as expressed in Eq. (1).

$$\dot{m}_v = \Delta AH \cdot \dot{m}_{air} \tag{1}$$

The specific vapor transportation rate (J) is expressed with Eq. (2):

$$J = \frac{\dot{m}_v}{A_{eff}} \tag{2}$$

where m_v is the moisture removal rate, and A_{eff} is the effective contact area.

The effective permeance of the MILDAD (P) is calculated with Eq. (3).

$$P = \frac{J}{\Delta P_v} \tag{3}$$

where ΔP_v is the vapor pressure difference between two surfaces of the membrane.

The latent cooling capacity of the MILDAD (Q) is calculated with Eq. (4):

$$Q = \dot{m}_v \times L \tag{4}$$

where L is the latent heat of vaporization of water, 2260 J/g at 20 °C.

The latent effectiveness (ε_{lat}) is the ratio of the actual to the maximum possible water vapor transfer rates of the MILDAD, as expressed with Eq. (5):

$$\varepsilon_{lat} = \frac{w_{air,in} - w_{air,out}}{w_{air,in} - w_{sol,in}}, \tag{5}$$

where w is the humidity ratio referring to the moisture content in the air (i.e., grams of water vapor in each kilogram of dry air), and for liquid desiccant, w_{sol} represents the equilibrium humidity ratio of the liquid desiccant solution, which is determined by the temperature and concentration of a given liquid desiccant solution.

4.1. Experimental Apparatus

Figure 5 shows the experimental apparatus for the tests, which were performed in a national lab climate chamber. The prototype was placed in the middle of an Omega WT4401-D wind tunnel, which measures the airflow rate going through the prototype based on the measured pressure drop across the prototype. The airflow rate can be adjusted by regulating the wind tunnel's variable speed fan. The wind tunnel was in a climate chamber, in which the air temperature and relative humidity could be maintained within a small range (±0.5ºC temperature and ±1% relative humidity) of specific conditions. During a test, room air in the precisely controlled climate chamber was drawn through the small-scale prototype MILDAD. The air pressure, temperature, and relative humidity at the inlet and outlet of the MILDAD were measured by individual sensors. The ILD solution was circulated through the prototype at a fixed flow rate by a solution pump. A small reservoir was placed in the solution loop. The solution temperature in the reservoir was maintained at a specified setpoint by a refrigerated/heated circulating water bath. A high solution electronic scale was applied to weigh the solution reservoir in order to calculate the vapor absorbed by the ILD solution. A data acquisition

system was used to collect and save data from the sensors during each test. The measurement devices and corresponding accuracies are shown in Table 1.

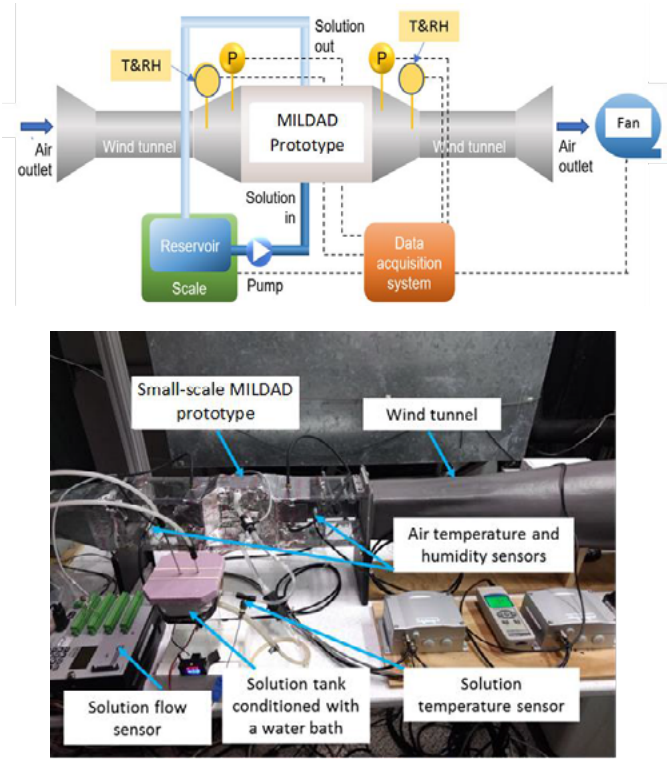

Fig. 5. The experimental apparatus for testing a small-scale MILDAD prototype: schematic diagram (top); and actual setup (bottom)

Table 1. Sensor Specifications

Target parameters	Measurement devices	Corresponding accuracies	Range
Temperature	Vaisala HMT330	± 0.25 C	-15~ +40 C
Relative humidity	Vaisala HMT330	± (1.0 + 0.008 X reading) %	0 – 95%
Differential air pressure	Omega PX02K1-16A5T	0.25%	0 – 32 in. Hg
Scale	Torbal AG4000	0.01 gram	4,000 grams

4.2. Test Results of the small-scale prototype

The tests were separated into the following five groups based on the conditions of the solution in the membrane tubes and the room air in the climate chamber. Each group included two to three tests with different airflow rates. Test results are summarized in the Table 2. The results of test group 5 were not included because leakage of the ILD solution was observed during the tests.

- **Case 1**: Humidification (membrane tubes filled with pure water) at 35°C and 20% relative humidity (RH) chamber condition, with 0.49 liters per minute (LPM) solution flow rate
- **Case 2**: Humidification (membrane tubes filled with pure water) at 25°C and 80% RH chamber condition, with 0.49 LPM solution flow rate
- **Case 3**: Humidification (membrane tubes filled with pure water) at 25°C and 80% RH chamber condition with lower water flow, with 0.30 LPM solution flow rate

- **Case 4**: Dehumidification (membrane tubes filled with EMIMOAc solution with 75% concentration) at 25°C and 80% RH chamber condition, with 0.15 LPM solution flow rate
- **Case 5**: Regeneration (membrane tubes filled with EMIMOAc solution with 75% concentration) at 35°C and 20% RH chamber condition, with 0.30 LPM solution flow rate

The test results indicate that the small-scale prototype MILDAD can humidify (Cases 1 through 3) and dehumidify (Case 4) air. The specific vapor transportation rate ranged from 53 to 105 g/(h-m^2) for humidification, and it was between 32 to 47 g/(h-m^2) for dehumidification. Figure 6 shows that the specific vapor transportation rate of the MILDAD was affected by the airflow rates, but the trend was determined by other factors, including chamber condition and solution flow rate. For humidification, when the chamber condition was very dry (Case 1), increasing the airflow resulted in a decrease in the specific vapor transportation rate. However, when the chamber condition was humid (Cases 2 and 3), the specific vapor transportation rate was not as sensitive to the airflow rate as it was under dry condition. Furthermore, under the same chamber condition and with the same airflow rate, lowering the solution flow rate decreased the specific vapor transportation rate. For dehumidification (Case 4), increasing the airflow from 4.6 to 10.6 m^3/h increased the vapor transportation rate, but further increases in the airflow rate resulted in a decrease in the vapor transportation rate.

The measured overall permeance of the small-scale prototype MILDAD ranged from 0.4 to 0.6 E-8 kg/(m^2-s-Pa) in dehumidification mode and from 0.4 to 2.9 E-8 kg/(m^2-s-Pa) in humidification mode.

Table 2. Test conditions and results

Case	Test Conditions (Measured Data)								Measured Performance

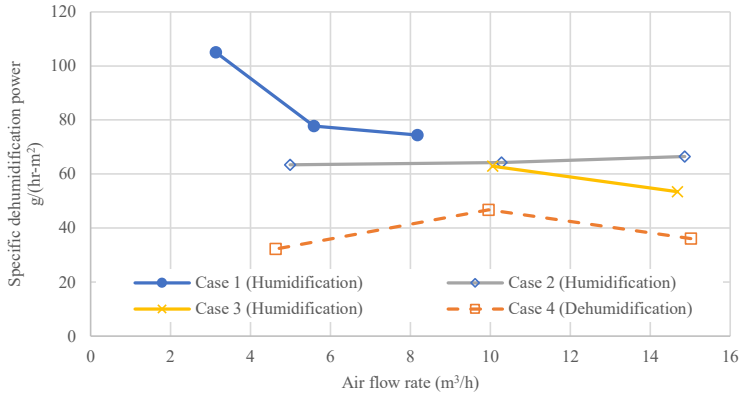

Figure 6. Measured specific vapor transportation rate of the small-scale MLDAD prototype in dehumidification and humidification operation at various airflow rates.

4.3. Test results of a medium-scale prototype

A medium-scale MILDAD prototype is tested in a wind tunnel, as shown in Fig. 7. The air velocity; and temperature, relative humidity at the inlet and outlet of the MILDAD are measured. A data acquisition system is used to collect and save data from all sensors during each test. The measurement devices and corresponding accuracies are shown in Table 3. The volumetric flow rate of the system is calculated by multiplying the cross-sectional area of the air channel with the air velocity. To smooth the air circulation in the test chamber, louvers are added at the air-side inlet and outlet of the MILDAD. The air circulation inside the wind tunnel is maintained at a rate of 10 CFM (0.28 m^3/min) with a fan. Humidity was measured both upstream and downstream of the MILDAD prototype.

Figure 7: Experimental Apparatus for characterizing the performance a medium-scale MILDAD prototype

Table 3. The measurement devices and corresponding accuracies

Target parameters	Measurement devices	Corresponding accuracies	Range
Temperature	Vaisala HMT330	± 0.25°F	-15 … +40°F
Relative humidity	Vaisala HMT330	± (1.0 + 0.008 X reading) %	0 – 95%
Flow Rate	PerfectPrime WD9829, Precise Sensitive Hotwire Thermal Anemometer Probe	Resolution: 0.01 m/s ± (0.05 X reading)	0.1 ∽ 25.0 m/s

The results of the dehumidification test are as shown in Table 4. The relative humidity upstream and downstream of the MILDAD prototype are plotted with respect to time as shown in Fig. 8. The specific vapor transportation rate of the medium-scale prototype, 111 g/(m^2-hr), is about 3 time higher than that of the small-scale prototype. It is thought to be due to higher flow rate and the longer tube length, which increase the contacting time for heat and mass exchange between ILD and air.

Table 4. Results from dehumidification test

Total testing time*	79.33	minutes
Air Flow Rate	0.28	m^3/min
Total Volume of Air Processed	22.5	m^3
Average ΔAH	1.3	g/m^3
Total Moisture Removed*	29.68	g
Specific Water Removal Rate	0.03	g/m^2/s
Cumulative latent cooling	72,843	J
Latent cooling power	15.3	W
Power consumption of fan and pump	14.4	W
Estimated COP of latent cooling	1.06	W/W

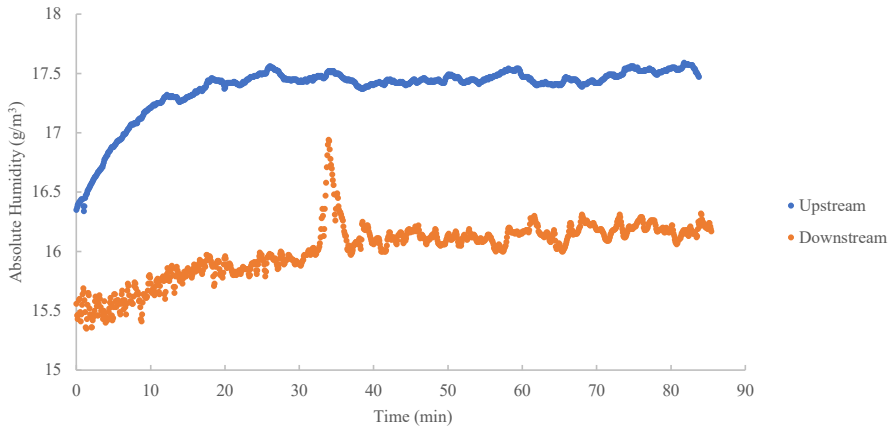

Figure 8: Dehumidification performance of dehumidifier module at 0.28 m^3/min. *Note that the spike in AH between 30 and 40 min was caused by a leak in the system. This leak was resolved during the test and these data points were disregarded in the analysis.

5. Design and Expected Performance of a Full-sized MILDAD

It is calculated that 1,371 membrane tubes are needed to have the same latent cooling capacity of a conventional 5,000 Btu (1.5 kW) air-conditioner—0.3 kW latent cooling capacity, or 0.12 g/s water vapor removal rate. Dimensions of a MILDAD with 0.3 kW latent cooling capacity are listed in Table 5.

The humidity ratio of typical entering air, $w_{air,in}$, of a room air-conditioner is 10.95 g/kg (26.7ºC and 50% relative humidity). The airflow rate of a 5,000 Btu (1.5 kW) air-conditioner is 170 CFM, or 0.095 kg/s. With a 0.12 g/s water vapor removal rate, the humidity ratio of the exiting air ($w_{air,out}$) will be reduced to 9.69 g/kg. The equilibrium humidity ratio of an ILD solution ($w_{sol,in}$) at 68% concentration and 26ºC is 6.53 g/kg. Based on these values, the latent effectiveness of the full-size MILDAD is calculated as 0.3.

Table 5. Dimensions of a MILDAD with 0.3 kW latent cooling capacity

Overall permeance	0.000027	g/(m^2-s-Pa)
Vapor pressure difference	700	Pa
Water removal rate	0.0189	g/(m^2-s)
Total membrane surface area	6.5	m^2

Tube diameter	0.003	m
Tube length	0.457	m
Surface area per tube	0.005	m^2
Total number of tubes	1371	[-]
Tube length	0.457	m
Tube spacing (2× dia.)	0.007	m
MILDAD width	0.762	m
MILDAD height	0.076	m

6. Conclusions

Small- and medium-scale prototypes of MILDAD using hollow tubes made with nonporous membranes and an ILD was successfully built. The small-scale prototype was evaluated for both dehumidification and humidification (regeneration) performance under various operating conditions. The test results provided a proof of concept of the nonporous MILDAD system to effectively humidify and dehumidify air. The specific vapor transportation rate ranged from 53 to 105 g/(h-m^2) for humidification, and it was between 32 to 47 g/(h-m^2) for dehumidification, depending on operating conditions. The measured permeance of the prototype ranged from 0.4 to 0.6 E-8 kg/(m^2-s-Pa) in dehumidification mode and from 0.4 to 2.9 E-8 kg/(m^2-s-Pa) in humidification mode. The technology was found to scale well, as the specific vapor transportation rate of the medium-scale prototype, 144 g/(h-m^2), is about 3 times higher than that of the small-scale prototype. It is thought to be due to higher flow rate and the longer tube length, which increase the contacting time for more heat and mass exchange between ILD and air.

Based on the measured permeance, a full-size MILDAD unit would require 1,371 membrane tubes to meet the latent cooling load of a 5,000 Btu (1.5 kW) air-conditioner with a 0.3 latent effectiveness. Coordinating with a commercial air conditioner manufacturer will be key to the development of a full-sized MILDAD.

Electrochemical inerting (oxygen control) for food preservation

Jacob Zerby[a], Bamdad Bahar[a]*

[a]*Xergy, Inc., 299A Cluckey Dr, Harrington DE 19954, USA*

Abstract

One of the primary applications for heat pumps is for refrigeration as part of the food chain. Despite widescale adoption, approximately 1.3 billion tons of food is wasted per year around the world [1], leading to excess energy requirements and greenhouse gas emissions. An alternate approach to food preservation is to decrease the oxygen levels in a container to deter spoilage. Decreasing the oxygen levels by merely 3% improves the shelf life of meats and other foods from several days to upwards of weeks. In this paper we describe a solid-state method of oxygen control based on an electrolysis cell, a derivative technology of fuel cells. This technology is quiet, requires no maintenance, and takes up very little space in a refrigerator, making it superior to current pressure/membrane swing adsorption (PSA/MSA) systems employing compressors. This low energy system can be used in conjunction with heat pumps for refrigeration, and in some cases replace heat pumps completely. This paper provides real life, in situ operational data.

Keywords: Inerting; Electrolysis; Food Preservation;

1. Introduction

Creating an inert environment through electrochemical means is a disruptive method for food preservation that can reduce, and in some cases replace, the energy footprint required by heat pump technology to maintain reduced temperatures in a refrigerator.

Currently, inerting systems utilize PSA systems in which a gas stream is fed to a reactor bed by means of a compressor. Certain gas molecules preferentially absorb onto the reactor bed, while others pass through unreacted. The system then undergoes a pressure swing, or change in pressure, to remove the reacted molecules and regenerate the reactor bed. Because there is a regeneration phase the system operates in batch mode, typically requiring multiple beds out of phase This method is very noisy, due to the use of a compressor, bulky, due to the batch method of operation, and energy intensive. The purpose for developing an alternative method of oxygen removal is to reduce the noise, size, and energy requirement of the traditional PSA system.

Several years have been devoted to the development of these systems to assist standard refrigeration in the preservation of food. As depicted in Figure 1, 5 Generations of systems have been manufactured and implemented, each with increases in performance and decreases in cost from the previous generation [2].

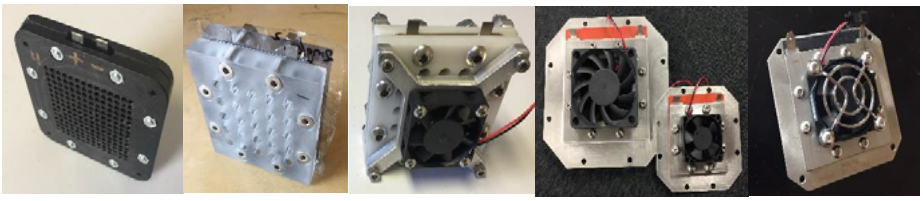

Fig. 1. The 5 generations of oxygen control devices

For an electrochemical inerting system, half of the electrochemical cell operates like the anode of a proton exchange membrane (PEM) water electrolyzer (PEMWE), and the other half of the cell operates like the cathode of a PEM fuel cell (PEMFC). Below, Figure 2 details the operation of all three systems.

The PEM is coated with catalyst on both the anode and cathodes, and then sandwiched by gas diffusion layers (GDL) to assist in electrical conductivity and gas/liquid diffusion to and from the membrane. In PEMWE, water is introduced at the anode side of the system and broken down to oxygen and protons. The protons transport across the membrane to the cathode and react to form hydrogen. In PEMFC, hydrogen is introduced at the anode and reacted to form protons. The protons transport across the membrane and react with oxygen at the cathode to form water and energy.

The PEM inerting system takes moisture out of the air and reacts that moisture at the anode to generate protons and oxygen. The protons transport across the PEM to the cathode and react with oxygen to reform water. The formation of water depletes oxygen in the environment making it rich with nitrogen. The additional water can back diffuse across the PEM or be removed via another dehumidification technology.

Table 1. PEM water electrolysis technology reaction pathways

2. Testing and Results

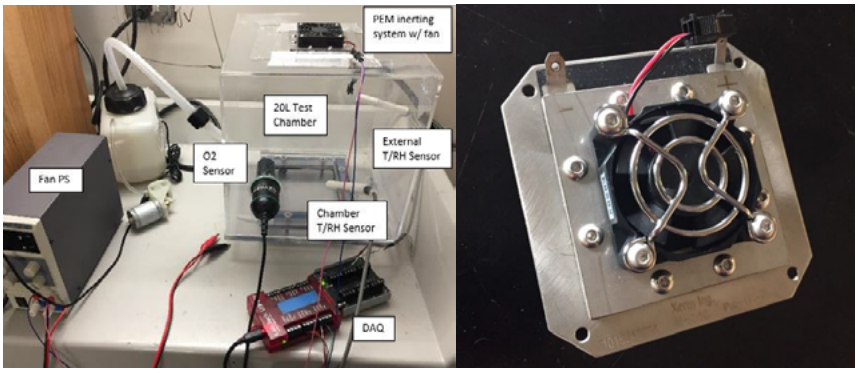

Fig. 3. Oxygen control chamber test set up (left); Sample oxygen cell (right)

The oxygen control chamber test was set up as depicted in Figure 3. Single cell membrane electrode assemblies (MEAs) were sandwiched between current collectors and housings to conduct performance testing. Several membranes were then tested to characterize the performance and determine feasibility of an air-based oxygen depletion system, including commercially produced perfluorosulfonic acid/PTFE copolymer membranes and in-house developed composite membranes. Testing was carried out in a 20 L container, while monitoring cell performance (voltage and current), temperature, humidity, and chamber oxygen levels. All cells were equipped with fans to improve mass flow of moisture to the membrane surface. The room RH was maintained between 45-55% and the room temperature was maintained between 22-23C. A constant 2 V was applied to each cell to carry out inerting.

Three composites of varying thickness (<50 µm) and ionomer composition were assembled into housings and testing against commercially produced 50.8 µm (212) and 127 µm (115) membranes. All systems achieved 75% efficiency for oxygen removal. The composite membranes all gave equivalent performance of around 1 g/hr. while NR212 and N115 achieved oxygen removal rates of 0.58 g/hr. and 0.23 g/hr. respectively. Composites A and B had the highest levels of back diffusion, leading to the lowest humidity increase of all the systems during the inerting process. This is desirable as an environment below 100% RH is preferred for food preservation. The difference in moisture addition to the box for the various membranes highlights the ability to adjust the internal conditions of the chamber through membrane customization.

The results of this testing (Figure 4) shows a power consumption of approximately 10.7 W (membrane - 4.75A @ 2V, fan – 12V @ 0.1A) for the membrane system used in testing. It took approximately 0.64 hours to drop the oxygen from 20.8% to 17.8%, giving the energy consumption of the system to be approximately 6.8 Wh or 9.5 Wh/g-O_2. This system would typically cycle three times a day, for three hours each cycle, putting

its average daily energy consumption at about 61 Wh/day. Large-scale PSA systems, the energy consumption is around 500 kWh/tonne-O_2 (0.0005 Wh/g-O_2) [3]. Figure 5 provides an image of a refrigerator equipped with a commercial PSA-type oxygen control system now available in China. While the electrochemical system requires water vapor to operate, the bulk humidity in empty refrigerators is sufficient. Refrigerators to tend to have a bulk relative humidity in the range of 20%-50%, and only increase as food is added.

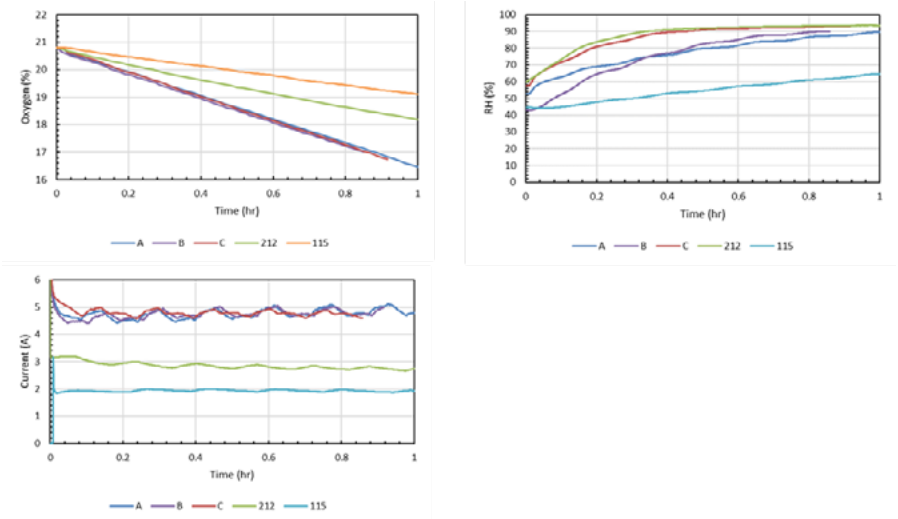

Fig. 4. Test results (in clockwise order, starting with the top left), Oxygen control results; Relative humidity change during oxygen control; Current draw during testing.

Fig. 5. Commercial Refrigerator with PSA type Oxygen control system

The fan system of the electrochemical system emits a faint noise of 20 dBa and is the only component significantly contributing to the noise of the system. As seen in Figure 6, this noise is quieter than a bedroom at night. Micro-compressors in PSA-type systems have noise levels upwards of 65 dBa [4]. This is as loud as normal conversation. In fact, 60 dBa is the threshold of possible permanent damage, thus this noise level is not appropriate for consumers [5].

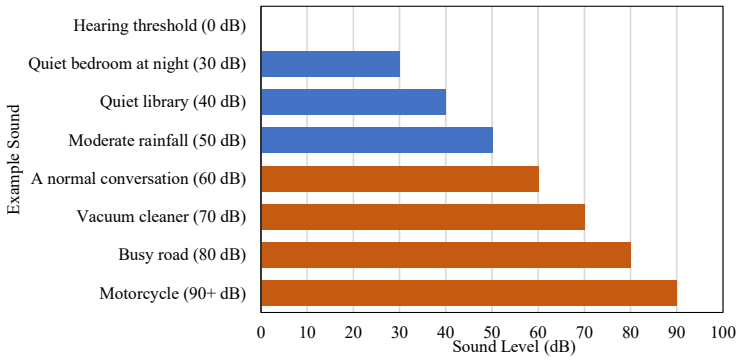

Fig. 6. Decibel levels of common sounds (sound levels at which long-term exposure can lead to hearing damage in orange) [4]

3. Conclusion

An electrochemical inerting system provides a much simpler, sleek, less complex, and lower noise alternative to PSA systems. The largest downside to the novel system is the greater energy consumption. Despite this increased energy consumption, the daily energy consumption of the system is still minimal; its daily power consumption is less than 4% of a typical 2 kWh/day refrigerator [6]. This system still has the potential for further development, exploring new membranes and decreasing the catalyst loading to improve its efficiency and decrease the system cost.

Thin composite membranes achieve the oxygen depletion rates in an electrochemical device, which is required for food preservation, whereas conventional free-standing membranes in the same devices do not [3]. This is a unique aspect of this technology and has resulted in dramatic performance improvements in food preservation applications.

Active humidity control for refrigeration applications

Jacob Zerby[a], Bamdad Bahar[a*]

[a]*Xergy, Inc., 299A Cluckey Dr., Harrington DE 19952, USA*

Abstract

According to the Food and Agriculture Organization of the UN, approximately 1.3 billion tonnes of food is wasted per year around the world [1], leading to excess energy requirements and greenhouse gas emissions. It is important to control all aspects of spoilage, including food storage during refrigeration. Maintaining adequate humidity levels during the storage of foods is essential to increasing their shelf life. In this paper we describe a solid-state method of humidity control based on an electrolysis cell, a derivative technology of fuel cells. The technology operates by interacting with moisture in the air, leading to a novel method of simple and accurate control of humidity levels inside an enclosure such as a refrigerator. It requires no maintenance, is quiet, and takes up very little space in a refrigerator. Current technology is limited to one-way operation, either as a humidifier or dehumidifier, and requires either a drain of liquid water for dehumidification or a source of water for humidification. The system can work in conjunction with a heat pump to manage moisture levels inside a refrigerator. Real life, in-situ performance data is provided.

Keywords: Active Humidity Control; Electrolysis; Refrigeration;

1. Introduction

There are many foods stored in a refrigerator that require different levels of humidity to increase their shelf life. In some instances, like vegetables, the foods may off-gas moisture during storage, which can lead to saturated environments. These saturated environments lead to pooling off water and subsequent rotting of food.

Current methods to avoid this issue include vents that allow the moisture to be pulled out of the container and the use of pervaporative membranes, which only allow moisture to pass through based on a humidity gradient. These are methods of passive control and their effectiveness depends on the food and conditions within the refrigerator. An electrochemical humidity control device allows for both humidification and dehumidification at precise levels, something no other technology can do.

Several years have been devoted to the development of these systems to assist standard refrigeration in the preservation of food. As depicted in Figure 1, 5 Generations of systems have been manufactured and implemented, each with increases in performance and decreases in cost from the previous generation [5].

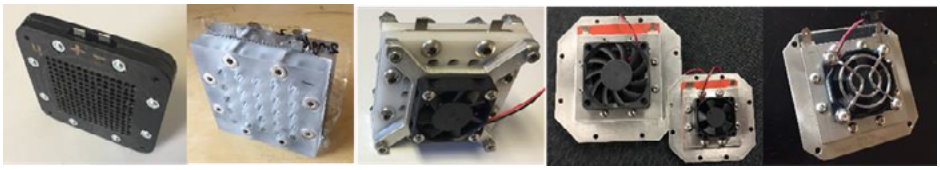

Fig. 1. The development of electrochemical humidity control systems over five generations

For the humidity control system, half of the electrochemical cell operates like the anode of a proton exchange membrane (PEM) water electrolyzer (PEMWE), and the other half of the cell operates like the cathode of a PEM fuel cell (PEMFC). Figure 2 details the operation of all three systems.

The PEM is coated with catalyst on both the anode and cathodes, and then sandwiched by gas diffusion layers (GDL) to assist in electrical conductivity and gas/liquid diffusion to and from the membrane. In PEMWE, water is introduced at the anode side of the system and broken down to oxygen and protons. The protons transport across the membrane to the cathode and react to form hydrogen. In PEMFC, hydrogen is introduced at the anode and reacted to form protons. The protons transport across the membrane and react with oxygen at the cathode to form water and energy.

The PEM humidity control system takes moisture out of the air and reacts that moisture at the anode to generate protons and oxygen. The protons transport across the PEM to the cathode and react with oxygen to reform water. If the anode is interfaced with the chamber then dehumidification is performed, if the cathode is interfaced with the chamber then humidification is performed.

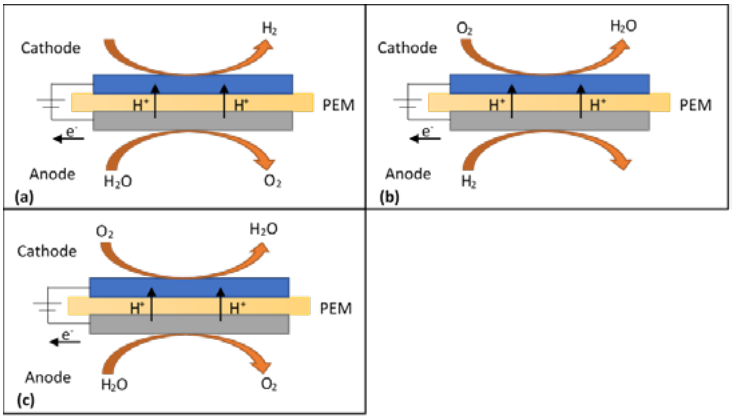

Fig. 2. Operation of (a) a PEMWE for hydrogen generation, (b) a PEMFC for power generation, and (c) a PEM humidity control system for oxygen removal

2. Testing and Results

Single cell MEAs were sandwiched between current collectors and housings to conduct performance testing. Several membranes were then tested to characterize the performance and determine feasibility of a water-vapor-based humidity control system. Testing was carried out in a 20 L container, while monitoring cell current, temperature, and humidity.

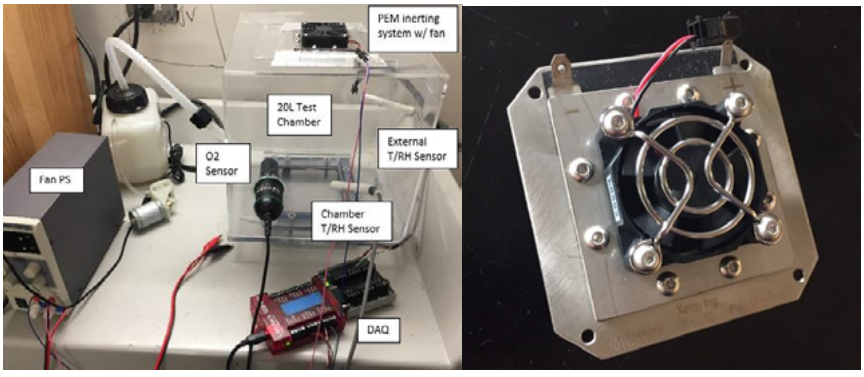

Fig. 3. Humidification testing set up (left); Sample commercial humidity control cell (right)

Membranes of various thicknesses were tested to determine the effect of thickness on moisture transfer rate. The test was terminated when the target relative humidity level, 15% RH, was reached. Membrane A was the thinnest membrane, while membrane C was the thickest membrane. As, as seen in Figure 4, membrane thickness increases the moisture transfer rate increase. However, the increase in thickness comes with an increase in cost, so it is essential to balance the two variables for a commercially viable moisture control system. Although membrane C reached the target relative humidity the fastest, its thickness left it cost prohibitively expensive and membrane B was selected for further testing and production.

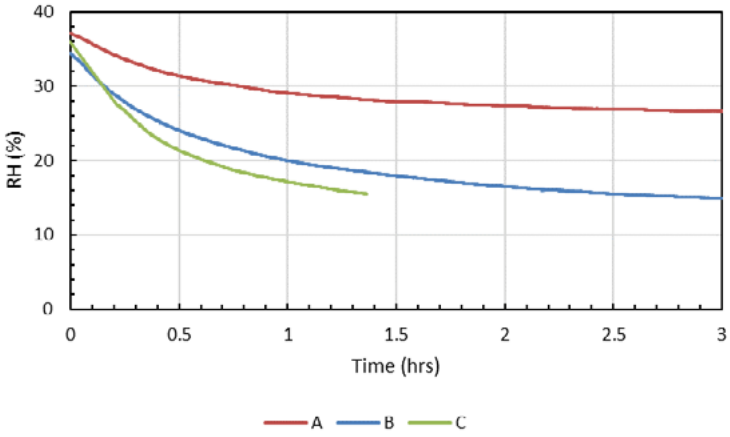

Fig. 4. Humidity control performance of membranes A, B, and C

A cell was run with and without a fan system to determine the improvement to the overall system (Figure 5) [2]. At the low external humidity conditions during testing, 30% RH at 18°C, the moisture transfer rate was 1.65 g/day and 8.5 g/day for the system without a fan and with a fan, respectively. Running solely on moisture available in the air makes this technology simple and compact but does limit the capacity to humidify and dehumidify. Improving the mass transfer of water molecules to the system has shown to improve rates by upwards of 5 times. Any increase in performance equates to a decrease in size, so the improved fan system allows for a 5 times reduction in size, leading to less catalyst and membrane, and makes the electrochemical humidity control system commercially viable.

A similar test was conducted for the humidification at low external humidity conditions, 22% RH at 18°C, and the moisture transfer rates were 1.2 g/day and 1.7 g/day for the system without a fan and with a fan, respectively. Note: at higher humidity conditions the membrane will exhibit a higher conductivity and the moisture transfer rate increases. The increase in humidification is less than that for dehumidification at these reduced moisture levels due to an overall decrease in membrane conductivity; the fan system only improves the performance by around 1.5 times.

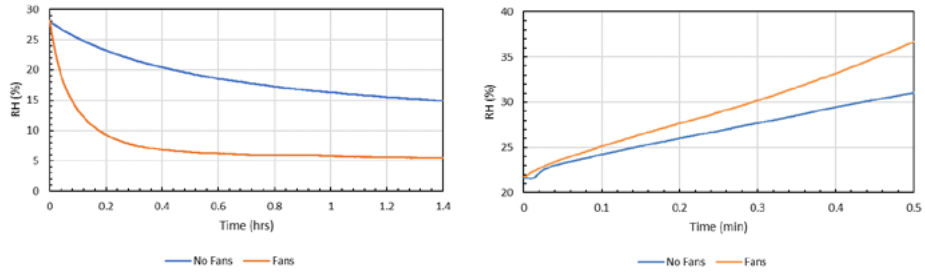

Fig. 5. Results of humidity test

After selecting the appropriate membrane thickness and fan system, the modules were tested in a fridge. Typically, temperature has a negative impact on chemical reactions, so it is essential to prove feasibility at the temperatures experienced in a fridge. As seen in Figure 6, the system was able to both humidify and dehumidify around the humidity level inside the fridge at temperatures between 8°C and -1°C.

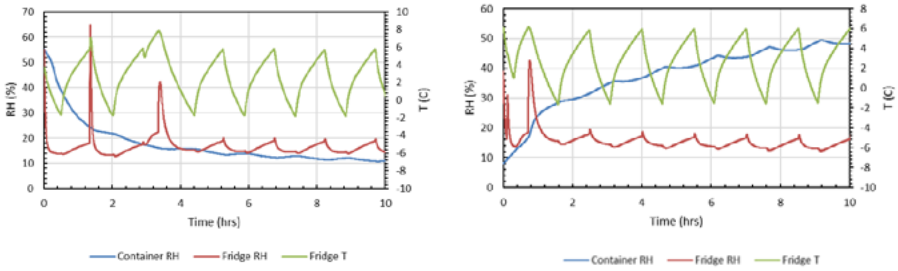

Fig. 6. Dehumidification (left) and humidification (right) testing in a refrigerator

3. Conclusions

Electrochemical cells have successfully been developed and demonstrated to provide both humidification and dehumidification, with the target of improving food preservation and aiding in refrigeration. Performance and cost targets have been met to make this product commercially viable for appliances and reduce the burden for heat pumps used in refrigeration. The proposed system is able to humidify a 35 L enclosure from 30% to 80% RH in less than 3 hrs or dehumidify the same enclosure from 80% to 30% RH in the same amount of time. There are many other applications for this technology including in controlling humidity in museum displays, and moisture/condensation sensitive optics and electronics applications.

Pervaporation Membrane for Refrigerator Vegetable Tray Applications

Jacob Zerby[a], Bamdad Bahar[a*], Anderson Bortoletto[b]

[a] *Xergy Inc. 299 A Cluckey Drive, Harrington, DE 19952*
[b] *Sub-Zero Group, Inc. 4717 Hammersley Road, Madison, WI 53711*

Abstract

Many vegetables produce moisture and need moisture for preservation. Higher relative humidity in the vegetable trays or crisper drawers helps to keep vegetables sturdy and fresh. However, cold surfaces can result in condensation and the presence of liquid water inside the unit. One disadvantage of using heat pumps in refrigerators, it the propensity to develop condensation inside vegetable trays. Approximately 1.3 billion tonnes of food is wasted per year around the world [1], leading to excess energy requirements and greenhouse gas emissions. It is important to control all aspects of spoilage, including food storage during refrigeration. One method to increase the storage time of vegetables is to control moisture inside these trays and reduce dehydration, while preventing condensation, or pooling of water. In this paper we describe a pervaporation method, utilizing advanced composite ionic membranes, to control the humidity levels of a sealed box. The system involves an ultra-thin, ultra-strong, ultra-high-water permeability ionic membrane, with a circulation system for enhanced pervaporation. The system improvements allow for a sealed box, Air Exchange Rate (AER) <0.5/hr, with a large reduction in membrane area and reduced dehydration of food illustrated by reduced fluctuations of the internal relative humidity. Membrane properties, chemistry selection and methods of operation for optimal design of a vegetable tray preservation system with heads of lettuce as the source of moisture. Real life, in-situ performance data is provided.

Keywords: Membrane; Humidity Control; Vegetable Tray; Refrigerator;

1. Main text

1.1. Introduction

During storage of vegetables in vegetable trays, water vapor is released from the vegetables and must be removed at a specified, preferably variable, rate to eliminate condensation and rotting of the produce. Currently, the main method for reducing condensation in a vegetable tray is through an opening that can be manually adjusted to let out water vapor as needed. This requires the customer to adjust the opening on the food being stored and is prone to user error. A smarter, more elegant solution with adaptive moisture transfer rates is required to meet the growing demands of food preservation.

The proposed pervaporative solution, portrayed in Figure 1, allows a pathway for high levels of moisture to diffuse to an environment with less moisture, while cutting off the transport of other gaseous species. Pervaporation through a membrane is the process of a liquid or gas-sorbing onto the feed side of a membrane, permeating through the membrane, and subsequently evaporating off at the permeate side of the membrane. The driving force across the membrane is the concentration gradient, with high humidity inside the tray transferring to the low humidity environment in the refrigerator. The dense membrane only allows the transport

* Corresponding author. Tel.: 1-302-629-5768
E-mail address: bamdad.bahar@xergyinc.com

of polar species through, i.e. water, and acts as a barrier to nitrogen and oxygen. High moisture levels are desirable to maintain the freshness of the vegetable and extend the shelf life, whereas allowing too much water vapor to leave the tray causes the vegetable to dry out and be thrown away. There is a need to remove just enough moisture to prevent condensation, without drying out the vegetables.

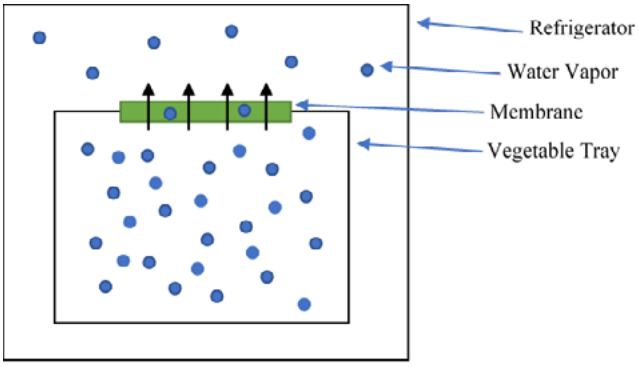

Fig. 1. Diagram of Pervaporative Solution for Humidity Control for Vegetable Trays

1.2. Testing

Initial testing and down selection of membranes was conducting at ambient conditions in the 20 L enclosure, depicted in Figure 2. The room was held around 50% RH and 20°C for all tests. An ultrasonic humidifier was placed in a water bath and plumbed to the box. An air compressor was hooked up to the humidification setup to increase the amount of water vapor entering the box. The humidification system was turned on until the humidity inside the box reached ~90% RH. The test ran until the box hit below 75% RH.

Tests were conducted with and without a fan system to quantify the enhancement to pervaporation.

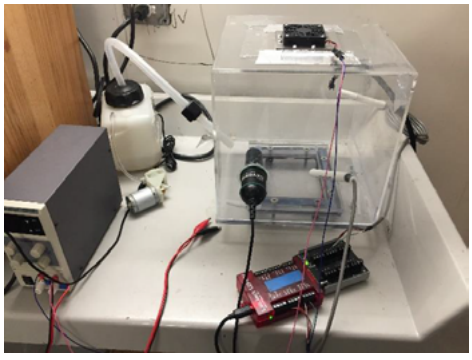

Fig. 2. Membrane Testing Enclosure

1.3. Results and Discussion

The slope of the change in absolute humidity over time was calculated between the range of 85-75% RH and multiplied by the volume of the box, giving the estimated flux rate of the membrane with a box RH of 80% and a room RH of 50%. The following equation was used to calculate the permeance of the membrane:

$$Permeance = \frac{Flux}{(Active\ Area) * (VP_{box} - VP_{ambient})}$$

where the Active Area is the open area of the membrane, VP_{box} is the vapor pressure inside the box (at ~80% RH and ~20°C), and $VP_{ambient}$ is the ambient vapor pressure. Note that the testing methods differ from the ASTM E96; the test method was modified to more closely resemble the actual in application use of the membrane [2]. Instead of maintaining a constant RH in the test chamber, as in the ASTM method, the chamber was charged with an initial 80% RH, which was then allowed to decrease over the period of the test. This batch-like test is reflective of the actual vegetable tray application.

The permeance of the membranes increased with decreasing thickness as expected, as there is less material for the moisture to permeate through. While small changes where not found to have a statistically significant effect on the permeance, as in the range of thickness of membranes B in Figure 3, the permeance of membranes significantly increases with large decreases in thickness, as in membrane A. The best two performing membranes, A and C, are derived from fluorinated ionomers, while membrane B is a non-fluorinated ionomer.

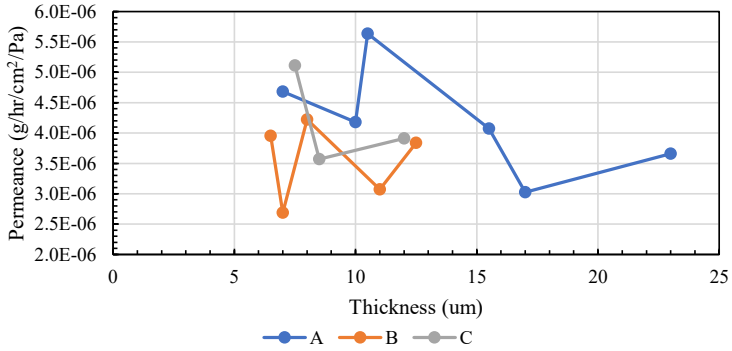

Fig. 3. Permeance of membranes without fan systems

The same test was carried out to analyses various fan systems. As depicted in Figure 4, using a single fan on the inside or outside of the membrane led to a minimal increase in moisture removal rate. However, using a fan on both sides improved the pervaporation by 25x. This suggests that the rate limiting steps are the sorption onto the membrane surface and evaporation from the permeate side, and that they are around the same magnitude and must be addressed simultaneously, as seen in Figure 5. Having such a large increase in performance from the fan system allows for a smarter humidity control system to be used. The fan speeds can be adjusted to adjust the moisture transfer rate based on a sensor in the enclosure; the slower the fan the slower the moisture transfer rate. Employing the fan system is essentially employing a “switch”. By sizing the membrane appropriately, the membrane acts as a poor transmitter of moisture when the fans are off, or a moisture barrier, and rapidly removes humidity when the fans are on the and the membrane is “switched” on.

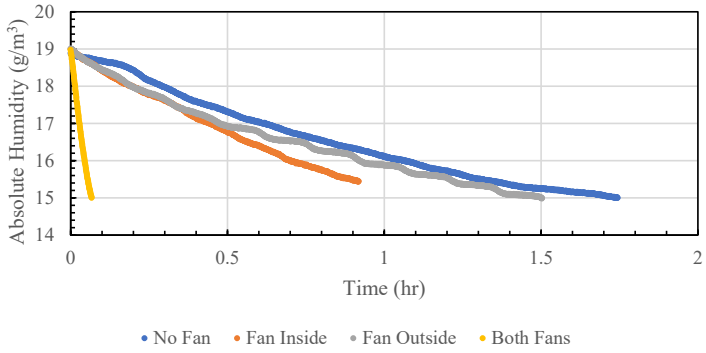

Fig. 4. Results of Fan Configuration Testing

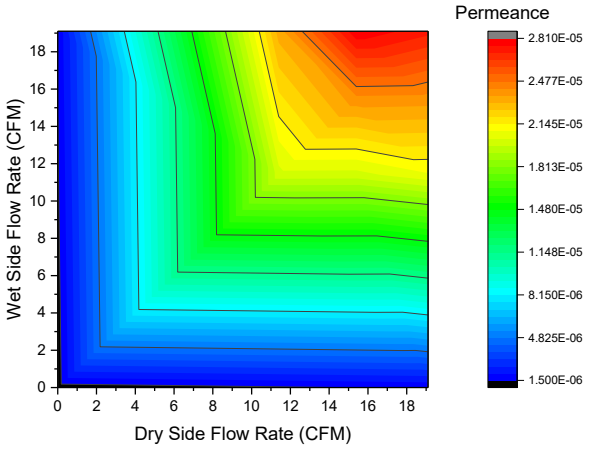

Fig. 5. Results of Flow Rate Analysis

All membranes tested were composite structures, with a base polymer imbibed into a porous support layer. The composite structure allowed for membranes almost 5 µm thick to be evaluated, allowing for high moisture permeance, without sacrificing on the mechanical properties of the membrane. In Table 1, the various support structure-polymer architectures were analyzed, and several (containing Support 1 and 2) were found to have enough mechanical strength for use in a vegetable tray.

Table 1. Mechanical strength of various combinations of base polymer and support material

Architecture	Support 1 – Chemistry 1	Support 1 – Chemistry 2	Support 2 – Chemistry 1	Support 2 – Chemistry 2	Support 3 – Chemistry 2	Support 4 – Chemistry 1
Force (N)	24.76	12.48	6.11	5.57	3.60	1.16
Ultimate Tensile Strength (MPa)	247.6	124.8	58.2	50.6	36.0	11.6

Figures 6 illustrate prototype membrane systems for humidity control for a vegetable tray inside a refrigerator.

Fig. 6. Vegetable Tray with Prototype Membrane System and a fan system (left) and without a fan system (right) Installed for Testing

2. Conclusions

The high permeability and tensile strength of the tested membranes shows strong potential for their application in vegetable trays and crisper drawers. During in-refrigerator application testing, the bulk refrigerated space was found to cycle between 20% and 50% RH. Without a pervaporative membrane the loaded vegetable tray tended have a very high relative humidity, condensing and pooling water. In application, the pervaporative membrane was able to maintain the optimal RH of over 90% without condensation. This system does not have a significant power requirement. The fan system draws 12 V at 0.1 A and the remainder of the system does not draw any power. The fan system can be set to a timer or humidity sensor as a method of controlling the humidity of the tray. Even if the fans ran 24 hours a day, would increase the total daily energy consumption of a typical refrigerator by less than 2%. In the future, thinner membranes and new materials can continued to be explored for higher performance, strength, and permeability.

Abstract

A one-time heating R32 two-stage air source heat pump water heater was experimentally studied under various working conditions, and compared with a static heating type. The tested results show that when the inlet water temperature and the outlet water temperature are fixed, the heating COP is almost unchanged with the increase of the heating capacity; when the heating capacity is fixed, the heating COP decreases with the increase of the inlet water temperature or the outlet water temperature; the condensation temperature of one-time heating type is much lower than that of the static heating type, and also lower than the outlet water temperature. A one-time heating two-stage compression cycle can effectively reduce the discharge temperature and broaden the operating range of the R32 air source heat pump water heater, and improve the reliability of R32 compressor under low ambient temperature and high outlet water temperature conditions.

Keywords: R32; heat pump water heater; one-time heating; static heating

1. Introduction

With the improvement of living standards, the water heater has become an indispensable living facility in people's lives. Air source heat pump water heater (HPWH) is increasingly popular for its energy saving and environmental protection. At present, most of refrigerants for use in the domestic HPWHs are R22 and R134a, and a few R410A. R22 is listed as a phased-out refrigerant for its ODP (ozone depletion potential) above zero, while R134a and R410A acting as transitional refrigerants will be phased out for their relatively high GWP (greenhouse effect potential). R32 is one of components of R410A and is classified as A2L safety class according to the standard ANSI/ASHRAE 34-2013[1]. ODP and GWP of R32 is zero and 675, respectively. A large number of experimental researches and theoretical analyses on R32 and its system have been carried out [2~5]. The results show that R32 is a good alternative refrigerant in terms of climate impact and safety use. Theoretical analysis [2~3] shows that the energy efficiency ratio (EER) of R32 compression cycle is improved by 5.3% and the cooling capacity is improved by 12.7% compared with R410A. Tu et al [4] carried out a drop-in test to compare R32 with R410A in a fixed speed room air conditioner. The results show that the cooling capacity and EER are improved by 8.04% and 3.27%, respectively, under rated cooling condition, while the charge of R32 is reduced by 24%. Mei et al [5] carried out a comparative experimental study on the cycle characteristics of R32 and R410A in air-cooled chillers. The results show that the cooling capacity of R32 is about 10% higher than that of R410A, and EER is slightly increased. Huang et al [6] pointed out that R32 is more suitable for one-time heating HPWH than R410A.

However, the discharge temperature of R32 is about 10~25℃ higher than that of R410A. The high discharge temperature problem is more prominent on R32 HPWH due to its high condensation temperature. The high discharge temperature can cause a series of reliability issues, including accelerating the

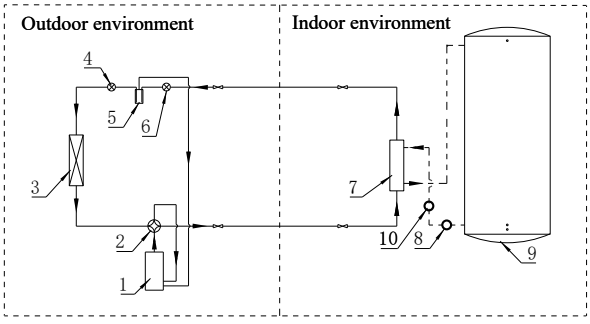
decomposition of lubricant oils, the deterioration of various non-metallic materials in compressor, and the reduction of viscosity of lubricant oil. According to theoretical analysis, when the evaporation temperature is -20℃ and the condensation temperature is 45℃, the discharge temperature can be kept below 135℃ as long as the suction vapor quality of compressor is controlled to 0.93 [7]. That is, the high discharge temperature problem can be solved by reducing the suction vapor quality of the compressor. For two-stage air source HPWH with vapor injection system [8], the high discharge temperature problem can be solved by vapor injection under low ambient temperature.

Reducing the suction vapor quality of the compressor can reduce the discharge temperature effectively. However, the capacity and EER decrease with the decrease of the suction vapor quality of the compressor [9]. If the discharge temperature can be reduced by reducing the condensation temperature, then the high discharge temperature problem of R32 can be solved, moreover the system energy efficiency can be improved.

According to the national standard on HPWH [10-11], the HPWH has three types based on the heating mode, which are the static heating type, the circulating heating type and the one-time heating type. The one-time heating type means that the initial cold water reaches the target water temperature through the heat exchanger of the HPWH once. In this paper, the characteristics of the one-time heating R32 HPWH are researched to provide guidance for design.



2. Experiment and data analysis

2.1. Experiment

The one-time heating R32 HPWH experimental system is shown in Fig.1, which consists of the heat pump system and the water system. The detailed information is shown in Table 1. The heat pump consists of a two-stage rotary compressor, a tube-in-tube condenser, an electronic expansion valve, an evaporator and a flash tank. The water system consists of a water tank, a water pump and the tube-in-tube condenser. Fig.2 shows a cross-sectional view of the tube-in-tube condenser, which is a counterflow heat exchanger and optimized based on the characteristics of one-time heating HPWH and R32 heat transfer characteristics.

The experiment was carried out on the water-enthalpy laboratory, which includes a indoor chamber and an outdoor chamber. The compressor, the evaporator, the electronic expansion valve and the flash tank of the heat pump system were placed in the outdoor chamber, and the water system was placed in the indoor chamber. The tested conditions and water temperature are listed in Table 2.

In the experiment, the inlet water temperature and the outlet water temperature of the tube-in-tube condenser were measured by Pt100, the circulating water flow rate was measured by a magnetic flowmeter, and the pressure and the temperature of the heat pump system were measured by the pressure sensor and T-type thermocouple respectively. The uncertainties of the instruments are listed in Table 3.

Flowmeter	0~30L/min	±0.35%
Pressure sensor	0~5MPa	±0.5%
T-type thermocouple	-50~150℃	±0.5℃

2.2. Data analysis

The heating capacity and the heating COP are calculated based on the parameters of the water, the equations are as follows.

$$Q_w = \rho_w V_w C_{P,w}\left(T_{w,out} - T_{w,in}\right) \quad (1)$$

$$COP = Q_w / W_{input} \quad (2)$$

Where, Q_w is the heating capacity, ρ_w is the density of water, V_w is the water volume flow rate, $C_{P,w}$ is the specific heat of water, $T_{w,in}$ is the inlet water temperature of tube-in-tube condenser, $T_{w,out}$ is the outlet water temperature of tube-in-tube condenser, W_{input} is the input power(including the power of the heat pump system and the power of water pump).

3. Result and discussion

3.1. Characteristics under different conditions

Fig.3 shows the curves that the COP changes with the heating capacity. Under different conditions, the heating capacity has little effect on the COP. Analyses are as follows. The increase of the heating capacity is achieved by increasing the rotary speed of the compressor. As the increase of the rotary speed of the compressor, the refrigerant mass flow rate increases, the heat exchange capacity of the evaporator and the condenser increase. The heat transfer of the refrigerant in both evaporator and condenser enhance due to the increase of the refrigerant mass flow rate increases. The heat exchange temperature difference in both evaporator and condenser increase due to the increase of the heat exchange capacity. Because the inlet water temperature and the outlet water temperature keep constantly, so the condensation temperature increases and the evaporation temperature decreases. But the enhancement of the heat transfer weakens the increase of the condensation temperature. Meanwhile, because the inlet water temperature and the outlet water temperature are fixed, the water flow rate increases with the increase of the heating capacity, which enhances the heat transfer on the water side of the condenser, further suppresses the increase of the condensation temperature. Therefore, the change of the condensation temperature is not obvious. The enhancement of the heat transfer of the refrigerant in the evaporator weakens the decrease of the evaporation temperature, so the change of the evaporation temperature is not obvious. Thus, the change of the pressure ratio is not obvious (Fig.4) and the increase of the specific compression work is not obvious. The change of the temperature and the pressure of the refrigerant at the inlet and the outlet of the condenser are not obvious, so the change of the refrigerant specific enthalpy difference between the inlet and the outlet of the condenser is not obvious. Therefore, the input power of the compressor increases with a definite proportion with the increase of the heating capacity. Because the input power of the water pump is very small in comparison with the compressor, so the change of the COP is not obvious.

Fig.5 and Fig.6 show the curves that the COP changes with inlet water temperature and outlet water temperature. In Fig.5, the COPs decrease with the increase of the inlet water temperature when the outlet water temperature is fixed. Analyses are as follows. The heat exchange temperature difference between the refrigerant and the water of the condenser keeps constantly when the heating capacity is fixed, the average temperature on the water side of the condenser increases with the increase of the inlet water temperature, then the condensation temperature increases (Fig.7), and the COP decreases. In Fig.6, under the same condition, when the inlet water temperature is fixed, the higher the outlet water temperature is, the lower the COP is. For the same reason, the condensation temperature increases (Fig.8) with the increase of the average temperature on the water side of the condenser, then the COP decreases. At the same time, it can be seen that when the outdoor ambient temperature decreases, the influence of the inlet water temperature or the outlet water temperature on the COP becomes smaller.

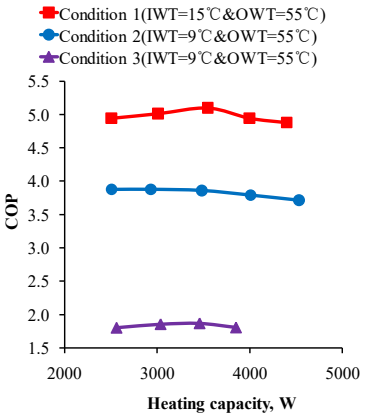

Fig. 3. Curves of the COP with the heating capacity

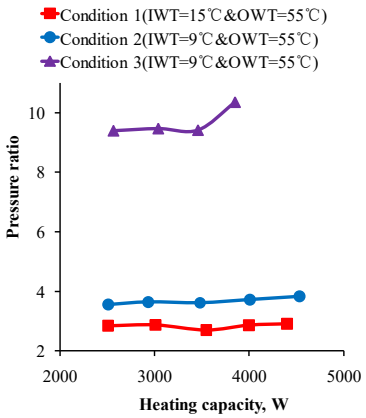

Fig. 4. Curves of the pressure ratio with the heating capacity

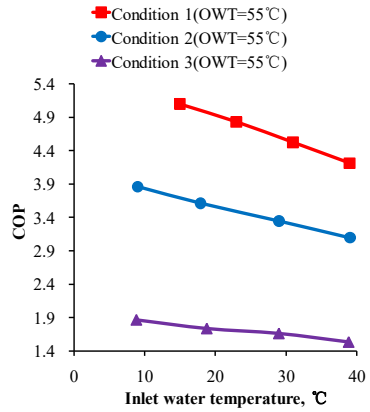

Fig. 5. Curves of the COP with the inlet water temperature

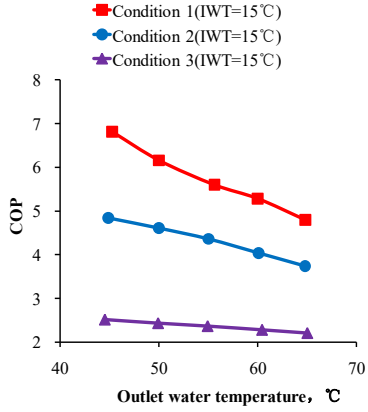

Fig. 6. Curves of the COP with the outlet water temperature

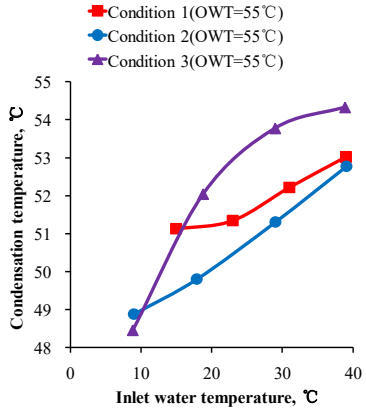

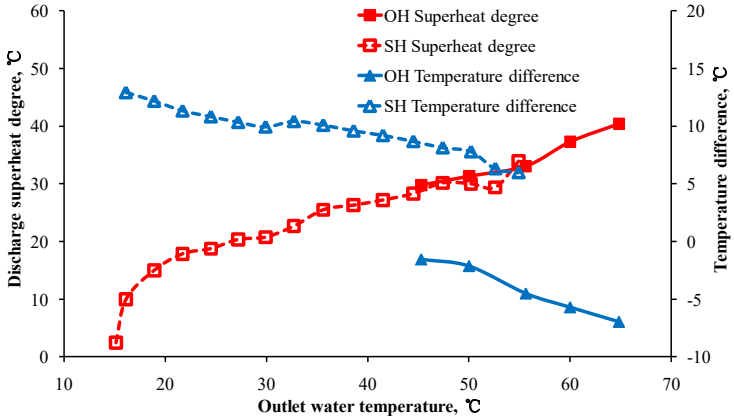

Fig. 7. Curves of the condensation temperature with the water temperature

3.2. Characteristics of system parameters

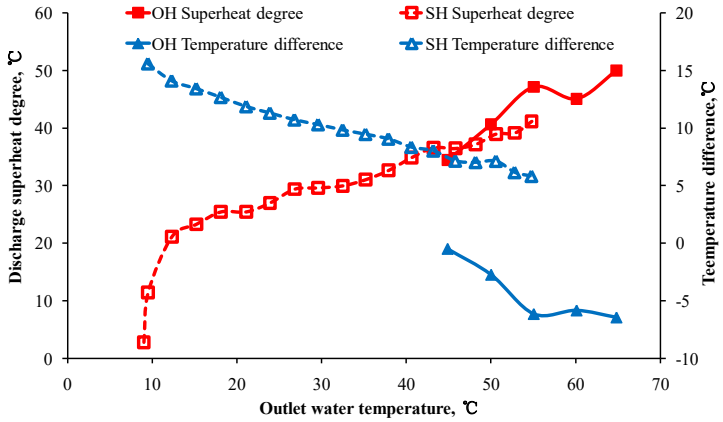

Fig.8 shows the discharge superheat degree (the temperature difference between the discharge temperature and the condensation temperature) and the temperature difference between the condensation temperature and the outlet water temperature changing along with the outlet water temperature under different conditions for the one-time heating(OH in figure) R32 HPWH, and the static heating(SH in figure) R32 HPWH is added for comparison, the discharge temperature curves are shown in Fig.9. For the static heating type, the inlet water temperature means the initial water temperature and the outlet water temperature means the final water temperature. It can be seen as follows.

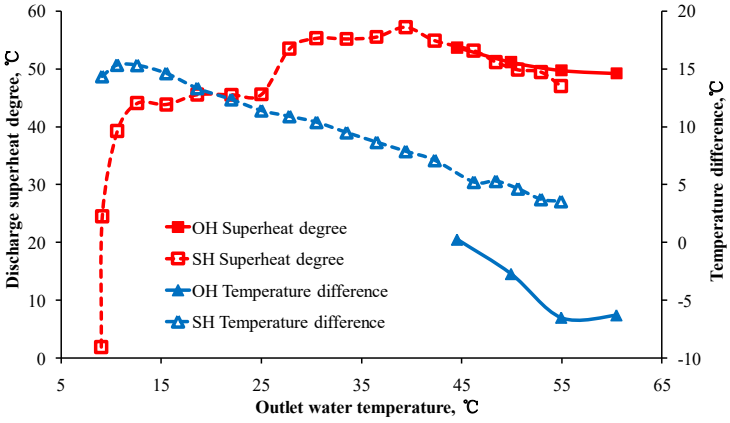
When the discharge superheat degrees are equivalent, the temperature differences between the condensation temperature and the outlet water temperature of the one-time heating R32 HPWH are always less than the static heating type and also less than zero. This indicates that, the condensation temperature of the one-time heating R32 HPWH is much lower than the static heating type and lower than the outlet water temperature. Taking Fig.8(c) as an example, the condensation temperature of the one-time heating R32 HPWH is 10℃ lower than the static heating type, but the discharge superheat degrees of the two types are comparative, that is, the discharge temperature of the one-time heating R32 HPWH is about 10℃ lower than the static heating type. Analyses are as follows. The tube-in-tube condenser is a counter flow heat exchanger, which is helpful to fully utilize the heat of the superheated refrigerant gas to heat the water, so that the target water temperature can be achieved at a condensation temperature lower than the target water temperature. This is very beneficial to reduce the discharge temperature of R32, broaden the operating temperature range, and also increase the COP.



For the one-time heating R32 HPWH under condition 1, as the outlet water temperature increases, the discharge temperature increases, the discharge superheat degree increases and the absolute value of the temperature difference between the condensation temperature and the outlet water temperature increases. This can be explained that, when the outlet water temperature is relatively lower, the condensation temperature is relatively lower, the discharge temperature is relatively lower and the discharge superheat degree is relatively smaller, the heat of the superheated refrigerant gas is not enough to achieve the target water temperature under a relatively lower condensation temperature, so the absolute value of the difference between the condensation temperature and the outlet water temperature is relatively smaller. Along with the increase of the outlet water temperature, the condensation temperature increases, the discharge temperature increases and the discharge superheat degree becomes larger, the heat of the superheated refrigerant gas increases, and so the absolute value of the temperature difference between the condensation temperature and the outlet water temperature increases.

(a) Condition 1 (Inlet water Temperature =15℃)

(b) Condition 2 (Inlet water Temperature = 9℃)

(c) Condition 3 (Inlet water Temperature =9℃)

Fig. 8. Temperature curves of the heating process

For the one-time heating R32 HPWH under condition 3, with the increase of the outlet water temperature, the discharge temperature increases, the discharge superheat degree decreases, and the absolute value of the temperature difference between the condensation temperature and the outlet water temperature increases firstly and then keeps constantly. This can be explained that, the evaporation temperature is very lower and the discharge temperature is very high under low outdoor ambient temperature, when the discharge temperature exceeds the allowable limit value(in this paper, the allowable limit value is 100℃), specific measures must be taken to reduce the discharge temperature, the discharge superheat degree decreases accordingly and the heat of the superheated refrigerant gas decreases. For this reason, no other than to rise the condensation temperature, the target water temperature can be achieved. Thus, the condensation temperature increases with an equivalent value with the increase of the outlet water temperature, and the absolute value of the temperature difference between the condensation temperature and the outlet water temperature keeps constantly.

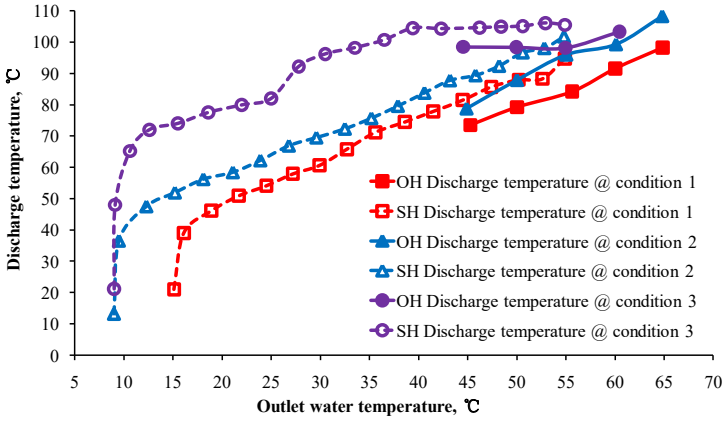


Fig. 9. Curves of the discharge temperature

4. Conclusions

A one-time heating R32 two-stage air source HPWH was experimentally studied under various working conditions, and compared with a static heating type. Conclusions are as follows. For the one-time heating R32 HPWH, the COP is almost unchanged when the inlet water temperature and the outlet water temperature are fixed and the heating capacity increases with the increase of the rotary speed of the compressor; when the heating capacity is fixed, the COP decreases with the increase of the inlet water temperature or the outlet water temperature; when the outlet water temperature is fixed and the discharge superheat degree is comparative, the condensation temperature of the one-time heating R32 HPWH is about 10℃ lower than the static heating type and also lower than the outlet water temperature; under normal temperature conditions, the absolute value of the temperature difference between the condensation temperature and the outlet water temperature increases with the increase of the outlet water temperature; under low temperature conditions, the absolute value of the temperature difference between the condensation temperature and the outlet water temperature increases firstly and then keeps constantly with the increase of the outlet water temperature.

The characteristic of the one-time heating R32 HPWH that the condensation temperature is lower than the outlet water temperature can be fully utilized to reduce the discharge temperature, broaden the operating temperature range and improve the compressor reliability under low ambient temperature and high outlet water temperature.

Optimization of Phase Change Thermal Energy Storage Unit Based on a New Thermal Resistance Model

Lingkun Liu[a], Xiangfei Liang[a,b,*]

[a]Refrigeration Institute of Gree Electric Appliances, Inc.of Zhuhai, Zhuhai 519070, China
[b]National Engineering Research Center of Green Refrigeration Equipment, Zhuhai 519070, China

Abstract

Considering the lack of the heat transfer behavior calculation methods of the phase change thermal energy storage (PCTES) unit, a new comprehensive model based on the effective thermal resistance coupled with heat transfer temperature difference is established and validated by CFD results. The effects of relative physical properties of the phase change material (PCM) and all the configuration parameters of the PCTES unit have been implemented into the model. It is proved that the average heat transfer rate and time duration for the PCM to be fully melt/solidified can be well predicted. To achieve better heat transfer behavior and larger heat storage density with acceptable cost, the optimization of fin-and-tube PCTES unit is established. Based on the average heat transfer rate per unit cost, the recommended structural parameters and PCM properties for PCTES unit are given.

1. Introduction

As a new thermal energy storage medium, phase change material (PCM) has been widely used in energy peak-to-valley transfer, building energy conservation, industrial waste heat recovery, electronic device heat dissipation, etc [1]. Phase change materials are generally classified into low temperature phase change

* Corresponding author. Tel.: +86-756-8589554; fax: +86-756-8668982.
E-mail address: liangxf@cn.gree.com.

materials (less than 80℃), medium temperature phase change materials (80-200℃) and high temperature phase change materials (above 200℃). Medium and low temperature PCMs have been widely used in various thermal energy storage systems [2]. In applications, the thermal performance of thermal energy storage systems is limited by the low thermal conductivity, subcooling and phase separation of PCMs. Fan and Khodadadi [3] summarized the experimental and theoretical approaches of enhancing the thermal conductivity of PCM in past studies. Safari et al. [4] summarized the effects of subcooling on the thermal performance of phase-change energy storage systems, analyzed various methods to improve or control the degree of subcooling, and conducted a method for optimizing the phase-change energy storage system with subcooling. Gunasekara et al. [5] analyzed the phase change properties of PCMs from the perspective of phase diagram based on phase equilibrium theory, and summarized the causes of instability of phase change systems and methods to solve them. In addition to directly improving the performance of the PCM, the optimization of the thermal energy storage device, such as the addition of fins and the improvement of its structure, has also become a research aspect [6]. Chang et al. [7] studied the variation of the heat transfer coefficient outside the small-diameter light tube with different structural arrangements.

For the theoretical and numerical study of the phase change process of PCMs, Neumann [8] obtained the analytical solution of the semi-infinite large plane case by the mathematical method. Subsequent studies have been applied to more complex situations. With the development of numerical methods, various physical models have emerged to replace mathematical analytical solutions, which can be applied to any complex geometric conditions. Voller [9] proposed a melting/solidification model based on a fixed grid method. The energy equation is expressed by enthalpy, and a mushy zone constant is used to solve the momentum transfer near the phase change interface. Further, Chen et al. [10] studied the effect of this mushy zone constant on melting/solidification characteristics and overall heat transfer performance. Meanwhile, various simplified phase-change thermal models have also been applied by various building energy analysis software [11].

When studying a specific type of TES device filled with PCM, the thermal resistance model based on the heat flow is also proposed and improved due to its simplicity and good reliability. Tay et al. [12] proposed a thermal resistance model of a flat fin-and-tube PCTES unit, which splits the heat flow into an isothermal heat flow and a parallel heat flow, and correspondingly establishes the corresponding thermal resistance network. An empirical constant P factor is used to calculate the ratio of the two heat fluxes. The model can be used for thermal resistance analysis and evaluate the efficiency of the heat transfer unit using the Effectiveness-NTU method. Similarly for the flat fin-and-tube PCTES unit, Chen et al. [13] proposed a more concise parallel thermal resistance network model, which approximates the total transferred heat to the heat passing through the solid-liquid interface. This method does not require the P factor, and still possesses small deviations.

The effectiveness of the PCTES unit based on the above thermal resistance model is the integral average of thermal resistance with respect to coordinates. However, due to the complexity of the phase change interface migration, the method of calculating the thermal resistance is not very accurate, and whether its effectiveness can accurately reflect its thermal performance is still a problem [14]. Moreover, the model can not calculate the phase change time and heat transfer rate of the specific TES unit under specific working conditions. In this situation, for the common PCTES unit filled with PCM outside the tube, this work proposes a method for establishing the effective thermal resistance based on Chen's phase interface thermal resistance model, and cooperates with a PCM temperature distribution hypothesis.

2. Physical model

2.1. Basic thermal resistance model of fin-and-tube PCTES unit

The schematic diagram of the structure of the fin-and-tube heat exchanger arranged in a regular triangular cross row is shown in Fig.1(a). Considering the heat flow flowing through a heat storage unit, it can be divided into two paths as shown in Fig.1(b). A part of heat flows from the in-tube heat transfer fluid through the tube wall and the flanged fins into the PCM, and the rest flows through the tube wall and the protruding fins into the PCM [13]. The equivalent thermal resistance network is shown in Fig.2. The expressions of the thermal resistance of each part in a PCTES unit are as follows

$$R_{fluid}=\frac{1}{2\pi r_{in}Lh_{fluid}},\quad R_{tube}=\frac{ln(r_{out}/r_{in})}{2\pi L\lambda_{tube}},\quad R_{collar}=\frac{ln(r_{out2}/r_{out})}{2\pi L\lambda_{collar}},\quad R_{fin}=\frac{ln(r_e/r_{out})}{2\pi\delta_{fin}\lambda_{fin}} \tag{1}$$

$$R_{PCM,1} = \frac{(r_{pci} - r_{out2})/(r_e - r_{out2}) \cdot (F_p - \delta_{fin})/2}{\pi(r_e^{\,2} - r_{out2}^{\,2})\lambda_{PCM}} \tag{2}$$

$$R_{PCM,2} = \frac{ln(r_{pci}/r_{out2})}{2\pi(F_p - \delta_{fin})\lambda_{PCM}} \tag{3}$$

$$R_{PCM\&fin} = \left(\frac{1}{R_{fin} + R_{PCM,1}/2} + \frac{1}{R_{PCM,2}} \right)^{-1} \tag{4}$$

$$R_{total} = R_{fluid} + R_{tube} + R_{collar} + R_{PCM\&fin} \tag{5}$$

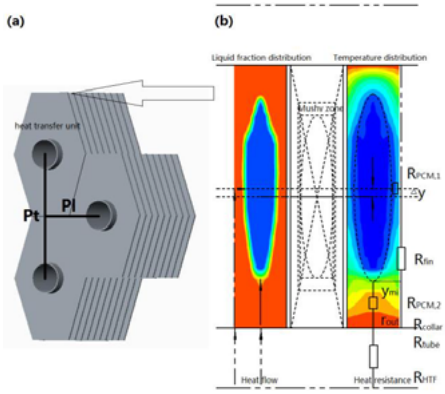

Figure 1 (a) Fin-and-tube heat exchanger structure (b) Fin-parallel cross section between two neighboring tubes of PCTES unit: heat flow paths (left), thermal resistance (right), liquid fraction distribution (left), solid-liquid interface approximation rectangular (middle) and temperature distribution (right)

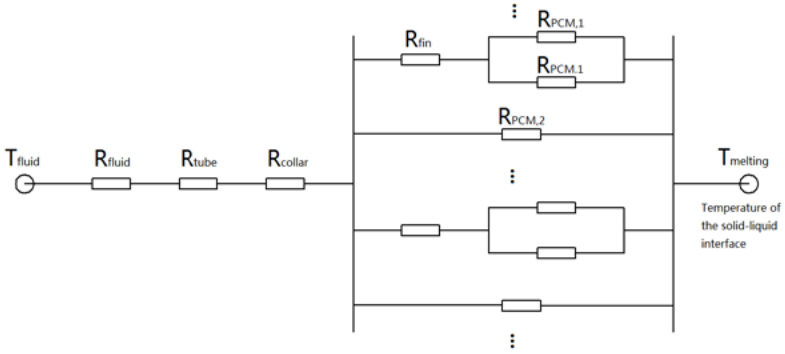

Figure 2 Schematic diagram of the thermal resistance network

In order to calculate the instantaneous heat transfer rate in the whole phase change process, it is also necessary to define the heat transfer temperature difference between the in-tube fluid and the PCM corresponding to the total thermal resistance of the network. The PCM temperature distribution assumption is brought out, where the PCM average temperature in the specific region is used as the PCM side characterization temperature, and the semi-theoretical semi-empirical corrections based on the CFD simulation results are carried out to obtain the outside-tube thermal resistance $R_{PCM\&fin.}$ For the sake of brevity, the following discussion is based on a single PCTES unit, ignoring the finless zone in the TES container.

2.2. Heat transfer temperature difference distribution assumption

The temperature distribution assumptions of the PCM depending on time and space are presented as follows.

(1) As shown in Fig.3(a), the phase change process is artificially divided into two periods noted as p1 and p2, the PCM enthalpy increment in the p1 period includes all sensible heat from the initial temperature to the melting point and partial latent heat. A rough approximation is used for the p1 period: when integrating time, the PCM average temperature and the phase change fraction are assumed to vary linearly with time, and the ratio of their variation rate is set to a constant value.

(2) Fig.1(b) shows the liquid fraction distribution (left side) and temperature distribution (right side) of the intermediate surface between the adjacent fins in the TES unit presented by the CFD simulation result. It is assumed that the temperature distribution law along the tube radial and fin normal direction of the PCM is the same.

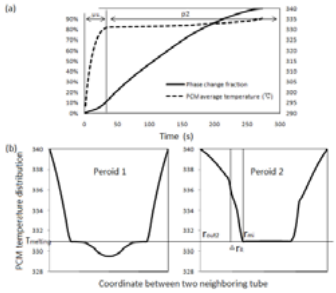

Figure 3 Schematic diagram of the (a) segmentation during a phase change process (b) PCM temperature distribution between neighboring heat transfer unit

(3) As shown in Fig.3(b), it indicates that during the p2 period, the temperature of the non-phase-change region has reached a constant value of $T_{melting}$. And in the already-phase-change region, it suggests that the equivalent PCM thermal resistance layer is thinned due to the temperature of the near-tube region has approached the fluid temperature. The thickness of the effective thermal resistance layer is approximated by an empirical formula:

$$\Delta r_R = m(r_{mi} - r_{out2}) \tag{6}$$

Where r_{mi} is the coordinate of the mushy zone inner interface, r_{out2} is the coordinate of outer wall of the fin flange and m is an empirical constant. In the region of r_{out2} to r_{mi}–Δr_R, the temperature is assumed to be equal to the fluid temperature T_f, and in the region *of* r_{mi}–Δr_R, the temperature distribution is

$$T(r) = (T_f - T_{melting})\frac{r - r_{mi}}{m(r_{out2} - r_{mi})} + T_{melting} \tag{7}$$

From the assumption (2), the average PCM temperature of the region corresponding to the effective thermal resistance is the expression of r_{mi}, denoted as $T_{eff}(r_{mi})$. Record the heat transfer temperature difference as $\Delta T_{eff}(r_{mi}) = T_f - T_{eff}(r_{mi})$, expressed by

$$\Delta T_{eff}(r_{mi}) = \frac{T_{melting} \cdot \pi(r_e^{\,2} - r_{mi}^{\,2}) + \int_{r_{mi}-\Delta r_R}^{r_{mi}} T(r) \cdot 2\pi r dr}{\pi[r_e^{\,2} - (r_{mi} - \Delta r_R)^2]} \tag{8}$$

2.3. Correction of thermal resistance outside the tube

The correction of the outer side thermal resistance from Eq.(4) includes these aspects: mushy zone correction; effective PCM thermal resistance layer correction; effective fin thermal resistance correction; TES unit shape correction; phase interface migration correction.

(1) Mushy zone correction

As shown in Fig.1(b), due to the amorphous nature of the specific PCM, resulting in a thin-layer solid-liquid interface instead of a sharp interface. In a common used solid-liquid phase enthalpy model [9], a mushy zone constant A_{mush} is used to reflect its amorphous nature. To describe this feature, a mushy zone shaped as a thin layer with the linearly distributed liquid fraction is established. The thickness of the mushy zone is described by the following correlation:

$$\Delta r_{mush} = n(r_{mi} - r_{out2}) \tag{9}$$

n is mainly affected by the mushy zone constant (which can be considered as a PCM inherent physical property) and viscosity. The data is fitted to the following relationship by CFD simulation results.

$$n = 0.5\left(A_{mush}^{\,1/3} \cdot \mu\right)^{-0.5} \tag{10}$$

Thus, the expression of the total phase change fraction of the PCM with respect to the interface coordinates r_{mi} in the mushy region can be obtained as $\gamma(r_{mi})$. Note that when the mushy zone advances to the boundary of the TES unit, the expression changes.

(2) Effective PCM thermal resistance layer correction

This correction has been described in Section 2.2. The two local thermal resistances corrected are

$$R_{eff,PCM,1}(r_{mi}) = \frac{\Delta r_R/(r_e - r_{out2}) \cdot (F_p - \delta_{fin})/2}{\pi(r_e^{\,2} - r_{out2}^{\,2})\lambda_{PCM}} \tag{11}$$

$$R_{eff,PCM,2}(r_{mi}) = \frac{ln[r_{mi}/(r_{mi} - \Delta r_R)]}{2\pi(F_p - \delta_{fin})\lambda_{PCM}} \tag{12}$$

(3) Effective fin thermal resistance correction

The fin thermal resistance calculated from Eq.(1) is the annular thermal resistance from the fin base to the fin tip, but the heat flow is through the side face of the fin. Thus the fin thermal resistance needs to be corrected. Assuming that the fin temperature distribution is linearly distributed in the radial direction, find the radial coordinate where the fin temperature is the mass average fin temperature. The annular thermal resistance from the fin base to the calculated coordinate is considered as the effective fin thermal resistance. Simplified expression is

$$R_{fin}=\frac{ln(r_e/r_{out2})}{2\pi\delta_{fin}\lambda_{fin}}\left(\frac{r_e^2}{r_e^2-r_{out2}^2}-\frac{1}{2ln(r_e/r_{out2})}\right) \quad (13)$$

(4) PCTES unit shape correction

As shown in Fig.4, the PCTES unit is divided into hexagons, since there is no analytical expression for the irregular hexagon shape factor, it is convenient to use the approximate ellipse to characterize the shape of PCTES unit. Its long and short axes are of a=2/3P$_l$ (horizontal direction) and b=1/2P$_t$ (gravity direction). It is assumed that the phase interface is from the outer wall of the tube at the beginning of the phase change, and gradually migrates to the end of the ellipse shown in Fig.4.

(5) Phase interface migration correction

As shown in Fig.4, due to the difference between solid and liquid density and natural convection, the low-density phase moves upward and the high-density phase moves downward, causing the overall migration Δy of the phase interface in the direction of gravity, mainly affected by the difference in solid-liquid density and PCM liquid viscosity. Fitting the CFD simulation results into a correlation:

$$\Delta y=(y_{mi}-y_{out2})[1-exp(-l\frac{\Delta\rho}{\mu})] \quad (14)$$

Where $\Delta\rho$ is the PCM density difference between solid and liquid phases in unit of kg/m^3, μ is the PCM liquid dynamic viscosity in unit of kg/m.s and l is an empirical constant.

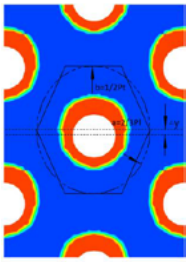

Fig.4 Schematic diagram of PCTES unit shape correction

So far, the total thermal resistance based on the effective PCM thermal resistance layer is obtained with respect to the boundary coordinate r of the mushy zone, and is denoted as $R_{eff,total}(r_{mi})$. The calculation of the instantaneous heat transfer rate can be done with the help of the previously obtained $\Delta T_{eff}(r_{mi})$ and $\gamma(r_{mi})$.

First, the total time of the phase change process is calculated by integration. The total enthalpy change of the PCM in each infinitesimal element period is equal to the total heat it receives:

$$t=\int_{t1|\gamma=\gamma1}^{t2|\gamma=\gamma2}dt=M_{PCM}\int_{\gamma=\gamma1}^{\gamma=\gamma2}\frac{C_p\cdot d\Delta T+LH\cdot d\gamma}{\Delta T_{eff}/R_{eff}}=M_{PCM}\int_{y_{mi2}|\gamma=\gamma1}^{y_{mi1}|\gamma=\gamma2}\frac{C_p\frac{\partial\Delta T}{\partial y_{mi}}+LH\frac{\partial\gamma}{\partial y_{mi}}}{\Delta T_{eff}/R_{eff}}dy_{mi} \quad (15)$$

Where y_{mi1} and y_{mi2} are interface coordinates in the y-direction mushy region corresponding to the phase change fractions γ1 and γ2 based on the expression of $\gamma(r_{mi})$. Similarly, the PCM average temperatures T1 and T2 corresponding to the phase change fractions γ1 and γ2 can be calculated from $T(r_{mi})$. Then the total transferred heat and average heat transfer rate of the considered process are

$$Q_{total}=M_{PCM}[C_p(T2-T1)+LH(\gamma2-\gamma1)] \quad (16)$$

$$P_{ave} = Q_{total} / t \tag{17}$$

Similarly, the time average of the effective heat transfer temperature difference and the effective thermal resistance can be integrated.

$$R_{eff,ave} = \int_{t1|\gamma=\gamma1}^{t2|\gamma=\gamma2} R_{eff}(y_{mi})dt \Big/ t \tag{18}$$

$$\Delta T_{eff,ave} = \int_{t1|\gamma=\gamma1}^{t2|\gamma=\gamma2} \Delta T_{eff}(y_{mi})dt \Big/ t \tag{19}$$

2.4. Model Validation

The CFD simulation on the fin-and-tube PCTES unit is as shown in Fig.6, the calculation domain includes the solid fin region and the solid-liquid PCM phase change region. The two regions are thermally coupled to each other, the upper and lower boundaries are periodic, and the left and right boundaries are symmetrical. Melting/solidification model is adopted and UDFs are used to set the changeable physical parameters. A series of non-steady-state phase change processes are simulated to fit the required empirical coefficients and relationships in this paper. After that, simulation results under arbitrary parameters and working conditions are used for the validation. The deviation between the CFD simulation and the model is shown in Table 1.

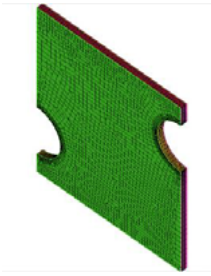

Fig.5 Mesh grid diagram of PCTES unit for CFD simulation

Table 1. Deviation between calculation model and CFD simulation results

		φ7 tube		φ6 tube	
		$\Delta T_{heating}$= 9K	$\Delta T_{heating}$= 6K	SAT	Paraffin
Phase change completed time-consuming (s)	CFD results	191	273	100	52.7
	Model results	198.42	279.53	100.21	51.20
	Deviation	3.88%	2.39%	0.21%	-2.85%
Average heat transfer rate (W/m^3)	CFD results	2.474E+06	1.700E+06	4.619E+06	3.662E+06
	Model results	2.468E+06	1.724E+06	4.781E+06	3.752E+06
	Deviation	-0.24%	1.41%	3.51%	2.46%

It can be seen that the model can accurately predict the heat transfer performance for different heat transfer conditions with variable structure parameters and PCM types. The deviation of the average heat transfer rate between the model results and CFD results is below 4%. It can be considered that the performance of the fin-and-tube PCTES calculated by this model is with enough accuracy and versatility.

3. PCTES unit structure parameters optimization

The thermal performances of the PCTES unit for the fin-and-tube under a constant wall temperature boundary condition are investigated. The focused performances are as follows: the PCTES unit cost C (RMB/m^3), the latent heat storage density (MJ/m^3) of the TES unit, and the average heat transfer rate P_{ave} (W/m^3) during the whole phase change process.

The latent heat storage density = PCM density × PCM volume fraction in the PCTES unit × PCM melting enthalpy

The PCTES unit cost = Tube cost + Fin cost + PCM cost

The average heat transfer rate = Total amount of transferred heat / Time-consuming during the whole phase change process

The latter two are combined to form a new performance that reflects the unit cost performance of the TES unit: heat transfer rate per unit cost = P_{ave}/C (W/RMB).

Table 2 shows the fixed parameters, the reference structure parameters and heat transfer conditions for the discussed fin-and-tube PCTES unit.

Table 2. Parameters set for the fin-and-tube PCTES unit calculation

Copper tube specifications	φ7(54g/m)	φ5(34.2g/m)	φ4(24.6g/m)
Reference structure parameters (mm)	Pt=22, Pl=19.05	Pt=19.05, Pl=16.5	Pt=14.7, Pl=13.8
	Fp=1.7, δ_{fin}=0.105	Fp=1.4, δ_{fin}=0.105	Fp=1.3, δ_{fin}=0.105
Working conditions	PCM initial temperature 15℃, $\Delta T_{heating}$= 9℃		
Material price (RMB/kg)	Copper (tube material): 50; Aluminum (fin material): 16;		
	PCM: Sodium acetate trihydrate (SAT): 5; Paraffin: 4；		

For the fin-and-tube, the change of structural parameters has much greater influence on the heat transfer rate than the energy storage density. Therefore, the influence on heat storage density is ignored. The heat transfer rate per unit cost under various structural parameters of different tube diameters is shown in Fig.6-8. The x, y, and z axes respectively represent the change of the transversal tube pitch, the longitudinal tube pitch, and the fin pitch of the PCTES unit structure, the pentagonal point is a commonly used structure. Each colored surface represents structural parameter combinations that possess the equal heat transfer rate per unit cost. The right side box compares the heat transfer rate per unit cost when the two PCMs are used under the reference structure at pentagonal point.

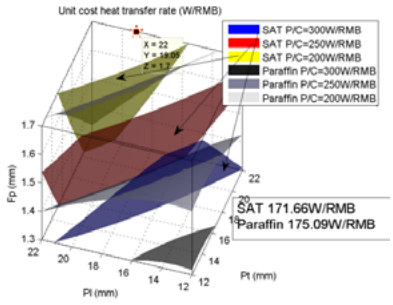

Figure 6 φ7 fin-and-tube PCTES unit cost performance with structural parameters

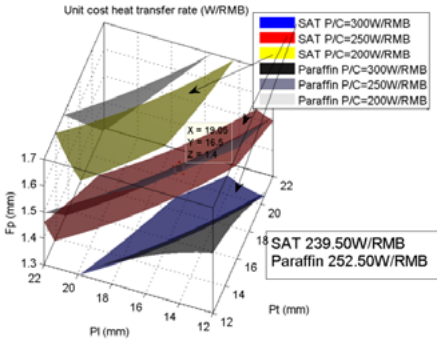

Figure 7 φ5 fin-and-tube PCTES unit cost performance with structural parameters

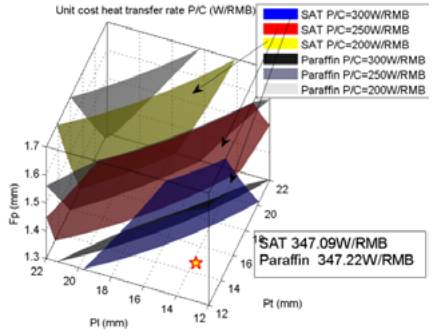

Figure 8 φ4 fin-and-tube PCTES unit cost performance with structural parameters

It can be seen that, the smaller the tube pitch and the fin pitch, the higher the heat transfer rate per unit cost. The influence of the transversal and longitudinal tube pitch is similar, and simultaneously reducing the transversal and longitudinal tube pitch is better than reducing only one of them. In the case of a large tube pitch, the fin pitch variation within the range of the figure has little effect on the heat transfer rate per unit cost, which is due to the effective fin thermal resistance expression of the annular fin thermal resistance in the equation (13). As the heat transfer unit characteristic radius re increases, it increases sharply and will dominate the thermal resistance outside the tube.

It can be seen that for paraffin and SAT used as PCM, the heat transfer rate per unit cost is very close to each other under the PCTES structure at pentagonal point. The decline in performance due to the low thermal conductivity and high viscosity of paraffin is compensated by its low mushy zone constant and low cost. But it should be noted that in terms of heat storage density, SAT is about (264*1300)/(168*830)=2.46 times of paraffin. Generally, the higher the thermal conductivity of PCM, the lower the viscosity, the stronger the amorphous and the larger the ratio of latent-sensible heat, the better the average heat transfer rate of the PCTES unit.

It can also be seen from the figure that the dependency of heat transfer rate per unit cost on the fin pitch is more obvious for paraffin than SAT. When the fin pitch is greater than 1.5 mm, the P/C=300 surface shrinks sharply inward, that is, with the increase in film distance, the heat transfer rate per unit cost drops dramatically. It can be explained that when the PCM thermal conductivity is low, and the $R_{PCM,1}$ and $R_{PCM,2}$ in the outside-tube thermal resistance of Eq.(4) occupy a larger proportion. After the fin pitch increases to a certain extent, the outside-tube thermal resistance increases sharply, causing the overall performance deteriorates drastically.

When the PCM is SAT, the heat transfer rate per unit cost of the φ7, φ5 and φ4 fin-and-tube PCTES units is 172W/RMB, 239W/RMB and 330W/RMB, respectively. It indicates that the unit cost performance will increase with the decrease of the tube diameter. And there is a similar increase when the PCM is paraffin.

Therefore, in the currently used size range of fin-and-tube heat exchangers, when used as a PCTES container, smaller diameter should be selected.

4. Conclusion

A physical model based on the thermal resistance network that can be used for the non-steady state heat transfer calculation of the PCTES unit is established. The model can predict average heat transfer rate under different structural parameters, heat transfer conditions and PCM types with high accuracy. The following conclusions can be summarized:

(1) The model extends the conventional thermal resistance analysis methods of PCTES unit, making the model available for the calculation of actual heat transfer rate. Further, it has small deviation from CFD simulation results and high computational efficiency, and can be used for multi-dimensional multi-objective optimization of PCTES unit.

(2) In the structural parameters range of fin-and-tube PCTES unit currently used, the smaller the tube pitch and the fin pitch, the higher the heat transfer rate per unit cost. The heat transfer rate per unit cost of φ4, φ5 and φ7 fin-and-tube PCTES unit is 172W/RMB, 239W/RMB and 330W/RMB, respectively. Therefore, for the 4-10 mm tube diameter range of fin-and-tube heat exchangers, when used as a PCTES container, structure parameters with smaller diameter should be selected.

(3) In the case of a large tube pitch, the fin pitch variation within the range of 1.3-1.7mm has little effect on the heat transfer rate per unit cost. And its dependency on the fin pitch is more sensitive for the PCM with low thermal conductivity than that with high thermal conductivity. For paraffin and SAT used as PCM, the heat transfer rate per unit cost is coincidentally very close to each other under several commonly used PCTES structure.

Study on the smart operation approach of an air conditioner when occupants go out

Myung Sup YOON[a,*], Won Sik YOON[a]

[a]Energy Technology Center, Korea Testing Laboratory, 87 Digital-ro 26-gil, Guro-gu, Seoul, 08389, Republic of Korea

Abstract

This study demonstrates how to use an inverter air conditioner more effectively when a room is not occupied for a relatively short period of time (2 ~ 3 hours). We directly employed environmental changes (outdoor temperature, indoor building load) during daytime in a qualified test room with specific dimensions. The energy consumption of three behavioral cases was compared under several experimental simulation conditions. The first case involved turning on the air conditioner steadily using the same setting temperature without touching even if no occupants. The second involved turning off the air conditioner while occupants were out and restoring the set temperature rapidly after their return. The third case involved an artificial set temperature adjustment while occupants were out. Using several climate and building load data of Korea and the Middle East, the three air conditioner operation approaches were analyzed while occupants were out. Results showed that the first and third operating cases were energy saving depending on the environmental conditions. These results can be used for the design of smart air conditioners or policy guides for nationwide energy saving.

Keywords: Inverter air conditioner; Smart operation; Going out time operation; Energy saving; Smart home appliances

1. Introduction

According to IEA data [1], the number of air conditioners per population in homes is close to 90% in Japan, the United States, and Korea. Unexpectedly, however, the air conditioner penetration rate is presently low in many hot parts of the world (Saudi Arabia (~ 60%), China (~ 60%), Brazil (~ 15%), Mexico (~ 15%), Indonesia (~ 10%), South Africa (~ 10%), and India (~ 5%)). Therefore, this report predicts that energy consumption for space cooling will increase to nearly 40% by 2050 if no action is taken, due to the increase of air conditioners in the above developing countries.

In order to reduce the use of electricity caused by the increase of air conditioners, it is important for manufacturers to develop high-efficiency air conditioner products and for consumers to operate them efficiently. For some time, a lot of research has been undertaken to increase the efficiency of air conditioners. In particular, the efficiency of each component (e.g., compressor, heat exchanger, fan, valve, etc.) constituting an air conditioner can be improved to increase the efficiency of the final product [2,3]. Over the past 20 years, inverter compressors and vapor injection technology have been used to improve product efficiency [3,4]. In the future, technologies such as high-efficiency refrigerants, multi-stage cycles, and human recognition sensors are expected to be used widely [5–7].

Consumers are also required to take action to save air conditioner energy, such as by purchasing high-efficiency products referring to energy labels, refraining from open-door cooling, and maintaining proper room temperature. One of the important questions related to the third area is how to operate an air conditioner while occupants are out. Is it good to turn off an air conditioner when occupants go out? If the going out time is long enough, such as one day, cooling supply energy is not necessary, but if the going out time is short, as in a few

* Corresponding author. Tel.: +82-2-860-1555 ; Fax: +82-2-860-1559
E-mail address: msyun95@ktl.re.kr

hours, we need to worry about what to do with the air conditioner. This was not a problem in the past when air conditioner control technology was not very sophisticated and the thermal insulation of a typical home was poor. However, if it is possible to precisely control the part-load of the cooling capacity of an air conditioner and offer good insulation conditions such as in a zero-energy building, careful research on the approach to air conditioner operation is necessary. When operating an inverter compressor, in order to save energy by the efficient low-speed driven compressor, it may be better to set the temperature slightly higher than the ordinary set temperature while an occupant is out, rather than turning it off when going out and turning it on again rapidly after returning home. In particular, if IoT or AI technology is further developed, it will be driven automatically by using real-time weather status, weather forecast, and occupant status information without worrying about energy saving.

With this in mind, the present study experimented with various operation conditions to discover the energy saving effect of an inverter air conditioner according to the operation approach of an air conditioner during occupants' absence.

2. Experimental Approach

2.1. Preliminary work

It is well known that inverter air conditioners have a higher operating efficiency than constant speed air conditioners. However, even if an air conditioner uses inverter compressor technology, an efficiency difference between inverter products may occur due to the performance difference in an inverter compressor and control technology depending on the manufacturer and model of the product. Figure 1 shows the operation of three different inverter air conditioner models when the remote controller's set temperature is maintained at 26°C. Under the same time-dependent outdoor temperature and indoor building load condition during the day, the change in room temperature and power input shows different patterns.

If it is an ideally designed product, the room temperature should remain constant at a set temperature of 26°C, and the instantaneous power input should have a smooth, cubic function curve with a peak at 16:00 and a minimum at 06:00, following the same building load or outdoor temperature variation patterns. The exact design specifications and technology of the products are unknown, but Fig. 1 shows the desirable control pattern toward the right in the order of (a), (b), and (c). In the case of (a), the power input and room temperature vary largely in all regions of the graph. In (b), there are large deviations of power input and room temperature under large building load and high outdoor temperature (12:00 – 14:00) regions. A near ideal product case is (c), which has a small variation in room temperature and the smoothest change in power consumption among the three cases.

Although it is difficult to state directly what the quantitative energy saving effects between the products are because of the different product specifications (such as the rated capacity and rated power consumption of the three products), it can be reckoned that case (c) is the most energy efficient case judging by the simple insight. Therefore, the product corresponding to Fig. 1(c), which allows precise control, was selected and experimented with throughout this paper. Details of the specifications are in Table 1.

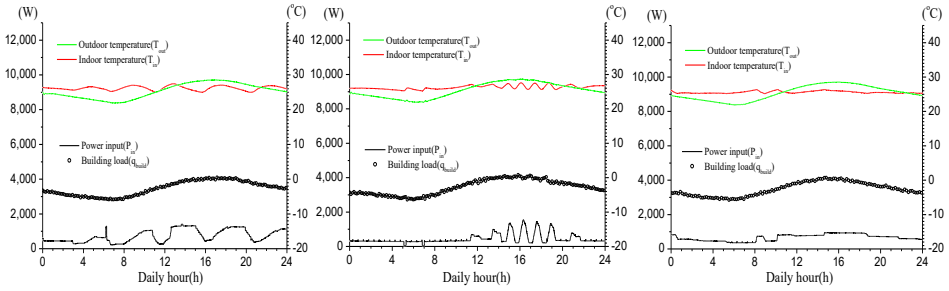

Fig. 1. Improvements in the control aspects of an inverter air conditioner ((b) is reproduced from Yoon et al [8,9])

Table 1 Specifications of the tested inverter product

Contents	Specification
Electricity	220 V, 60 Hz
Rated cooling capacity	7 000 W
Rated power input	2 010 W
Middle cooling capacity	4 700 W
Middle power input	1 250 W
Minimum cooling capacity	1 600 W
Minimum power input	330 W
Refrigerant	R410a
Product type	Floor stand split type

2.2. Problem set up

In this study, three behavior cases of air conditioner operation while occupants were out were experimentally set up, as shown in Fig. 2. In the first case, the air conditioner was operated without being turned off regardless of occupants' going out for a few hours. In the second case, the air conditioner was turned off when occupants went out and was turned back on to the target temperature immediately after returning home. In the third case, the air conditioner's compressor ran at low speed at a slightly higher set temperature and was activated again to reach the target temperature just before occupants returned.

If we go out for a day or for a few days, turning off air conditioners in uninhabited spaces is a good thing. However, if we need to go out for a short time (a few hours), we should consider whether to turn on (case 1) an air conditioner or not (case 2). And if an air conditioner can automatically adjust the temperature, it is also possible to raise the set temperature slightly while occupants are absent and return the temperature before they come back (case 3). These three behavioral cases were experimented with under the various climate environments of Table 2.

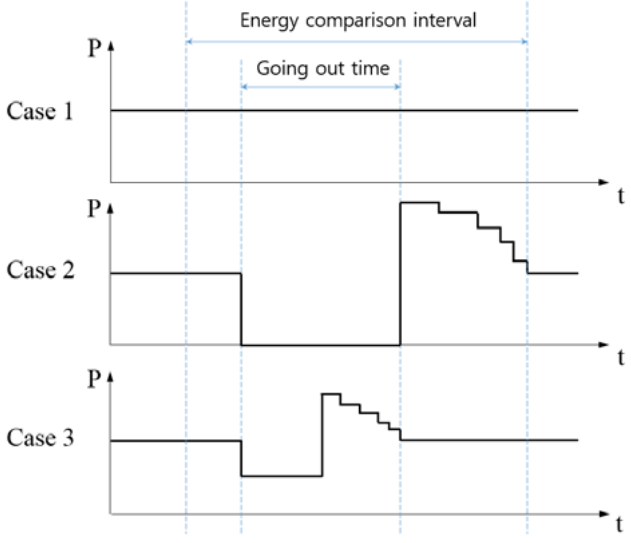

Fig. 2. Energy consumption comparison concept

Table 2 Comparison environments

	Climate condition	Behavioral case	Going out time	Total test time	Energy comparison interval	Remarks (Case 3 artificial T_{set} operation)
Env. 1	Middle East (October)	Case 1	12:00 ~ 14:30	10:00 ~ 23:00	12:00 ~ 22:00	~ 12:00 (T_{set} = 26°C)
		Case 2				12:00 ~ 14:00 (T_{set} =27°C)
		Case 3				14:00 ~ (T_{set} =26°C)
Env. 2	Seoul (August)	Case 1	12:00 ~ 15:30	Same as above	Same as above	~ 12:00 (T_{set} = 26°C)
		Case 2				12:00 ~ 14:30 (T_{set} =28°C)
		Case 3				14:30 ~ (T_{set} =26°C)
Env. 3	Seoul (August)	Case 1	12:00 ~ 15:30	Same as above	Same as above	~ 12:00 (T_{set} = 26°C)
		Case 2				12:00 ~ 15:00 (T_{set} =27°C)
		Case 3				15:00 ~ (T_{set} =26°C)
Env. 4	Middle East (April)	Case 1	12:00 ~ 15:30	Same as above	Same as above	~ 12:00 (T_{set} = 26°C)
		Case 2				12:00 ~ 15:00 (T_{set} =27°C)
		Case 3				15:00 ~ (T_{set} =26°C)
Env. 5	Middle East (October)	Case 1	14:00 ~ 16:30	Same as above	Same as above	~ 14:00 (T_{set} = 26°C)
		Case 2				14:00 ~ 16:00 (T_{set} =27°C)
		Case 3				16:00 ~ (T_{set} =26°C)

The going out time started at midday, except for Environment 5 (14:00), and the duration of the going out time was set to 2.5 (Env. 1 and 5) or 3.5 hours (Env. 2 ~ 4). Three climate conditions were used for the outdoor temperature and indoor building load, as in Fig. 3. The total test time during the day was 13 hours from 10 to 23 h, but the power consumption from 12 to 22 h was calculated to compare at the same room temperature conditions (26°C) of the start and the end between cases 1, 2, and 3 (energy comparison interval of Fig. 2).

Inverter air conditioner compressors improve efficiency at minimum operation [4], so it is important to identify what the effect is of increasing the remote control set temperature slightly during a short period of non-occupancy, as long as it has the 26°C room temperature again at the moment of occupants' return. Throughout the test environments of case 3, T_{set} was raised to 27 or 28°C during the going out period, and the T_{set} was adjusted again to 26°C a few minutes before occupants returned home (remarks of Table 3).

TRNSYS simulation was used to generate the test environments of the outdoor side temperature ($T_{out}(t)$) and indoor side building load ($q_{build}(t)$). The same methodology was used as previous studies [8,9]. In previous studies, the building load ($q_{build}(t)$) was determined under the condition that the interior room temperature was constant at 26°C. Although this hypothesis does not exactly fit behaviors 2 and 3 in this study, behavior 3 would not have a significant effect because the difference between the indoor target temperature and the instantaneous temperature is within 2°C.

Table 3 TRNSYS simulation conditions in Seoul and the Middle East [8,9]

Input variable	Seoul	Middle East
Space size (single zone)	10m × 8m × 2.5m	10m × 8m × 2.5m

3. Results and Discussions

3.1. Environment 1 results

This is the climate case of October in the Middle East. For case 3, T_{set} was adjusted to 26 → 27 → 26 °C, as in the remarks of Table 2. For case 1 in Fig. 4, even if T_{set} is kept at 26°C, the power consumption of case 1 shows a parabolic shape from 12 h to 22 h with a maximum value at the vicinity of 16 h. This power input variation is due to the variations of the T_{out}(t) and q_{build}(t) during the day. In general, the instantaneous power input of the air conditioner is proportional to the compressor operation rate according to the outdoor side temperature and the internal building load (Figs. 1(c) and 4(a)). In case 2, the power input is zero during the going out time because the air conditioner is turned off, and the indoor temperature soars due to the heat of the building load. Even though the external outdoor temperature reaches up to 35°C (Fig. 3), the internal indoor temperature rise to close to 45°C is somewhat unrealistic and seems to be overestimated even when explained by radiative heat transfer through windows. This is due to the assumption of a constant indoor temperature of 26°C when simulating TRNSYS (Table 3). Because the heat intrusion from the outside of the building is qualitatively proportional to the temperature difference between the outside and the indoor temperature, that is, $q_{build} \sim (T_{out} - T_{in})$, the q_{build}(t) graph of Fig. 3 is overestimated when it assumes constant indoor temperature of 26°C. For accurate quantitative assessments in the future, instantaneous TRNSYS simulations are required to take into account changes in the indoor room temperature (T_{in}(t)) caused by the air conditioner test sample.

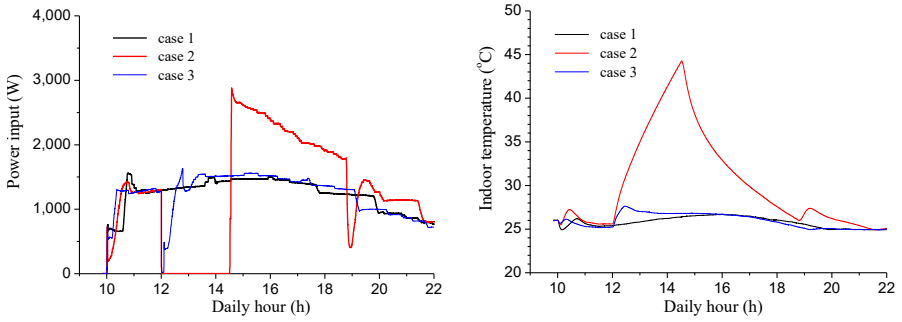

Fig. 4. Power consumption and indoor temperature variation (Environment 1)

In case 3 (blue line), during the non-occupancy period, less power is consumed than case 1 (black line), and the total final power consumption for the energy comparison interval is lowest in case 3 (12 474 Wh), as shown in Table 4. Considering the actual room temperature of 27 to 28°C, not 26°C when occupants are out, the power input of case 3 was also slightly overestimated. Therefore, an operation similar to case 3 seems to be more energy saving in practice (less than 12 474 Wh).

3.2. Environment 2 results

In order to increase the energy saving, the test conditions were changed by allowing the compressor to be in minimum load operation while occupants were out. The climate condition was set as August in Korean, which has a lower heat load than the Middle East, and T_{set} was adjusted to 26 → 28 → 26 °C for the behavior 3 case. In addition, in order to observe the energy saving effect over a longer period, we increased the going out time (total 3.5 hours).

Contrary to expectations, however, case 3 consumed more electricity energy (7 814 Wh) than case 1 (7 258 Wh) in Environment 2. This is evident in the case 3 graph of Fig. 5(a). When returning the set temperature from 28°C to 26°C in advance in preparation for an occupant returning at 15:30, it consumes more electricity than case 1 as a side effect. In other words, raising and lowering the temperature by 2°C may consume more electricity than adjusting by 1°C.

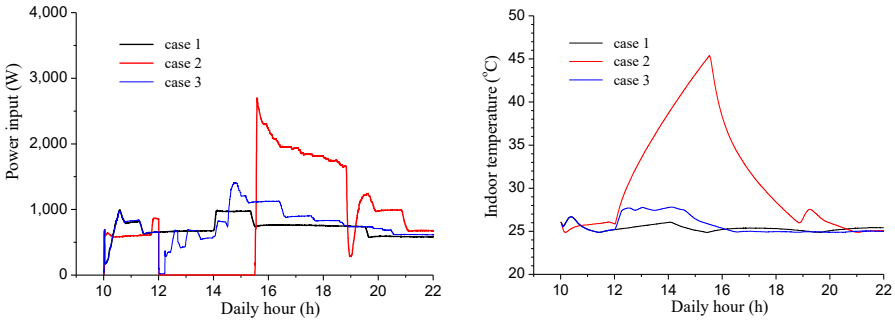

Fig. 5. Power consumption and indoor temperature variation (Environment 2)

3.3. Environment 3 results

This time, to eliminate the adverse effect of the suspect 2°C adjustment in Environment 2 – case 3, the temperature adjustment in Environment 3 – case 3 was limited to 1°C, and it was restored to 26°C, 30 minutes before the occupants' return.

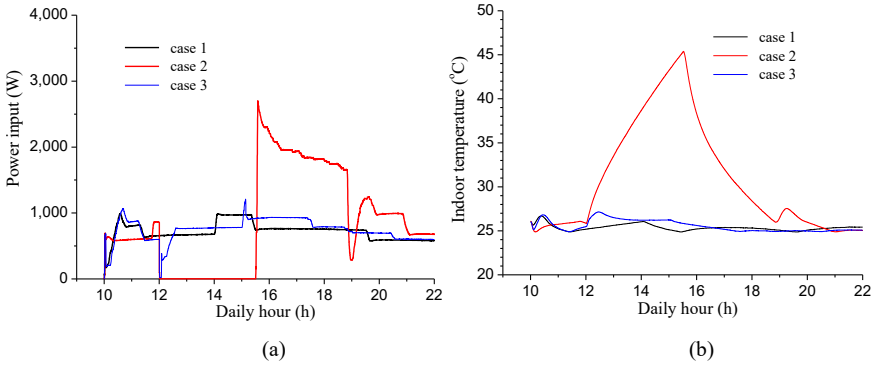

Fig. 6. Power consumption and indoor temperature variation (Environment 3)

Environment 3 – case 3 recorded energy consumption of 7 562 Wh, which is less than Environment 2 – case 3 of 7 814 Wh, but still more than the energy consumption of case 1 (7 258 Wh). This shows that 1°C of temperature adjustment is somewhat effective, but not the main point of the energy saving as in Environment 1 – case 3. Environments 4 and 5 impose Middle East climate conditions where energy saving in case 3 occurred (Environment 1).

3.4. Environments 4 and 5 results

Figures 7 (Env. 4) and 8 (Env. 5) show the test results for the April and October climate and building load conditions in the Middle East, respectively. Because the Middle East's April condition (Env. 4) is similar to Seoul's August condition, the energy saving aspect is similar to Environments 2 or 3. In the case of Environment 5, the test conditions of Environment 1 were slightly modified to change the going out time from 14:00 to 16:30 when the $T_{out}(t)$ and $q_{build}(t)$ are relatively higher than the going out time of Environment 1 – case 3 (from 12:00 to 14:30). Then, the energy consumption of Environment 3 – case 3 (11 735 Wh) becomes smaller than Environment 1 – case 3 (12 474 Wh). These results indirectly show that in order for inverter air conditioners to achieve energy saving with minimal operation, the product must be operated in a partial cooling load range where inverter compressor efficiency can be achieved to some extent.

The part-load operation rate of Environment 5 – case 3 is approximately 67% (= building load, 4 700 W / product rating, 7 000 W). As future work, it will be necessary to further verify the energy saving effect under various conditions in terms of part-load operation rate.

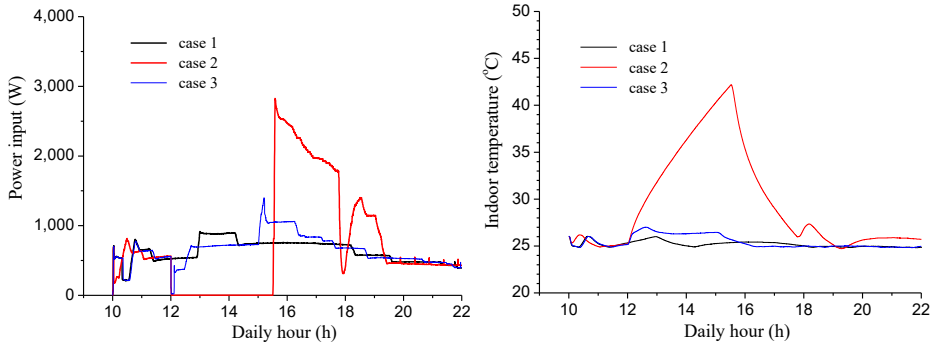

Fig. 7. Power consumption and indoor temperature variation (Environment 4)

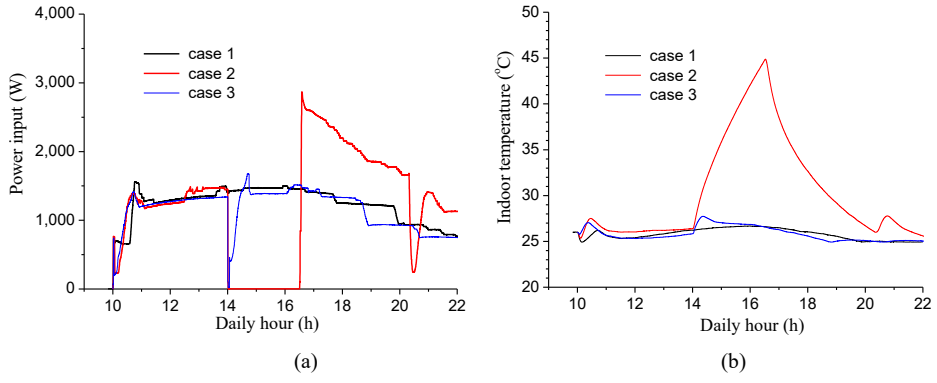

Fig. 8. Power consumption and indoor temperature variation (Environment 5)

3.5. Summary

The summarized energy consumptions (Wh) for the energy comparison interval (12:00 ~ 22:00) are shown in Table 4. There exist obviously smart operational approaches of an air conditioner that can save energy for a short period of non-occupancy of 2.5 or 3.5 hours at special environment conditions. Environments 1 and 5 could reduce the energy consumption when occupants were out by 139 Wh and 878 Wh, respectively, during 2.5 hours without occupancy. This amount is replaced by 56 W and 351 W per hour, respectively.

Table 4 Summary of the energy consumption for each test case

	Climate condition	Behavioral case	Energy consumption (Wh) between 12:00 ~ 22:00
Env. 1	Middle East (October)	Case 1	12 613
		Case 2	12 963
		Case 3	12 474
Env. 2	Seoul (August)	Case 1	7 258
		Case 2	9 118
		Case 3	7 814
Env. 3	Seoul (August)	Case 1	7 258
		Case 2	9 118
		Case 3	7 562
Env. 4	Middle East (April)	Case 1	6 521
		Case 2	7 592
		Case 3	6 770
Env. 5	Middle East (October)	Case 1	12 613
		Case 2	12 557
		Case 3	11 735

4. Conclusion and Future Work

Considering that inverter air conditioners are highly efficient at low-speed operation, energy consumption was compared for three behavioral cases: turned on (behavior case 1), turned off (behavior case 2), or the set temperature was adjusted to minimal operation (behavior case 3) while occupants were out for a short time. If air conditioner technology is further improved, it will be developed to save energy by inputting the outdoor condition, building load condition, and a user's usage pattern by combining with IoT and AI technology. In order to evolve in this direction, it is necessary to pre-study under what conditions an inverter air conditioner can be operated in an energy saving manner and whether current products have the hardware capability to perform such selective operation. With several arbitrary environmental conditions, we found that inverter air conditioners can save electricity by adjusting the set temperature when occupants go out. Assuming 2.5 or 3.5 hours of going out time in Korea and the Middle East climates, three air conditioner operational behaviors during non-occupancy were examined. Under certain conditions when the part-load operation rate was near 65%, the electrical energy consumption order was case 3 < case 1 < case 2, and under some conditions the order was case 1 < case 3 < case 2 when the part-load operation rate had small values under 65%.

In future work, however, TRNSYS analysis is needed to reflect the temperature change ($T_{in}(t)$) inside a building by the test product instead of assuming constant T_{in} (= 26°C). This will yield more accurate and realistic results for case 2. In addition, a wider investigation of the part-load operation rate and going out time environmental conditions is required for various types of inverter air conditioners.

Abstract

Recently, the application of thermal energy storage systems using phase change materials (PCM) is expanding in many fields due to the high energy storage density of PCMs and the narrow phase-change temperature range. In this paper, we conducted a numerical investigation on a shell-and-tube configured PCM-to-refrigerant heat exchanger (PCMHX) coupled in a vapor compression cycle for personal cooling. The enthalpy method was applied to the phase change analysis. The finite-volume method was employed to address the two-dimensional PCMHX numerical solution. Different from most of the previous studies on PCM-to-water heat exchangers, the proposed PCMHX works as a condenser. We validated the simulation results against the experiment data, including condenser pressure, capacity, and PCM temperature profiles. Since the refrigerant-side heat transfer coefficient changes along the condenser length, the heat transfer flux is not uniform across the PCM. Therefore, we analyzed the uneven PCM melting and its effects on the condensing temperature. Results show that PCM near the condenser outlet melts slower than other sections because of the low heat transfer coefficient and small temperature difference in a subcooled liquid region. The developed PCMHX model can reasonably predict the time-dependent heat transfer performance and the PCM melting process.

1. Introduction

Phase change material (PCM) coupled heat exchangers are attracting more attention recently since PCM can absorb or release heat within a narrow temperature range. Most PCMHX (PCM heat exchangers) models were developed by commercial CFD software and only a few through self-developed programming [1]. The two most common numerical methods can be used to build the PCM numerical heat transfer model: (1) enthalpy method, (2) effective heat capacity method [1,2]. In the enthalpy method, by introducing enthalpy, the phase change process can be much more straightforward. Latent heat and sensible heat are combined as the enthalpy in the energy equation to avoid nonlinearity in the heat conduction problem [3]. The governing equation is the same for the liquid phase, mushy phase, and solid phase. The melting interface conditions are automatically achieved by evaluating the PCM enthalpy [2,4]. Most PCMs are not pure, and thus phase change occurs over a range of temperatures rather than at a constant temperature. In this paper, a vapor compression cycle (VCC) coupled with PCM through PCMHX was proposed and modeled. The proposed system could be used as a personal cooling system [5,6], in which PCMHX worked as a condenser to store the waste heat to avoid dumping heat to the ambient and reducing human comfort. The enthalpy method was applied to develop the transient model of the refrigerant-to-PCM heat exchanger. We validated the transient VCC system model and PCMHX model against the experimental results, and PCMHX heat transfer characteristics and system performance were also analyzed and discussed in this study.

2. System description

The PCM coupled VCC system can be used as a personal cooling system. Using the personal cooling system, the thermal state setting of the building can be higher to reduce the building energy consumption, and meanwhile, occupants can feel comfortable with the localized cooling. The schematic diagram of VCC coupled with PCM through PCMHX is illustrated in Fig. 1(a), in which PCMHX works as a condenser in the VCC system to store the waste heat from refrigerant condensation. So that the heat is not to the ambient and cannot reduce the human comfort. Therefore, the whole system including the PCMHX can be assembled together on a robotic base and powered by an electric battery to achieve the movability in buildings. The air-to-refrigerant evaporator is used for providing personal cooling in the VCC-based system. A more comprehensive system experimental investigation could be found in [5]. PCMHX was designed with multiple parallel tubes with the refrigerant flowing inside tubes and PCM was filled in the annular space between PCM container and tubes as illustrated in Fig. 1(b). R134a worked as a refrigerant flowing vertically downward. Paraffin/graphite was selected as the PCM composite, in which paraffin was immersed inside the compressed, expanded natural graphite (CENG) matrix. A refrigerant distribution header and collection header were installed at the top and bottom of PCMHX, respectively, in which the refrigerant was assumed to be uniformly distributed to eight copper branch tubes. PCMHX specifications are listed in Table 1.

3. PCM condenser model

A segment-by-segment condenser model was developed for the PCMHX. Assumptions of the PCMHX model used were: (1) radiation heat to the surrounding was neglected, (2) refrigerant conduction, viscous dissipation, kinetic energy, and potential energy were neglected, (3) only thermal conduction in the CENG matrix was considered, and the effective thermal conductivity was different in the axial and radial directions, (4) the specific heat of PCM was different for the solid and liquid phases, and (5) a unit of a single tube and PCM cylinder can represent the heat transfer performance of original eight-tube PCMHX design. Fig. 1(c) is the single tube unit. To keep the same mass of PCM per tube, the cross-section of the single-tube unit was 1/8 of the original cross-section. To maintain the same heat transfer area per tube, the tube length of the single unit (L) was the same as the eight-tube design. Paraffin wax, PureTemp37, was selected as the PCM with a melting temperature of 37°C. The thermal properties of PureTemp37 are listed in Table 2.

Table 1: PCMHX design properties

Parameters	Unit	Value
PCM container diameter	mm	265
PCM composite height	mm	280
Tube length	mm	300
Tube without PCM length	mm	20
Numbers of tubes	--	8
Tube inside diameter	mm	4.8
Tube outside diameter	mm	6.4
Header length	mm	51.8
Header inside diameter	mm	7.9
Header outside diameter	mm	9.5

Table 2. Properties of PureTemp37

Properties	Unit	Value
Melting temperature	°C	36.5~37.5
Latent heat	kJ·kg^{-1}	210
Thermal conductivity	W·m^{-1}·K^{-1}	0.15 (liquid), 0.25 (solid)
Density	kg·m^{-3}	840 (liquid), 920 (solid)
Specific heat	kJ·kg^{-1}·K^{-1}	2.63 (liquid), 2.21 (solid)

3.1. PCM side model

Under the cylindrical coordinate system, there is a rotation symmetric heat transfer to PCM with respect to the longitudinal axis (see Fig. 1(c)). Therefore, a transient two-dimensional (2D) numerical model was used to simulate heat transfer and PCM melting process in the PCM condenser. The enthalpy method was adopted for the 2-D PCM modeling. The energy equation is given by Eq. (1). T_p and h_p are PCM temperature and enthalpy, respectively. h_p is a function of PCM temperature. $k_{p,r}$ and $k_{p,z}$ are PCM effective thermal conductivity in radial direction and axial direction, respectively. PCM enthalpy and effective thermal conductivity are two crucial parameters that need to be determined to solve this energy equation.

$$\rho_p \frac{\partial h_p}{\partial t} = k_{p,r} \frac{1}{r} \frac{\partial}{\partial r}\left(r \frac{\partial T_p}{\partial r}\right) + k_{p,z} \frac{\partial^2 T_p}{\partial z^2} \tag{1}$$

PCM liquid fraction is given by Eq. (2) to evaluate the PCM melting process. T_s and T_l are PCM temperatures at the beginning and the end of the phase change process, respectively.

$$\lambda(T_p) = \begin{cases} 0 & h \le h_s \\ \dfrac{T_p - T_s}{T_l - T_s} & h(T_s) < h < h(T_l) \\ 1 & h \ge h_l \end{cases} \tag{2}$$

The PCM effective thermal conductivity in the radial direction, $k_{p,r}$, and that in the axial direction, $k_{p,z}$ are significant parameters to address this numerical problem as in Eq. (1). $k_{p,r}$ and $k_{p,z}$ are different due to the manufacturing process of PCM/CENG composite [7]. The thermal conductivity of the CENG matrix in the compression force direction is less than the perpendicular direction. The correlations used for effective conductivities $k_{p,r}$ and $k_{p,z}$ are proposed by Py et al. [8].

Boundary conditions for PCM temperature are given in Eqs. (3) to (6). R_i is the inner radius of the PCM cylinder, which is the same as the tube outer radius. R_o and L are the outer radius of the single-tube unit and the cylinder length, respectively. A_i and A_{top} is the heat transfer area contacted tube walls and the top area of the PCM cylinder, respectively. A_o is the equivalent outer heat transfer area for the single-tube unit to the surrounding. $A_o = A_o'/8$, in which A_o is the outer surface area of the original multi-tube design. α_1, α_2 and α_3 are the natural convection heat transfer coefficient at the outer, top and bottom boundary, which are calculated by the correlation proposed by [9]. T_a and T_w are the surrounding and wall temperatures, respectively.

$$k_{p,r} \frac{\partial T_p(r,z,t)}{\partial r} = A_i \frac{2k_w}{\delta}\left(T_w(z,t) - T_p(r,z,t)\right) \quad r = R_i \tag{3}$$

$$k_{p,r} \frac{\partial T_p(r,z,t)}{\partial r} = \alpha_1 A_o\left(T_p(r,z,t) - T_a\right) \quad r = R_o \tag{4}$$

$$k_{p,z} \frac{\partial T_p(r,z,t)}{\partial r} = \alpha_2 A_{top}\left(T_p(r,z,t) - T_a\right) \quad z = 0 \tag{5}$$

$$k_{p,z} \frac{\partial T_p(r,z,t)}{\partial r} = \alpha_3 A_{top}\left(T_p(r,z,t) - T_a\right) \quad z = L \tag{6}$$

The initial condition for PCM temperature is as follows:

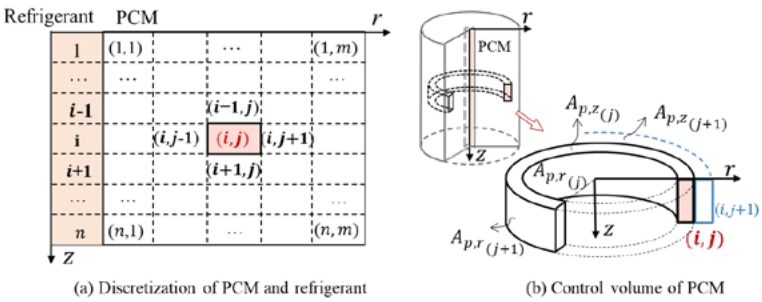
$$T_p(r,z,t) = T_{ini} \quad t = 0 \tag{7}$$

A finite-volume method was adopted to solve the aforementioned governing equations for PCM. As illustrated in Fig. 2, uniform segments were applied for the discretization along with axial and radial directions in the PCM domain. Control volumes in the axial and radial directions are designated by *i* and *j*. Each PCM control volume is an annular space. The discretized energy equation for PCM heat transfer using the enthalpy method is given in Eq. (8). $A_{p,r}$ and $A_{p,z}$ are the heat transfer areas of each control volume in the radial direction and axial direction, respectively.

$$m_{p_{(i,j)}}\frac{h_{p_{(i,j)}}}{\partial t}=\frac{k_{p,r}}{dr}A_{p,r_{(j)}}\left(T_{p_{(i,j-1)}}-T_{p_{(i,j)}}\right)-\frac{k_{p,r}}{dr}A_{p,r_{(j+1)}}\left(T_{p_{(i,j)}}-T_{p_{(i,j+1)}}\right)+\frac{k_{p,z}}{dz}A_{p,z_{(j)}}\left(T_{p_{(i-1,j)}}-T_{p_{(i,j)}}\right)-\frac{k_{p,z}}{dz}A_{p,z_{(j)}}\left(T_{p_{(i,j)}}-T_{p_{(i+1,j)}}\right) \quad (8)$$

3.2. Refrigerant side model

The refrigerant flow was one-dimensional, and the conduction term was neglected. The energy equation and continuity equations of the refrigerant flow are given in Eqs. (9) and (10), respectively. Pressure (P) and specific enthalpy (h) were selected as state variables [10,11]. Refrigerant properties including density, ρ, the partial derivative of density with respect to enthalpy, $(d\rho/dh)|_p$, and that with respect to pressure, $(d\rho/dP)|_h$, were obtained by refrigerant property functions proposed in [12].



$$\frac{dU}{dt}=\mathrm{V}\left[\left(h\left.\frac{d\rho}{dP}\right|_h-1\right)\frac{dP}{dt}+\left(h\left.\frac{d\rho}{dh}\right|_p+\rho\right)\frac{dh}{dt}\right] \quad (9)$$

$$\frac{dm}{dt}=\mathrm{V}\left(\left.\frac{d\rho}{dP}\right|_h\frac{dP}{dt}+\left.\frac{d\rho}{dh}\right|_p\frac{dh}{dt}\right) \quad (10)$$

As shown in Fig. 2, spatial discretization along the axial direction was adopted for the refrigerant flow as well. Discretized energy and continuity equations for the refrigerant are given in Eqs. (11) and (12), respectively. h_{in} and h_{out} are refrigerant enthalpy flowing into and out of the selected cross section. $\dot{m}_{in}$ and $\dot{m}_{out}$ are refrigerant mass flow rate flowing into and out of the selected section. α_{ref} is the convective heat transfer coefficient. For single-phase flow, α_{ref} is calculated from correlations proposed in [13]. For two-phase flow, α_{ref} calculation was based on the correlation in [14]. α_{ref} of two-phase flow changes with quality x, and the smooth function was used at $x < 0.05$ and $x > 0.95$ to prevent discontinuities of the heat transfer coefficient at the phase transition point.

$$V_{(i)}\left(\left.\frac{d\rho}{dP}\right|_{h_{(i)}}\frac{dP}{dt}_{(i)}+\left.\frac{d\rho}{dh}\right|_{p_{(i)}}\frac{dh}{dt}_{(i)}\right)=\dot{m}_{(i)}-\dot{m}_{(i+1)} \quad (11)$$

$$V_{(i)}\left[\left(h(i)\left.\frac{d\rho}{dP}\right|_{h_{(i)}}-1\right)\frac{dP}{dt}_{(i)}+\left(h(i)\left.\frac{d\rho}{dh}\right|_{p_{(i)}}+\rho_{(i)}\right)\frac{dh}{dt}_{(i)}\right]=\dot{m}_{(i)}h_{(i)}-\dot{m}_{(i+1)}h_{(i+1)}+\alpha_{ref(i)}A_{p,r_{(1)}}(T_{HTF\,(i)}-T_{w(i)}) \quad (12)$$

(a) Discretization of PCM and refrigerant (b) Control volume of PCM

Fig. 2. Discretization of PCMHX

4. Other component models

Different from most of the previous studies on water-to-PCM heat exchangers, in this paper, the refrigerant flowing inside PCM tubes is the refrigerant. Since PCM temperature profiles vary during the melting process, and affect the PCMHX performance, and thus for the VCC the refrigerant inlet states and heat transfer coefficient along the flow direction vary with time in the PCMHX. This variation can also be reflected by Eq. (3), showing that the PCM boundary condition at R_i is neither the constant heat flux nor the constant wall temperature. Therefore, to simulate the PCMHX performance, the VCC system should be modeled. Components include an evaporator, thermostatic expansion valve (TXV), compressor, receiver, and pipes.

4.1. Evaporator model

A fin-and-tube heat exchanger was selected as the evaporator design. Discretized governing equations of refrigerant in evaporator are the same as those in the PCM condenser, as described in Eqs. (11) and (12). Heat transfer coefficient of refrigerant, α_{ref}, was calculated using correlations propose by [15] for two-phase flow and by [13] for single-phase flow. For tube wall and fins, the energy equation is given by Eq. (13).

$$\begin{aligned}\left(M_w C_{p,w} + M_{fin} C_{p,fin}\right)\frac{dT_w}{dt} \\ = \alpha_{ref} A_{ref}\left(T_w - T_{ref}\right) + \dot{m}_a C_{p,a}\left(T_{a,in} - T_{a,out}\right) + \dot{m}_a H_a(\omega_{a,in} - \omega_{a,out})\end{aligned} \tag{13}$$

In Eq. (13), the first term at the right-hand side is the heat transfer between tube walls and refrigerant, the second term means sensible heat released from air to tube walls, and the third term is the latent heat from the air. $\dot{m}_a$, $C_{p,a}$ and H_a are air mass flow rate, air specific heat, and water vaporization heat, respectively. $T_{a,in}$, $T_{a,out}$, $\omega_{a,in}$ and $\omega_{a,out}$ are air inlet temperature, outlet temperature, inlet humidity ratio and outlet humidity ratio, respectively. $T_{a,in}$ and $\omega_{a,in}$ are known. $T_{a,out}$ and $\omega_{a,out}$ can be solved by Eqs. (14) and (15), yielding air side governing equations as described by [10].

$$T_{a,out} = T_{a,in} + (T_w - T_{a,in})\left\{1 - exp\left[-\frac{\alpha_a\left(A_t + \eta_{fin}A_{fin}\right)}{\dot{m}_a C_{p,a}}\right]\right\} \tag{14}$$

$$\omega_{a,out} = \omega_{a,in} + \left\{1 - exp\left[-\frac{\alpha_a\left(A_t + \eta_{fin}A_{fin}\right)}{\dot{m}_a C_{p,a} Le^{2/3}}\right]\right\} min\left(0, \omega_{a,sat} - \omega_{a,in}\right) \tag{15}$$

A_t and A_{fin} are heat transfer area of tube-side and fin-side, respectively. Fin efficiency, η_{fin} was calculated using correlations proposed by [16]. Airside heat transfer is enhanced by plate wavy-herringbone fins with a staggered tube layout. Thus, the air-side heat transfer coefficient, α_a, was obtained from the correlations proposed by [17]. *Le* is the Lewis number yielding $Le^{2/3}$=0.9 [18].

4.2. TXV model

The TXV model is described in [10] and [19]. TXV was assumed to be adiabatic. The expansion of the refrigerant was assumed to be isenthalpic. The refrigerant mass flow rate controlled by the TXV is given by Eq. (16), in which C_v is the flow coefficient, A_t is the flow area of the throttle, Δp is the pressure drop across the valve.

$$\dot{m} = C_v A_t (\rho_{in} \Delta p)^{1/2} \tag{16}$$

The refrigerant flow area was controlled by a needle movement, which reflects the superheat degree at the evaporator outlet. Valve geometry and a function to obtain the TXV bulb temperature are presented in [10]. The force balance on the diaphragm is given in Eq. (17). The sensor provides a force on the one side of the diaphragm, $P_b A_{dia}$, which is the same with the total forces on the other side supplied by evaporator pressure and the spring. k_{sp}, y_{sp} and $F_{sp,ini}$ are the spring constant, deflection and the initial force, respectively.

$$k_{sp} y_{sp} + F_{sp,ini} + P_{evap} A_{dia} = P_b A_{dia} \tag{17}$$

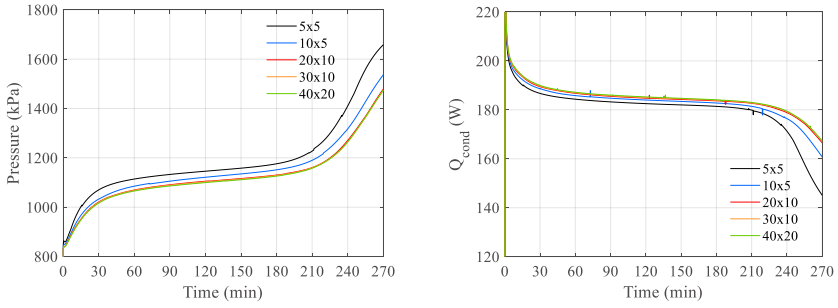
4.3. Compressor model

The compressor provides a refrigerant mass flow throughout the VCC. The efficiency-based compressor model was applied in this study. Volumetric efficiency, η_{vol}, isentropic efficiency, η_{isen} and motor efficiency, η_m, were used to calculate the compressor power consumption, W_{comp}, as given in Eqs. (18) to (20). $\dot{m}$ and N are the mass flow rate and compressor speed, respectively. ρ_{in} is the refrigerant density at the inlet of the compressor.

$$h_{out} = h_{in} + \frac{h_{out,s} - h_{in}}{\eta_{isen}} \tag{18}$$

$$\dot{m} = \frac{\eta_{vol}\rho_{in}V_{comp}N}{60} \tag{19}$$

$$W_{comp} = \dot{m}\frac{h_{out} - h_{in}}{\eta_m} \tag{20}$$



4.4. Receiver and pipe models

The receiver model and connecting pipe model are essentially the same as the evaporator model. As described before, the refrigerant side can be solved by discretized equations as in Eqs. (11) and (12). The air-side heat transfer was based on natural convection.

5. Results

5.1. Grid sensitivity

Sensitivities to grid size and aspect ratio were investigated. The model was simulated under different grid sizes and aspect ratios as follows: 40x20, 30x10, 20x10, 10x5, and 5x5. Results are shown in Fig. 3. The deviation of both pressure and capacity between grids 40x20 and 30x10 is less than 1.0%. Therefore, the grid of 30x10 was good enough to be adopted in the simulation.

(a) Condenser pressure

(b) PCM condenser capacity

Fig. 3. Grid independence of numerical solution.

The PCMHX model and system model were developed in Dymola®. The algorithm of Lsodar was adopted, which is an implicit multi-step method. The backward differentiation formula was applied in the algorithm to solve differential equations. Time step size was determined on every step with a tolerance of $1e^{-6}$.

5.2. Simulation results

Fig. 4 (a)-(e) show the comparison of the experimental and numerical results on system operating pressures, condenser outlet subcooling and evaporator outlet superheat, mass flow rate, COP, and heat exchanger capacities indicating that numerical results match well with the experimental results. The good agreements illustrate that the numerical model is reliable. Fig. 4(f) shows the PCM temperatures at 1/3 from the top and bottom of the PCMHX for both numerical and experimental results. From Fig. 4(a), evaporating pressure was

almost constant due to the steady surrounding temperature. The condenser pressure increased with the cooling time due to the process of PCM melting. As the PCM absorbed heat from the condenser tube, its average temperature increased (Fig. 4(f)) and thus the condensing temperature was increased, leading to the increased of subcooling at the condenser outlet as well. Fig. 4(c) indicates mass flow rate decreased gradually, which is because the higher condensing pressure led to lower volumetric efficiency. Fig. 4(d) and (e) show the slightly decreased COP and capacity due to the increase of the condensing pressure. As can be seen from Fig. 4(f), the proposed PCMHX model can predict the PCM melting process well.

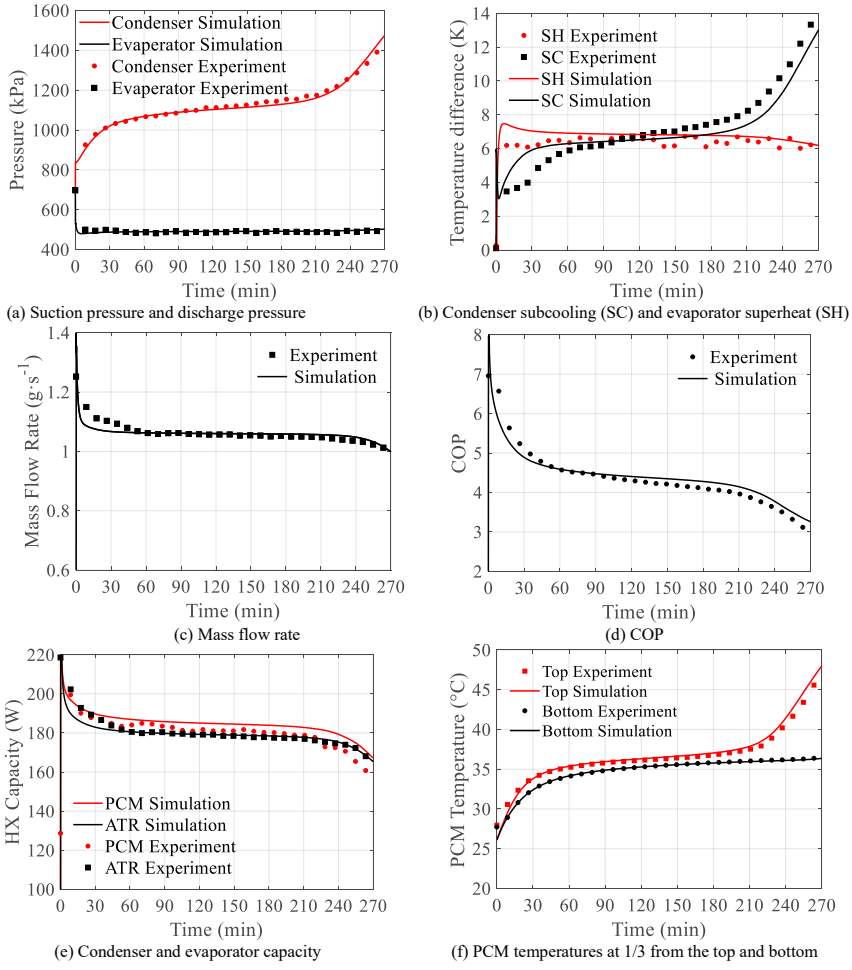


Fig. 4. Numerical results compared with experimental results.

Fig. 5 and Fig. 6 shows the numerical solution of the PCM temperature and melting fraction of the single-tube unit. The vertical direction means the condenser length direction, and the horizontal direction represents the radial direction. Refrigerant flowed downward from the top to the bottom. It can be found that the PCM melting rate decreased along the condenser length direction. The bottom PCM temperature was lower than the top and middle sections, which can also be verified by Fig. 4(f). The PCM temperature gradient in the radial direction was smaller than the axial direction. Besides, the heat transfer area of subcooled-liquid refrigerant increased with the cooling time. The refrigerant liquid zone at the bottom was greater than the vapor zone at the top near the condenser inlet. From Fig. 6, at 270 minutes, liquid fractions at the top 1/3 were higher than 0.9, while at the bottom 1/3 PCM liquid fractions were less than 0.4. This uneven PCM melting is due to the

uneven refrigerant heat transfer coefficient. At the top and middle section, the refrigerant-side heat transfer coefficient is much higher than that at the bottom because the refrigerant is in two-phase at the top and middle, while it becomes sub-cooled liquid at the bottom. It can be concluded that the utilization ratio of the PCM latent heat needs to be improved.

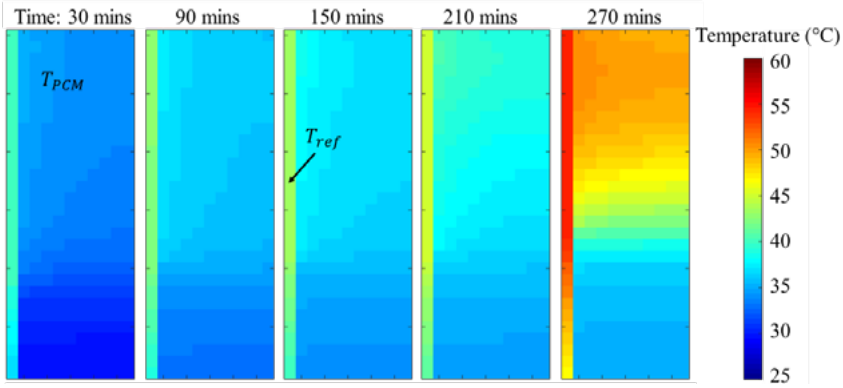

Fig. 5 PCM and refrigerant temperatures

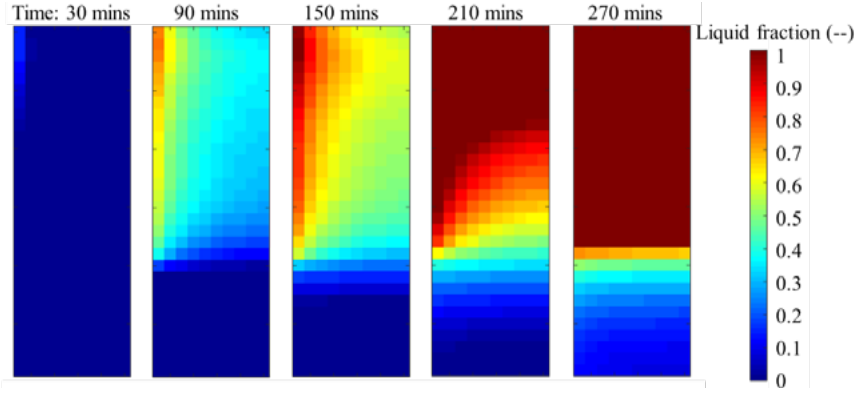

Fig. 6. PCM liquid fractions

Conclusions

In this paper, we developed the two-dimensional PCM-to-refrigerant heat exchanger model and transient system model of the VCC coupled with PCMHX in a personal cooling system. PCMHX works as a condenser of the VCC system and interface for thermal energy storage. Grid size sensitivity was checked, and numerical results were compared with the experimental results. It shows good agreements between simulation and experiment for both system performance and PCM heat transfer characteristics. Uneven PCM melting was also observed and reasoned due to the uneven heat transfer rate from the refrigerant to PCM along the condenser length. Therefore, a better PCMHX design should be further investigated to fully utilize the advantage of all the latent heat.

Abstract

A new PVT (Photovoltaic-Thermal) and ground coupled AWHP (Air to Water Heat Pump) system has been developed and verified with a TTC (Twin Test Cell) in Korea. This renewable energy hybrid system technology could support Korea government's energy policies about RE3020(20% by renewable energy in 2030) and the zero energy building policy for the public sector in 2020 and the private sector in 2030. In this paper, a photovoltaic-thermal and ground air heat exchanger hybrid technology will be introduced for local and global energy issues. SET (Separate Effect Test) models have been developed to verify PVT, GAHX and AWHP units performance. And also IET (Integral Effect Test) model with TTC has been developed to validate PVT-GAHX hybrid system performance. Initial commissioning of TTC both were matched in 99%. Seasonal test of heating and cooling weeks will be performed and introduced in terms of primary energy savings.

1. Introduction

Photovoltaic-thermal (PVT) and ground air heat exchanger (GAHX) hybrid system is a combined one with photovoltaic, solar thermal and geothermal technologies. The dual functions of the PVT system result in a higher overall solar conversion rate than that of solely photovoltaic or solar collectors and thus enable a more effective use of solar energy. GAHX system takes advantage of constant ground temperatures to precondition incoming fresh air hence reducing the heating and cooling loads. In this study, PVT and GAHX hybrid system were combined with air to water heat pump (AWHP). The concept and the TTC site of hybrid system are shown as Fig. 1.

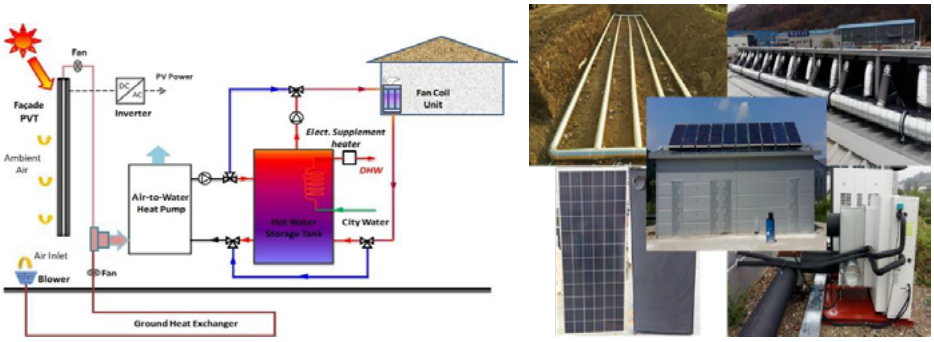

Fig. 1. PVT and ground coupled AWHP system (left) / IET TTC test site (right)

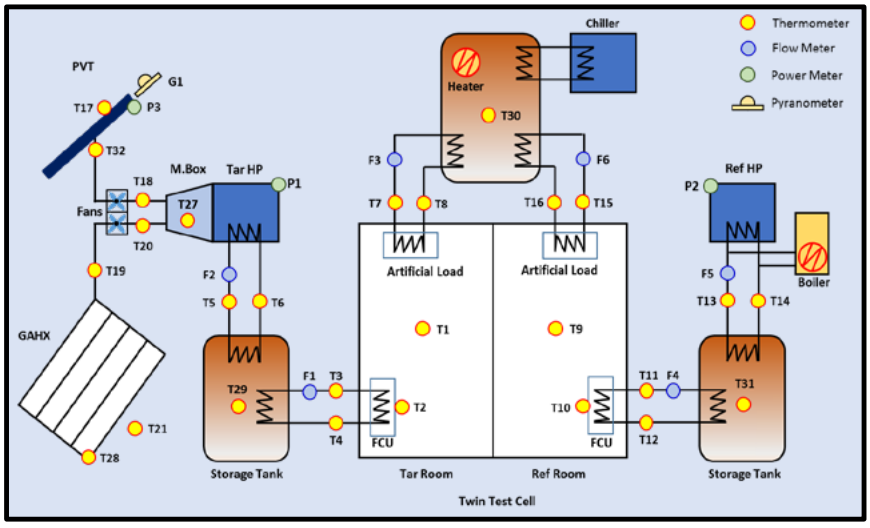

Fig. 2. TTC demonstration system schematic

2. PVT-GAHX Hybrid System TTC Study

The Twin-Test-Cell (TTC) facility (shown as Fig. 1) in Korea has been used as a testbed for HVAC components and systems testing and evaluation under real-life conditions. The Twin-Test-Cell consists of two identical rectangular-shaped rooms each with a dimension of 4m by 5m. Between the two test cells, there is a engineering room (3m by 5m) for locating the HVAC systems to be tested and compared. The horizontal ground-to-air heat exchanger is buried around the perimeter of the twin-test-cell and PVT panels are installed on the roof of the twin-cell.

The hybrid system to be installed at TTC is designed for an average detached house with the peak heating and cooling demand of 9 kW and 6 kW respectively. 10 PVT panels with a system power of 3.1 kW total have been installed power capacity and 40% of thermal efficiency and 200 m GAHX duct were installed in the ground and it is steel spiral type duct of 250 mm diameter. As the TTC (shown as Fig. 2) has the area of just 20 m2 and a volume of 54 m3 and 32 temperature sensors, 6 flow meters, 3 power meters and 1 pyranometer.

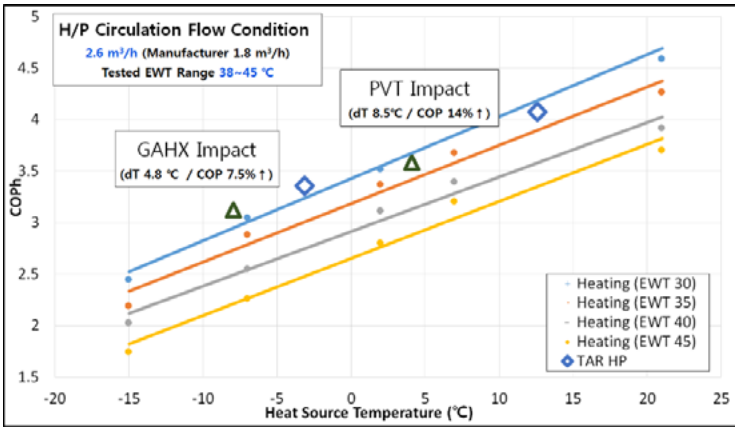

Fig. 3. AWHP SET/IET performance data mapping

The AWHP has 9.5 kWt heating capacity and its performance data are presented shown as Fig 3. PVT and GAHX's contribution are described on Fig.3. Heating week test (2018.02.15~2018.02.22) was conducted target system (PVT-GAHX hybrid H.P.) and reference system (conventional H.P.) at the same time for a week. The target AWHP COP was 4.0 while the reference was 3.4. The hybrid system's COP increase due to source temperature increase (Shown in Fig. 3) and it is about 15% performance improvement from the coupling of the PVT and ground heat exchanger system.

3. Conclusion

PVT and ground coupled TTC system has been introduced and developed to justify the IET model by comparing the reference and the target system with the solar and geothermal component. Twin test cell with the hybrid system was installed in a local actual site and initial commissioning test has been performed with a good accuracy more than 99%. The hybrid system's COP increase due to the source temperature advantage was consistent and justified with IET and SET. GAHX impact 4.8℃ on source temperature, contributed 7.5% COP and PVT impact 8.5℃ on source temperature, contributed 14% COP improve. For the heating season week performance comparison test, the target system with PVT-GAHX hybrid system showed a 15% energy saving of the target system in the location and the test cell conditions. In addition, the system achieves lower primary energy consumption in comparison to the Reference boiler-chiller system. The annual primary energy saving expected as 45% in Korea by yearly simulation methodology. The system components' contributions to these saving vary during the seasons but in general are due to the multipurpose renewable utilization and high heat pump COP. For the future work, a shoulder month week and cooling month week test will be conducted for a seasonal and yearly performance data improved justification.

Control strategies for modulating heat pumps in a plus energy building

Christina Betzold*, Susanna Bordin, Arno Dentel, Gunnar Harhausen

Technische Hochschule Nürnberg Georg Simon Ohm, 90429 Nuremberg, Germany

Abstract

Since the feed-in tariff of photovoltaics (PV) decreases [1], PV self-consumption becomes more profitable. Especially heat pumps, which are able to modulate the compressor speed, open up more flexibility for consuming fluctuating PV power. For exploiting the full potential of PV self-consumption smart control strategies for modulating heat pumps (MHPs) are needed. In this research, the development and the real application of optimized control strategies for MHPs in plus energy terraced houses, built in 2017, are realized. Two control strategies, a PV rule based (PVC) and a model predictive control (MPC) are tested and compared in simulation. Results for the MPC of a 12 months simulation show potential for a moderate increasing PV self-consumption up to 2.1 % and significant reducing operating costs up to 36.1 %. In real application in the terraced houses, the PVC offers an increase of PV self-consumption by 4.1 % for a monitored week, compared to a heat controlled operation.

Keywords: PV self-consumption;operating costs; modulating heat pumps; control strategies

1. Introduction

Since the feed-in tariff decreased and the electricity price of energy supply companies is increasing in Germany, PV self-consumption is becoming economically interesting for building owners. Smart control strategies in combination with thermal storage tanks have the potential to reduce operating costs by converting the PV surplus into thermal power. Battaglia, M. et al. [2] show, how control strategies can reduce costs for electricity by overheating thermal storage tanks. Psimopoulos et al. [3] investigate control algorithms and their contribution to final energy, solar fraction, self-consumption and seasonal performance factor in the simulation software TRNSYS. Results show an increase of PV self-consumption to 50.5 % by using control strategies in combination with thermal and electrical storage units.

High potential for reducing energy costs is expected by MPC as it uses numerical optimization algorithms and price or weather prediction. Fischer, D. et al. [4] shows in his research work that in a multi-family house MPC increases annual PV self-consumption from 56 % - 58 % up to 64 % - 71 % and decreases energy costs by 6 % - 16 % in the case of variable electricity prices. In his research work, Pichler, M. et al. [5] investigates the direct consumption of PV energy by controlling a heat pump with a MPC in an annual simulation. The MPC increased the direct consumption of PV energy from 20 % to 50 % in a single-family house.

In a previous simulation study, a control strategy, the Demand Side Management System (DMS), for the energy system of eight terraced houses was developed in TRNSYS [6] and is described by Dentel, A. et al. [7]. The DMS was changed during the implementation due to different configuration input parameters from the manufacturers. PV optimized control (PVC) was developed and is implemented in the building automation of the terraced houses since October 2018. The PVC includes the controlling of heat pumps and a battery in the energy system. The energy concept of the terraced houses consists of two shared MHPs, connected to a two storage cascade, eight decentralized domestic hot water heat pumps (DHW-HPs) with a 200 liter storage each and a shared battery of 40 kWh capacity. The first buffer storage has a size of 800 liters and is charged during

* Corresponding author. Tel.: +49-911-5880-3123; fax: +49-911-5880-7120.
E-mail address: christina.betzold@th-nuernberg.de.

grid and PV consumption. The second surplus storage in the storage cascade has a volume of 2000 liters and is charged only during PV production. The terraced houses represent a total energy system that includes thermal energy for heating and DHW as well as household electricity. Another control strategy, the Model Predictive Control (MPC), is developed in MATLAB [8] and will be implemented in the energy system as well.

In this research, two advanced control strategies, PVC and MPC, are compared to heat controlled strategies in a simulation environment in order to evaluate the potential for increasing PV self-consumption and reducing operating costs. All models and control strategies are developed and tested in MATLAB [8]. Furthermore, the PVC, realized in the terraced houses in October 2018, is compared to a heat controlled strategy by analyzing measurement data from the monitored terraced houses.

2. Method

2.1. PV optimized control (PVC)

The PVC is a rule-based control strategy and aims to increase the PV self-consumption by operating the heat pumps during PV production. As real application and simulation offer different implementation and parameter options, the PVC differs in the real application and simulation. A detailed description of the PVC and the implementation is published by Betzold, C. et al. [9].

In real application four different modes for the heat pump operation are defined:

1. Grid Mode: This mode is active, when PV production is off or already fully consumed by household electricity. The 800 liter buffer storage is charged to maximal 35 °C by the MHPs. The DHW storage tanks are charged up to 50 °C.
2. PV Mode: This mode is active, when there is PV production and a PV surplus is left after fulfilling the energy needs of the household electricity. The 800 liter buffer storage and the 2000 liter surplus storage are charged to 35 °C by the MHPs. The DHW storage tanks are charged up to 60 °C.
3. Load Management: The Load Management aims to avoid electrical load peaks of the terraced houses. The PVC switches all heat pumps off for 15 minutes, if a load peak of 16 kW is reached.
4. Priority Mode: This mode ensures that the thermal comfort in the terraced houses is fulfilled at all times. The Priority Mode starts, when the temperature falls under 27 °C in the 800 liter buffer storage, and ends, when the temperature reaches 32 °C. The DHW storage tanks are charged from 40 °C to 45 °C.

In simulation the energy system is simplified to a model that bases on energy flows coupled in an energy node. The energy node for the MHP system is shown in Equa. 1, where Q_{MHP} is the thermal energy of the MHP, $Q_{st,cap}$ is the thermal storage capacity, $Q_{st,loss}$ is the constant loss of the thermal storage and Q_{th} is the thermal load of the building. In Equa. 2 the DHW-HP system (i = 1-8) is shown, where $Q_{DHW\text{-}HP,i}$ is the thermal energy of each DHW_HP, $Q_{DHW\text{-}st,cap,i}$ is the thermal storage capacity of each DHW storage, $Q_{st,loss}$ is the constant loss of the DWH storage and $Q_{th\text{-}DHW,i}$ is the DWH load of each terraced house. Equa. 3 describes the battery system where P_{PV} is the PV surplus, $C_{bat,cap}$ is the electrical storage capacity, P_{MHP} is the electrical energy of the MHP and $P_{DHW\text{-}HP}$ is the electrical energy of the DHW-HP. The investigated control strategies use the same models to ensure comparability.

$$Q_{MHP1} + Q_{MHP2} + Q_{st,cap} = Q_{st,loss} + Q_{th} \quad (1)$$

$$Q_{DHW-HP,i} + Q_{DHW-st,cap,i} = Q_{DHW-st,loss} + Q_{th-DHW,i} \quad (2)$$

$$P_{PV} * n_{loss} + C_{bat,cap} = P_{MHP1} + P_{MHP2} + \sum_{n=1}^{8} P_{DHW-HP,n} \quad (3)$$

Mode 3, the Load Management and Mode 4, the Priority Mode are not integrated for this investigation of different control strategies. Thus, there are two modes in the PVC simulation:

1. Grid Mode: The MHPs only deliver as much thermal energy as necessary to cover the thermal load. If the DHW storage reaches the minimal storage capacity, the DHW-HP starts to charge the DHW storage with a constant thermal energy until the maximal storage capacity is reached.
2. PV Mode: The MHPs adapt to the available PV surplus power and deliver as much thermal energy as corresponds to the compressor speed. If the thermal load can not be covered during PV adaption, then the MHPs adapt the thermal energy to the thermal load as in the grid mode. The storage is charged to

its maximal capacity for 2800 liters. As soon as there is PV power left after the MHPs, the DHW-HPs start in row to charge the DHW storages tanks with a constant thermal energy until the maximal storage capacity is reached.

2.2. Model predictive control (MPC)

The MPC bases on the same simplified energy models of the heat pumps and storage tanks as shown in Equa. 1 - 3. In this research, a mixed-integer linear programming (MILP) optimization algorithm is used. The MPC is realized in MATLAB [8] with the additional software GUROBI [10], for using the Special Ordered Set (SOS) option. The SOS option enables an interpolation between defined operation points of the MHP in order to describe the MHP polynomial at every modulation step for B5 °C/W35 °C. Thus, the thermal power of the MHPs can be between 4.8 kW and 18.1 kW and the electrical power can be between 1.0 kW and 4.7 kW. The DHW-HPs have a thermal power of 2.2 kW and an electrical power of 0.5 kW. Each storage tank is modeled as an energy node that balances in- and output energy flows. Operating limits are defined by the minimal and maximal storage capacities and by the complete cover of the thermal and electrical load. The cost function bases on operating costs (c) for the household electricity ($P_{el,household}$), the MHPs ($P_{el,MHP,n}$) and the DHW-HPs ($P_{el,DHW\text{-}HP,n}$) depending on the consumption of grid, PV or battery as well as a bonus for grid feed-in (see Equa. 4 and Equa. 5).

$$min\,J = \sum_{t=1}^{t_{end}} P_{el,PV,t} * c_{PV} + \sum_{t=1}^{t_{end}} P_{el,Bat,t} * c_{Bat} + \cdots$$
$$\sum_{t=1}^{t_{end}} P_{el,Grid,t} * c_{Grid} - \sum_{t=1}^{t_{end}} P_{el,Feedin,t} * c_{Feedin} \quad (4)$$

$$P_{el} = P_{el,household} + \sum_{n=1}^{2} P_{el,MHP,n} + \sum_{n=1}^{8} P_{el,DHW-HP,n} \quad (5)$$

In this research work, the MPC has a 15 minute timestep and a 48 hours optimization horizon. After 24 hours the MPC is restarted with the boundary conditions at the end of the previous optimization at time 24 hours. The PV, thermal and electrical load prediction is ideal.

3. Simulation and comparison of PVC and MPC

For analyzing the potential of the MPC, regarding PV self-consumption (see Equa. 6) and operating costs, the MPC is compared to PVC and a heat controlled strategy (HC) for heat pumps for a 12 months period. The HC bases on the grid mode of the PVC and the two heat pumps are on/off heat pumps (no modulation). The PVC enables to adapt the MHPs to the thermal load or the available PV power. As first results have shown that the HC has higher energy consumption due to low COP at on/off HP operation (up to 11.8 %), a second HC variant with modulation option is introduced. The heat controlled modulation strategy (HCmod) operates like the grid mode of the PVC with the ability to adapt to the thermal load. Table 1 shows the four control strategies with the different heat pump models and the operation modes.

Table 1: Heat pump model and operation modes according to the control strategies

Control strategy	On/off HP	MHP	Grid Mode	PV Mode	Free Mode
HC	x		x		
HCmod		x	x		
PVC		x	x	x	
MPC		x			x

Real monitored measurement data of the energy system of the terraced houses is used for the comparison. For offering an overview of the potential a whole period of 12 months from October 2018 until September 2019 is chosen. The measured PV power as well as measured thermal and electrical load are used as ideal prediction for the MPC. For the HC, HCmod and PVC simulation the measurements serve as actual PV production and loads. The operation and comparison are implemented in MATLAB [8]. Boundary and start conditions are the same in the four cases. The energy consumption and production for the period of 12 months are shown in Table 2.

Table 2: Boundary conditions for the 12 month period from October 2018 until September 2019

Energy consumption	
Thermal load in MWh	39.60
DHW load in MWh	25.60
Electrical load in MWh	28.90
PV production in MWh	85.85

This research work is focused on the operation of the control strategies and its contribution to PV self-consumption and operating costs for the 12 months period. Economic efficiency and price increases are not observed in this analysis. Thus, the electricity prices for PV and battery do not include repayments of investments. The price for the PV self-consumption contains fees and taxes. The feed-in tariff depends on the year of commissioning and the PV plant size and is introduced for the terraced houses in 2017. Especially in MPC operation the usage of the battery is avoided due to battery prices that can not compete with grid electricity price and feed-in tariff. In this price scenario, the battery price has to be below 0.147 €/kWh (including battery losses of 30 %) to be cheaper than using the grid as an electricity storage, that costs 0.21 €/kWh. The prices for electricity are shown in Table 3.

Table 3: Energy prices for electricity consumption and PV feed-in

Energy prices	
Grid electricity	0.32 €/kWh
PV electricity	0.12 €/kWh
Battery electricity	0.14 €/kWh
PV feed-in electricity	0.11 €/kWh

The results of the simulation for the 12 months period from October 2018 until September 2019 are shown in Fig. 1 and Fig. 2. The end capacities of the storage tanks are taken into account for the cost calculation. Higher or lower end capacity is added as a bonus or substracted as an extra fee and is calculated by the average price of 0.19 €/kWh. The electricity consumption is calculated by a COP of 4.8 for the buffer storage and by a COP of 4.3 for the DHW storage tanks.

The results of the PV self-consumption and the self-sufficiency of the comparison are shown in Fig. 1. The definition of PV self-consumption and the self-sufficiency are explained in Equa. 6 and Equa. 7. In general, the results do not vary significantly between the different control strategies. Regarding the PV self-consumption the maximal variation for direct PV is up to 2.1 % and for grid feed-in is 6.0 %. Regarding the self-sufficiency, there is an increase of direct PV up to 9.5 % and a decrease of grid consumption up to 8.7 %.

$$PV\ self-consumption = \frac{\sum Direct\ PV}{\sum PV\ production} \tag{6}$$

$$Self-sufficiency = \frac{\sum Direct\ PV}{\sum Total\ energy\ consumption} \tag{7}$$

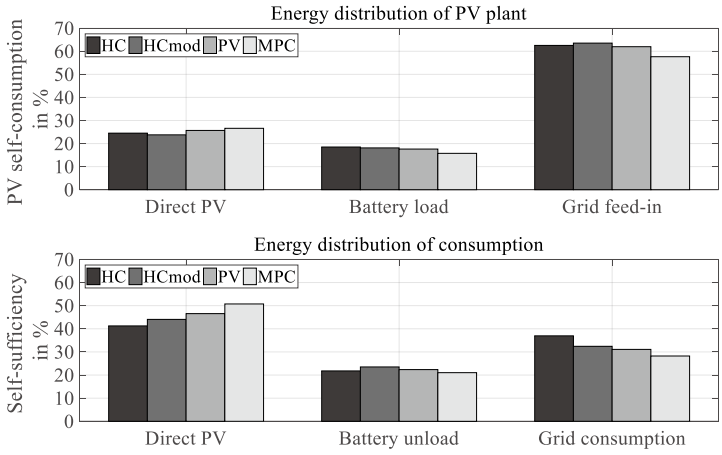

Fig. 1: Energy distribution regarding PV self-consumption and self-sufficiency

The results in Fig. 2 give an overview of operating costs and total energy consumption. Regarding the operating costs, the HC variant is the most expensive and the MPC is the cheapest strategy. However, comparing the HC and the HCmod, both operating in grid mode only, significant cost savings occur in the HCmod, which includes the ability of modulation. The HC also has the highest total energy consumption, which results from the on/off heat pump operation with lower COP. HCmod and MPC have quite similar total energy consumption, while PVC has a higher result for adapting the MHPs to the available PV power and thus, operating in lower COP.

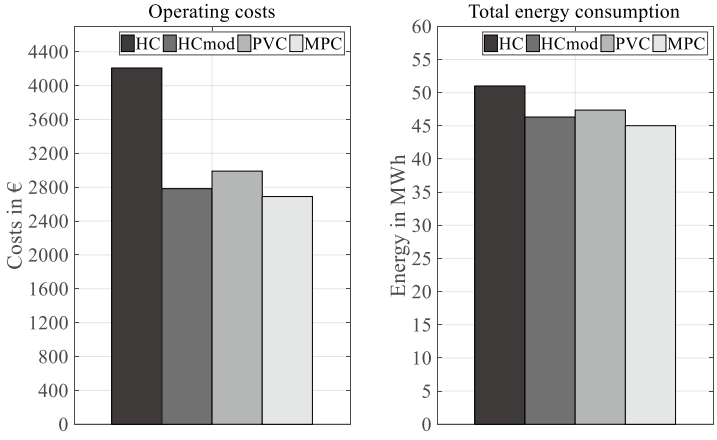

Fig. 2: Operating costs and total energy consumption of 12 months period

4. Comparison of measured operation of HCmod and PVC

The PVC is implemented in the energy system of the eight terraced houses since October 2018. For analyzing the influence of the PVC on the PV self-consumption two time periods are compared. The first time period is a week in December 2018 with low PV production, in which the MHPs operated only in grid mode (HCmod). The second time period is a week in February 2019 with higher PV production, in which the MHPs operated every day in PV mode. Both selected weeks start on Monday and end on Sunday.

For comparing the influence of the PVC on the PV self-consumption and the operating costs, the low PV production of the December week is replaced by the high PV production of the February week. The operation of the MHPs, DHW-HPs and the total energy consumption stays the same. As the operation of the battery is different due to higher load and unload, the battery is modelled as an energy node (see Equa. 3) with battery losses of 25 % from the February week. In contrast to the analysis of the HCmod in December and the PVC in February whose results are only measured, the HCmod with PV from February (HCmodPV) is a combined measured and simulated variant.

Fig. 3 shows the course of the PV production and the total energy consumption in the February week as well as the total energy consumption in the December week. The total energy consumption includes household electricity, MHPs and DHW-HPs electricity. In general, the course of the total energy consumption is quite similar in the two compared weeks, but in February there are higher load peaks. Table 4 gives an overview of the compared variants with the sum of measured energy consumption for both weeks.

Table 4: Overview of variants with measured energy consumption in one week in December 2018 and February 2019

Description	HCmod	PVC	HCmodPV
Time period	Week in December	Week in February	mixed
Control strategy	HCmod	PVC	HCmod
Thermal load in kWh	1.502	1.462	1.502
DHW load in kWh	543	675	543
Electrical load in kWh	480	483	480
PV production in kWh	255	1.191	1.191

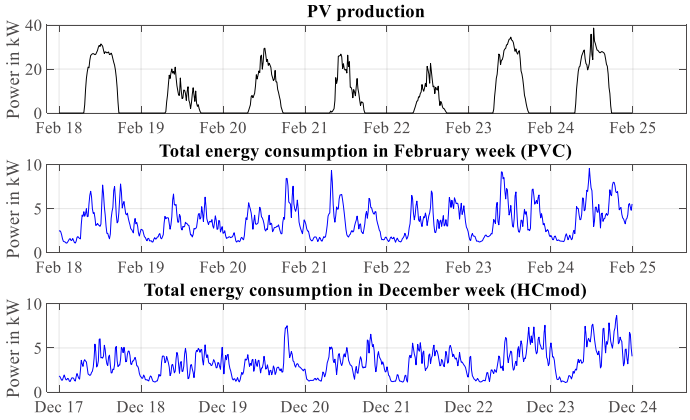

Fig. 3: Course of PV production in February week, total energy consumption of February and December week

The results of the comparison are shown in Fig. 4 and Fig. 5. In general, the total energy consumption of the PVC in February is higher (see Fig. 5 right) and a clear comparison of the variants, regarding operating costs, is not possible. Comparing the PV self-consumption of the variants PVC and HCmodPV, the PVC can increase the PV self-consumption up to moderate 4.1 %. On the other hand a higher grid feed-in of 6.7 % is visible in variant HCmodPV. The results for direct PV, battery load and unload and grid consumption do not vary a lot between the two variants.

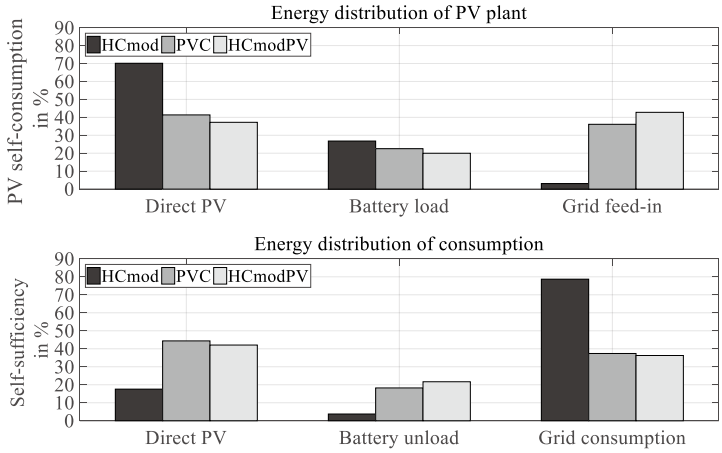

Fig. 4: Energy distribution regarding PV self-consumption and self-sufficiency, measured in variant HCmod and PVC and as well as combined measured and simulated in variant HCmodPV

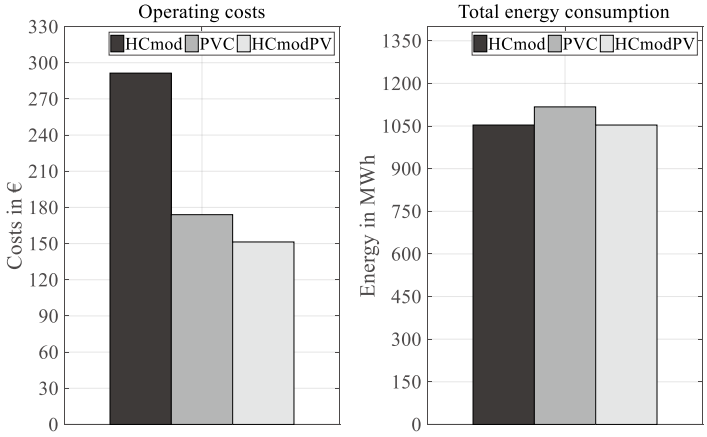

Fig. 5: Operating costs and total energy consumption, measured in variant HCmod and PVC and as well as combined measured and simulated in variant HCmodPV

Conclusion

In this research, two advanced control strategies, a PV rule based (PVC) and a model predictive control (MPC) are developed and compared in simulation with two different heat controlled strategies. Furthermore, the PVC was implemented in real application in eight terraced houses and was compared to a heat controlled operation.

In the simulation study, the control strategies of PVC and MPC increase PV self-consumption with low effect up to 2.1 % and reduce operating costs up to 36.1 % compared to a heat controlled strategy (HC) with on/off heat pumps. However the cost savings mainly result from less energy consumption of a more efficient operation of modulating HPs in part load. Table 5 shows the relative reduction of total energy consumption and cost savings and the relative increase of PV self-consumption and of the Seasonal Performance Factor (SPF) compared to the HC. A heat controlled strategy with the ability to modulate the HPs (HCmod) can easily compete with the advanced control strategies, and even gets partly better results as the PVC.

The influence of the advanced control strategies, PVC and MPC, on PV self-consumption and operating costs is limited. The actual PV and battery prices can not compete to reduce the energy costs significantly because the electricity price for grid and the feed-in tariff offer the economically attractive option to use the public grid as an electricity storage. An energy efficient operation in part load operation of the MHP, as shown in the HCmod, has higher influence than advanced control strategies, increasing PV self-consumption. In further research work, electricity prices are investigated to give an economically attractive solution for PVC and MPC.

Table 5: Relative energy reduction of total energy consumption and cost savings as well as relative increase of PV self-consumption and SPF compared to HC

	Energy reduction	Cost savings	PV self-consumption (without battery)	SPF
HCmod	-9.2 %	-33.9 %	-0.7 %	26.9 %
PVC	-7.1 %	-29.0 %	1.2 %	19.7 %
MPC	-11.8 %	-36.1 %	2.1 %	37.2 %

For comparing the operation of HCmod and PVC regarding PV self-consumption and operating costs in real operation, two periods are analyzed in the monitored terraced houses. The first time period is a week in December 2018 with low PV production, in which the MHPs operated only in grid mode (HCmod). The second time period is a week in February 2019 with higher PV production, in which the MHPs operated every day in PV mode (PVC). To compare the influence of the PVC on the PV self-consumption and the operating costs, the PV production of the December week is replaced by the PV production of the February week (HCmodPV). In general, this method represents a possibility to approximately compare HCmod and PVC mainly with measurements without using detailed simulation tools. The results of PVC show an increase of PV self-consumption of moderate 4.1 % compared to the HCmodPV. As well, the relative parts of battery load and unload and grid consumption do not vary a lot between PVC and HCmodPV. The influence of the PVC is also limited as the course of the total energy consumption in the December and February week are quite similar. In both weeks higher energy consumption occurs during the day and fits to periods of PV production.

In general, the total energy consumption of the variant PVC in February is higher and a clear comparison of the variants, regarding operating costs, is not possible. However under unfavorable assumption, that the additional consumption of the PVC was consumed by grid electricity and thus the highest price is taken into account, the operating costs of the PVC are still 1.5 % higher than the operating costs of the HCmodPV.

As shown in the simulation study and in the comparison of real operation, advanced control strategies increase PV self-consumption in a moderate amount. Furthermore, regarding the operating costs with the assumed electricity prices, it becomes clear, that an energy efficient operation of (modulating) heat pumps has higher influence on operating costs than the increase of PV self-consumption. Under these conditions PV or MPC driven control strategies are not able to compensate an inefficient operation during PV production by cost savings due to higher PV self-consumption.

Application of the DevOps methodology on heat pump controllers

Markus Nürenberg[a], Stephan Göbel[a], Philipp Mehrfeld[a], Dirk Müller[a]

Abstract

In the work, we show how the DevOps methodology supports the development of heat pump (HP) systems. Modern software development and operation control uses the DevOps method to roll out quickly new software, while keeping an overview of the effects and changes. These features are also applicable for HP controller software. Since rolling out new software to customers is a risky task, the deployment stage of the DevOps cycle runs additional hardware-in-the-loop (HiL) experiments first. If the result is sufficient, the next stage is carried out. Evidently, this requires a high level of automation. On the software side, we use the GitLab CI/CD infrastructure to validate software under static and dynamic measures. Once the HP software is ready to run on a real refrigerant circuit, it is automatically deployed to one. The HP within the HiL setup continues to run with the new software. Since the HiL experiments perform in real time, a continuous observation is necessary to abort the experiment once it fails. Thus, the HiL test bench requires a complex data handling and processing infrastructure.

1. Introduction

In this paper, we propose the use of the DevOps methodology to build the next generation of HP controllers. Various work (e.g. [1] and [2]) shows that more sophisticated HP controllers will achieve a major step towards more efficient HP systems. HP manufactures are bound be the obligation that their products shall work for several years, which implies a robust system. Within the software development domain, a uniformly and automatic testing of algorithms is state of the art [3]. Thus, controller software should also be designed and tested according to these standards. However, in the domain of HP software development we often find manually tested software. Especially, when software is applied on machines (like a HP) we have to assume a curtain amount of complexity. This even increases, when we add more components to a HP system and couple the on a data a hydraulic level. Disturbances permute thou the system and the controller work against that. The developer is not aware of all disturbances in advance, therefore, laboratory and field tests have to be conducted. Especially the dynamic behavior of the HP system is still not completely described by simulation. Therefore, HiL experiments are powerful method to gather a useful amount of data from a system under realistic conditions.

2. The DevOps mythology

The DevOps mythology is a relatively new concept within the agile work methods. The name “DevOps” consists of the two words “Development” and “Operations”. Development represents the whole process of factoring software code until the deployment phase. Once software is deployed, operations takes over. Typical

services are technical support, distribution of software, collecting user and technical feedback. In the best-case scenario these information then find a way back to the development department. The DevOps approach now forces these units together into a continuous workflow. However, this usually applies for software produces and services, but for hardware products. Especially for those who have a live span of a decade. The following graphic illustrates the DevOps concept. Starting in blue with the "Plan" phase of the development branch. In the next two phases, software is created and tested. After various successful tests the software is prepared for the deployment. In the "Release" and "Config." phase, the software is rolled out and databases and servers are reconfigured to match new requirements. During the "Monitoring" phase, the operations team gather data regarding the penetration of the update but also the feedback from costumers and their systems. These information lay the basis for further feature or fix development, which closes the cycle.

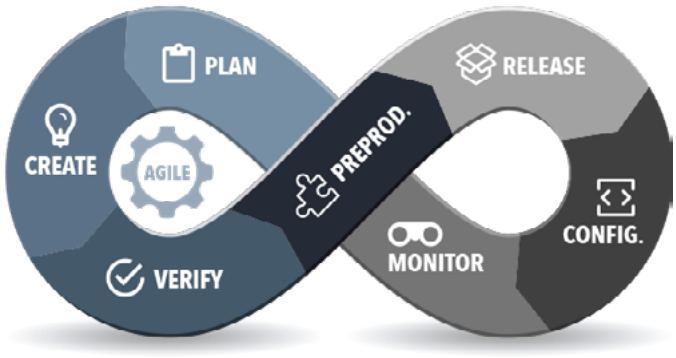

Fig. 1. The DevOps cycle [4]

3. DevOps for HP controller development

We will now propose the application of this DevOps methodology onto the development of a HP controller. Hereby, the controller could just be controlling the refrigerant cycle or the whole HP system, which consists of more other actors and sensors (e.g. pumps, storage temperature, etc.).

The start of our DevOps cycle is again the plan phase. Here, features are pronounced or derived from a requirements engineering process. Zia Babar [5] describes the process in his work. From a market research, customer surveys and user input a product backlog derives. After a grooming of the product backlog this merges into a planning release. However, smaller changes, parameter studies or design of experiments (DoE) studies, such as Mehrfeld [6] used to determine the influences on the seasonal performance of HP systems, can also be set up. If the changes is not based on a simple technical solution but more a holistic request such as "better system performance" or "faster defrost cycle", we will need to translate this into a technical problem first. One of the challenges during this process is the use of different languages, which are brought by the experts of different domains. For example has the word "faster" a different meaning in the field of thermal building processes than on an electrical scope. Therefore, a clear description of the changes and the expected is necessary and can be achieved by creating a specific "definition of done". In addition, the use of issue temples supports this process and ensures that all information, necessary to the task, are available. In fact, there are several platform tools available to support one in this task. We use GitLab as it supports the whole DevOps cycle and is hosted by the university.

After the planning, the coding process starts. Whether it is done in a high-level language such as C/C++ or with an interpreted language such as Python or Java, the source code needs to be available on the platform to run the next steps fully automated. Usually, for each issue a new branch of the project is created in order to separate contributions to different issues. All changes in the software code are committed and pushed to the platform. An ".yml" configuration file (depending on the platform) than leads through the following phases. In case of a parameter study or DoE automated code generation performs this step multiple times. Hereby, we use the CI capability of GitLab to start multiple tests sequences. These sequences are labeled pipeline and can

be tagged with various attributes to route their further way. The following graphic (Fig.2) illustrates the transition from the creating phase to the testing or verifying phase.

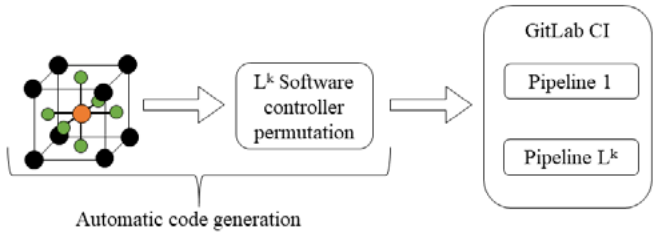

Fig. 2. DoE process as part of DevOps phase. L = Levels, k = number of factors

In this example automatic code generation sets up L^k permutation of the controller. For k being the number factors we want to change and L the number of levels each factor is set to. For a parameter study with no changes to the functionality or structure of the code, the first step of testing would be a simple unit test. When other changes are made, it is wise to run some static code tests first. Figure 3 illustrates a series of test, which can be performed to make sure the controller code matches the company standards towards naming and avoids security issues and common errors. Since errors are recognized before detecting them in expensive hardware tests that even might break the device under test money can be saved.

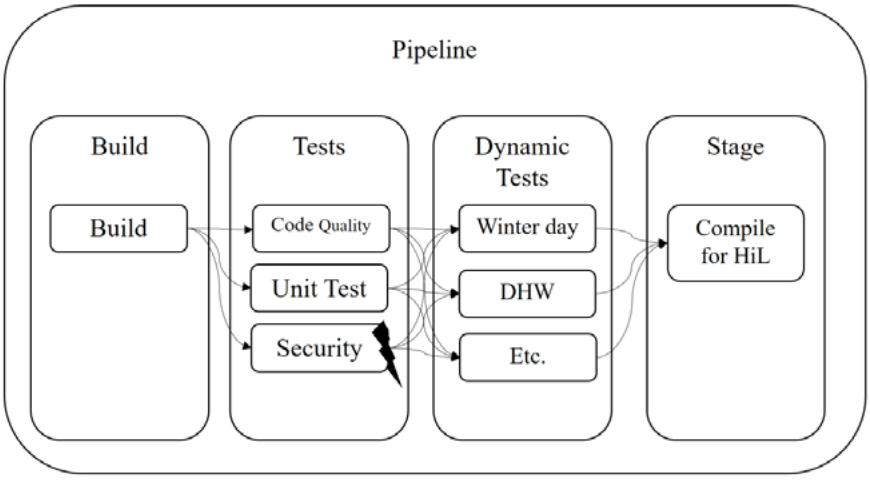

Fig. 3. Pipeline with four stages. Some of the tests are parallel, in order to skip them if necessary. In this case the security test fails but the process continues anyway. After dynamic performance tests a release candidate is compiled to run on the HP controller. The process chain ends with this stage. A HiL experiment toolchain is now able to pull the controller.

These static tests can run in sequel, parallel or as a combination. This depends on the usage of the test result. If the failure of a test represents an abort criteria, there is no need in pursuing any further test. In the example, a security test fails because of a hard coded ip address. This would not be acceptable for production, since the test is tagged accordingly for development, the testing continuous anyway. After the completion of all static tests, the unit testing starts. In a test driven development unit tests are written beforehand. This means, that any code that satisfies the test is consider acceptable. Therefore, the creation of unit tests should be done thoroughly. When focusing on the HP controller the following unit tests should be considered:

- Test for faulty input
    - This tests checks whether the controller reacts correctly to faulty sensor input (e.g. cable break) and if the HP then goes into the correct save or failure mode.

- Test for refrigerant cycle working envelop
  - The refrigerant cycle is bound by the chemical properties (decomposition risk) of the refrigerant and physical properties of the components (burst or vacuum limitations). Here, the temperature and the pressure of the refrigerant are to be handled by the controller within a working envelop.
- Test for correct state switches
  - When working with a state machine the transient conditions allow a step from one to the other state. This test should check if the conditions allow a correct operation or if a deadlock occurred.
- Test for critical comfort conditions
  - This test checks if comfort conditions like domestic hot water and space heating temperatures are met.
- Etc.

Most of these tests can be designed as a rule based sequence. If time constants or timers are involved in the controller function the test framework needs to be able to speed up the internal time, since tests would take too long to finish in real time. This quality is fundamental for any dynamic testing. With these kind of tests we do not only want to determine if a controller works, but how good according to several KPIs.

We use Modelica as modeling language and the ”Functional Mockup Interface” (FMI) [7] to connect the controller to a virtual environment. The FMI standard would allow us to use different modeling approaches as well. The models can vary from simple weather input to tapping profiles to building simulation with the duration from hours to months. If possible, a time clustering should be applied to shorten the simulation time, as Schütz et al [8] described.

If all tests are positive, the software candidate is passed to the next phase. This one is called preproduction and marks, in our case, the link between the virtual testing and hardware testing. The platform builds the controller software for the target HP platform. Thus, all libraries and additional software must be present or the process takes a detour to a manufacture’s building process. This might be necessary when third party intellectual property is involved. Figure 4 illustrates the building phase with known e.g. open source software and company owned closed source software.

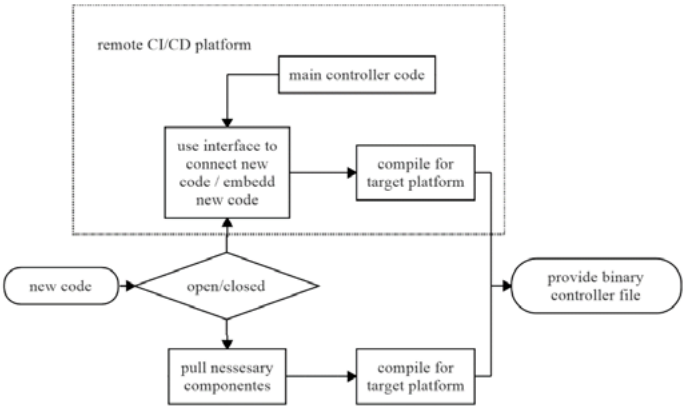

Fig. 4. Process of new code being added to the main controller code. Lower path for known e.g. open code. All necessary components such as libraries or the main code are pulled from registers and compiled according to the target systems’ specifications. The upper path couples a remote CI/CD platform or runner to the process. The main code or any library is unknown. The new code is either embedded into a function or uses an interface to connect to the main code. The code is then compiled by the remote system and a binary file of the controller is provided.

At this point we take the testing to our laboratory, which is equipped with a hardware-in-the-loop infrastructure. There, a HP system is set up according to the release plan. This marks the next phase of the DevOps cycle. This phase determines who will when get which update. When distributing updates to multiple

devices, it might be helpful to do so in waves. Hereby, occurring issues will not affect all devices at one time. Since we are focusing on one HP the HiL infrastructure will run one test at a time. The following figure 5 illustrates the digital setup of the HiL infrastructure. The config phase of the DevOps cycle stets up the production environment, in our case the HiL experiment. A service runner configures all software entities according to a predefined test plan.

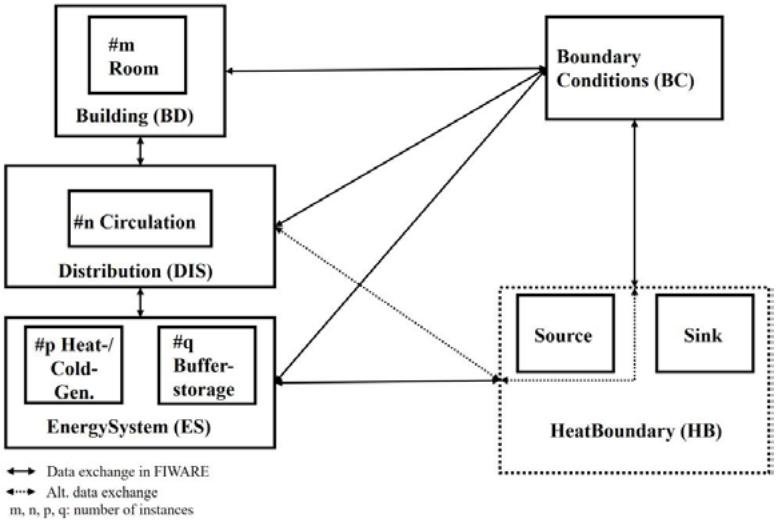

Fig. 5. HiL digital infrastructure. Each component is capsulated and is represented by hardware measurements or a simulation. The entities communicate via MQTT [9] within the FIWARE [10] platform. The installed HP is operated in a climate chamber (HB Source) and connected to a hydraulic test bench (DIS). The digital image of the HP is located in one ES instance. The building simulation BD operates as virtual sink for the HP system. Where the BC instance provides further conditions such as weather or user occupancy.

After the experiment is set up, the compiled controller is flashed onto the HP. The HP is then configured via automated procedure or manually (e.g. heating curve, etc.). From there on the monitoring phase begins. By gathering various data the experiment is evaluated in real time. Watchdog entities hook themselves onto the data streams and calculate various KPIs. In addition, they monitor the test bench behavior. Is either the test bench out of its limitations or a KPI is outside its acceptance, the experiment can be aborted early. The data is stored in a time series database and available for debugging. From there a decision can be made is the experiment and therefore the controller function or parameter set is an improvement and worth to be pursued. From here the DevOps cycle starts again with the planning phase.

4. Conclusion

In this paper we shine a spotlight on the possibilities of the DevOps for HP controller development. We start off with the general introduction of the DevOps methodology in the software development domain. Followed by a use case in the field of HP development. Hereby, we suggest an automated code generation for parameter studies, with creates a full factorial set of controllers, which have to be evaluated. Since the controller software is hosted on a CI/CD platform the following phases of the DevOps cycle are driven by the platform. After a series of tests and evaluations of the code, its performance or even feasibility is tested by dynamic simulations. Candidates, which outperform predefined KPIs are staged for a HiL infrastructure to be tested. A semi-automated process sets up the HiL experiment, while an extensive monitoring evaluates the experiment in real time. This data can then be used to measure the success of the implementation or be the basis for further work.

Three Years' Performance Monitoring of a Mixed-Use Ground Source Heat Pump System in Stockholm

Jeffrey D. Spitler[a, *], Signhild Gehlin[b]

[a]School of Mechanical and Aerospace Engineering, Oklahoma State University, Stillwater, Oklahoma, USA
[b]The Swedish Geoenergy Center, Box 1127, 22104 Lund, Sweden

Abstract

The student center, Studenthuset, at Stockholm University in Stockholm, completed in the fall of 2013, is a thoroughly instrumented mixed-use 6300 m^2 four-story building. Space heating and hot water are provided by a ground source heat pump (GSHP) system consisting of five 40 kW off-the-shelf water-to-water heat pumps connected to 20 boreholes in hard rock, drilled to a depth of 200 m. Space cooling is provided by direct cooling from the boreholes. The Studenthuset building monitoring project is part of the IEA HPT Annex 52 – *Long-term performance measurement of GSHP systems serving commercial, institutional and multi-family buildings*. This paper presents results from three years of measured performance data to calculate the long-term performance of the Studenthuset GSHP system. A number of performance indices are calculated and presented to describe the short-term and long-term system performance for selected system boundaries. Seasonal, monthly and binned performance coefficients for both heating and cooling operation are presented and discussed. The Legionella protection system, hot water continuous circulation system, and internal heating/cooling distribution system reduce the system energy performance.

Keywords: Ground source heat pumps; performance monitoring; COP; SPF; system effects

1. Introduction

It is well known that many building heating and cooling systems consume excess energy due to errors in design and installation, as well as non-optimal operating and control settings. Such problems may not be detected and mitigated for months or years, unless performance measurements are made. Despite the obvious need for better knowledge and means to secure optimal energy performance in buildings, published results from long-term performance monitoring of building energy systems are scarce.

Gleeson and Lowe [1] reviewed field measurements of heat pump systems for residential buildings, mainly single-family buildings, comprising 600 heat pump systems in six European countries. Of these 216 were ground source heat pump (GSHP) systems. There are few published long-term performance measurements of larger, non-residential GSHP systems. Spitler and Gehlin [2] give an overview of published long-term ($\geq$ 1 year) measured SPF and COP values reported in the literature for 55 GSHP systems worldwide. Such systems are necessarily more complex than GSHP systems for small residential buildings, and often include both heating and cooling as well as supplementary heating and cooling sources and heat recovery. With this in mind, a four-year international collaboration project IEA HPT Annex 52, *Long-term performance measurement of GSHP systems for commercial, institutional and multi-family buildings* [3] was initiated in 2018 with the aim to monitor and analyze the long-term performance of a large number of ground source heat pump systems in several countries. The emphasis is on heat pump and system performance, e.g. determining coefficients of performance, seasonal performance factors and other system efficiency indices.

* Corresponding author. Tel.: +1 405 744 6578.
E-mail address: spitler@okstate.edu.

One of these long-term performance monitoring projects within IEA HPT Annex 52 is the GSHP system at the student union building Studenthuset at Stockholm University in Sweden. Gehlin et al [4] and Spitler and Gehlin [2] analyze performance data for one year of operation (April 2016-March 2017) at Studenthuset including a detailed uncertainty analysis. The analyses include seasonal performance factors and monthly, daily, and binned average values of coefficients of performance. This paper aims to extend the analysis to include 45 months of monitoring (January 2016 through September 2019) and further investigate the correlation between performance factors and load provided.

1.1. Studenthuset building and GSHP system

The student union building Studenthuset is located within the large campus area of Stockholm University in central Stockholm, Sweden. The 6300 m^2 four-story building was completed in the fall of 2013 and contains office area, meeting rooms, study-booths for students and a café. The building services are thoroughly instrumented and maintained by highly skilled staff.

Space heating and hot water are provided by a ground source heat pump (GSHP) system consisting of five 40 kW off-the-shelf water-to-water heat pumps connected to a borehole field. Space cooling is provided by direct cooling from the boreholes; with the maximum fluid temperature leaving the boreholes not to exceed 16°C. Heat distribution inside the building is provided by radiators with a larger-than-usual surface area so that the distribution temperature is 40°C instead of 55°C, which is more common in Sweden. Cooling distribution is done by a combination of VAV-system (variable air volume) and CAV-system (constant air volume) with chilled beams for ventilation and cooling. The system also includes heat recovery from the kitchen cooling circuit. No auxiliary heating or cooling is installed, except for an electric resistance heater that boosts the hot water temperature to protect against Legionella.

The borefield consists of 20 groundwater-filled boreholes in hard rock, drilled to a depth of 200 m, and fitted with single u-tubes filled with an ethanol/water mixture. The borefield is located below a landscaped courtyard. The boreholes are drilled at an angle so that they reach under the surrounding building (Figure 1).

1.2. System performance indicators

Performance of a GSHP system and its individual parts may be indicated in various ways depending on the purpose of the performance analysis, e.g. energy performance, technical performance and economic performance. The overall system performance is affected by the performance of the source side ground circuit, as well as the heat pump (HP) unit performance and the load side circuit performance, including supplementary heating and cooling. Energy use intensity (EUI), often expressed in kWh/m^2, is an example of a commonly used performance indicator for building heating and cooling systems. However, it does not differentiate between the effects of the building envelope, its usage, and the performance of the heating and cooling system. Therefore, it gives little information about GSHP system performance. For GSHP systems, system coefficients of performance (COP and SCOP), energy efficiency ratio (EER and SEER) and seasonal performance factors (SPF) with various boundaries are used, however not in a consistent way [2]. Gehlin and Spitler [5] discuss target groups for GSHP system performance and indicators at various system levels identified by the IEA HPT Annex 52 workgroup. Such indicators, some of which we will use in this paper, are performance factors (PF) with a clear indicator of the time period (seasonal, monthly, weekly, daily, or binned – SPF, MPF, WPF, DPF, BPF) and with subscripts that correspond to the boundary conditions, e.g. H1, C4. Another type of performance indicator is the building energy signature, which shows the building heating and cooling loads at various

outdoor air temperatures. The ground heat exchanger pressure drop and exiting fluid temperature (GHE ExFT) variation over time (seasons and multiple years) give indications such as of possible ground source circulation failure and ground heat balance.

1.3. System boundaries

One reason of the confusion in GSHP performance literature, pointed out by Spitler and Gehlin [2], is the inconsistent or non-existent declaration of chosen system boundaries for performance evaluation. Within HPT Annex 52 the system boundary schema developed within the EU project SEPEMO [6] was used for calculation of COP and SPF as a starting point. The SEPEMO boundary schema was therefore used in the performance calculations of the Studenthuset operation in 2016 by Gehlin et al. [4] and Spitler and Gehlin [2]. The SEPEMO boundary schema was aimed at small monovalent or bivalent heat pump systems and has limitations when accounting for the complexity of larger GHSP systems such as Studenthuset. HPT Annex 52 has therefore proposed a new system boundary schema [5], consisting of six defined boundaries and an indicator for use of supplemental heating or cooling. This system boundary schema is used in this paper for the evaluation of the Studenthuset operation over the period January 2016-September 2019 (Figure 2). The Annex 52 boundary schema and its relation to the SEPEMO boundaries is shown in Table 1.

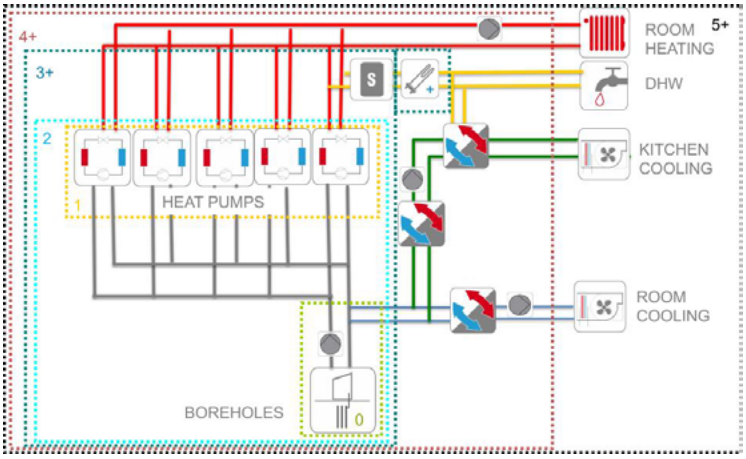

Fig. 2. Schematic and Annex 52 system boundaries for Studenthuset.
Pictograms in drawing used with permission from TU Braunschweig IGS.

Table 1: System boundaries according to the HPT Annex 52 schema and comparison with the SEPEMO boundaries. From [5].

Boundary description	HPT Annex 52 Boundary levels											
	0	0+	1	1+	2	2+	3	3+	4	4+	5	5+
Ground Source (circulation pumps+ ground source)	X	X			X	X	X	X	X	X	X	X
Heat pump unit including internal energy use, excluding internal circulation pump			X	X	X	X	X	X	X	X	X	X
Buffer tank (including circulation pumps between heat pump and buffer tank)							X	X	X	X	X	X
Circulation pump on load-side (between buffer tank & building H/C distribution system)									X	X	X	X
Building H/C distribution system											X	X
Auxiliary heating or cooling		X		X		X		X		X		X
Equivalent in the SEPEMO boundary schema			H1/C1		H2/C2	H3					C3	H4/C4

For Studenthuset the following performance factor levels exist and can theoretically be determined for the heating system; H0, H1, H2, H3+, H4+ and H5+. However, the available measurement data only allows for

H1 (approximately), H2, H3+ and H4+ to be calculated. For the cooling system C0, C2, C3, C4 and C5 exist, but only C2, C3 (C2 and C3 are the same for this system) and C4 are possible to calculate from the available measurement data with a sufficient degree of accuracy. There is no cooling machine in the cooling system and no supplementary cooling.

2. Measurements and Analysis

2.1. Instrumentation

Compared to many buildings, the Studenthuset GSHP system is extensively instrumented. There are, unfortunately, no measurements made of airflow rates, so it is not possible to estimate either the heating or cooling provided to the ventilation air or the building by the heat recovery systems, which means that level 5 performance factors cannot be determined. The level 1 boundary for heating cannot be calculated without also including internal electricity use in the heat pump unit, i.e. internal circulation pump and control board. We therefore denote the performance factors for level 1, included its internal electricity use, with an asterisk. With the existing measurements, it is possible to estimate performance factors for the Annex 52 boundary levels 1*, 2, 3+ and 4+ for heating, and levels 2 (= 3) and 4 for the cooling.

A full description of the instrumentation is given in [2]. Briefly, heat transfer rates from the heat pumps to the building heat distribution system are measured with an energy meter that determines the heat transfer rate calorimetrically. The heat provided by the heat pumps to the DHW is determined using the volume flow rate measured with a flow meter, the controlled temperature provided by the heat pumps (55°C) and the estimated incoming temperature from the Stockholm water supply based on measurements made at seven different buildings in Stockholm [7,8]. Heating provided by the Legionella protection system is estimated based on a steady consumption of 3 kW of electricity due to the recirculation pump and dissipated energy from the hot water that was continuously circulated around the building, and energy provided by the electric resistance heater to heat the DHW from 55°C to 60°C. The cooling provided by the system is measured with the same type of instrumentation as used for measuring the building heating provided.

The system electrical energy consumption is monitored continuously and recorded on an hourly basis. Electricity use for the five heat pumps including the heat pump that is dedicated to DHW heating and the electricity consumed by the Legionella protection system are measured by one electricity meter. Electrical energy consumed by the heat pumps for boundary H2 is estimated by subtracting the energy consumed by the Legionella protection system.

Electrical energy consumed by the source-side circulation pump was metered along with the electrical energy for fans used for air conditioning, circulation pumps on the load side (distribution), and circulation pumps on the source side (boreholes), as well as electricity used for running the rotary exhaust air heat exchangers in the kitchen and building. A separate set of measurements over a two-week period was made to allow estimation of the electricity used by the source-side circulation pump as a function of flow rate. The electricity used for heating and cooling respectively during those many hours of operation when both heating and cooling are being provided by the system, was allocated based on the amount of heating and cooling provided at each hour.

2.2. Analysis and uncertainty analysis

Estimation of the uncertainty of the performance factors is highly desirable to understand the significance of the results as well as to shed light on design and specification of instrumentation for future monitoring projects. The uncertainty analysis in this study is described in detail in [2]. It involves calculation of the propagation of uncertainties from the physical measurements to the final quantities of interest, and follows the general procedures described by Taylor [9]. The uncertainty in the performance factor calculations are represented with error bars in Figures 4-6 and 8-11.

3. Results

This paper uses measured performance data to characterize the actual thermal performance of the GSHP system over 45 months of operation. Measured data from the period January 1 2016 through October 15 2019, are used.

3.1. Heating and cooling loads

The annual energy loads for space heating (excluding heat recovery), space cooling and domestic hot water (DHW) including the Legionella protection system (LPS) over the measured period are shown in Table 2. The heating load for each of these years is around 200 MWh, which is in accordance with the design heating load. The cooling load for 2018 is nearly 50% higher than the other years due to an exceptionally warm summer in 2018.

Table 2. Annual energy loads 2016-2019

Year	2016	2017	2018	2019 Through Oct. 15th
Cooling (MWh)	111	114	161	107
Heating (MWh)	201	198	214	144
DHW including LPS	16	17	19	17

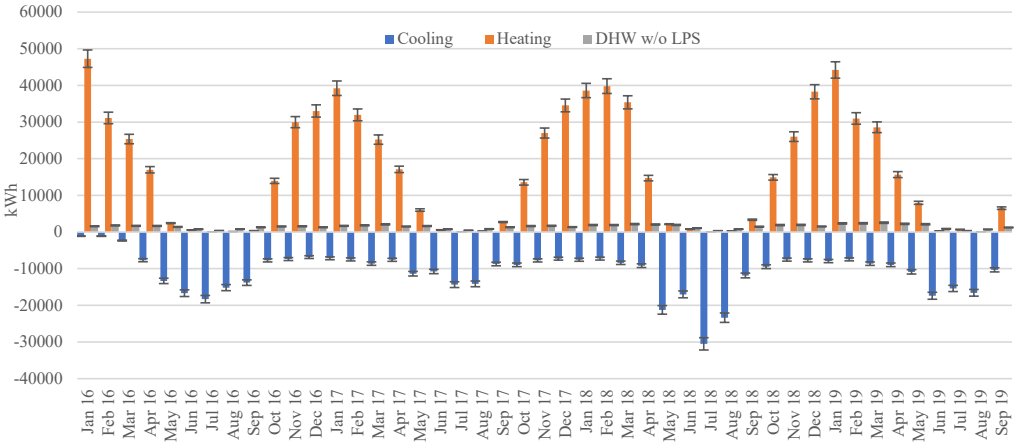

Fig. 3. Measured monthly heating and cooling loads for Studenthuset January 2016-September 2019.
(DHW w/o LPS refers to domestic hot water heating, not including Legionella protection system energy use)

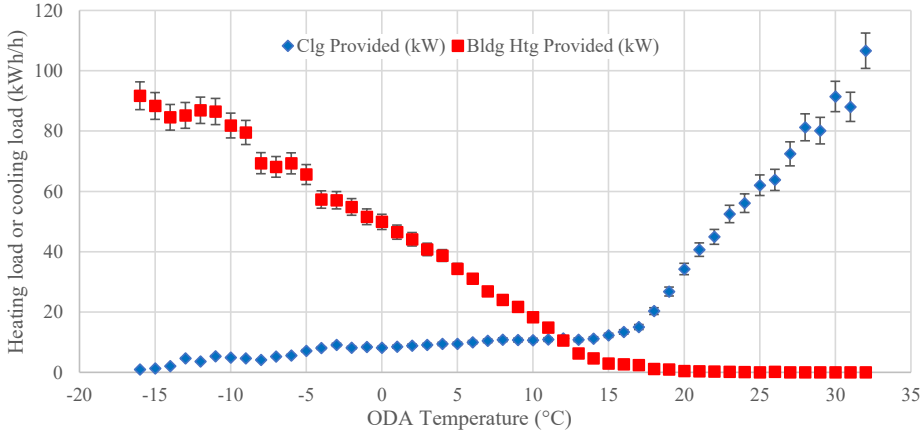

Fig. 4. Measured building energy signature for Studenthuset 2016-2019 with error bars.

Monthly energy loads for the measurement period are shown in Figure 3. Figure 4 shows the building energy signature for Studenthuset, i.e. the heating and cooling load respectively versus outdoor air temperature (ODA). As can be inferred from Figure 3 and 4, heating and cooling is provided simultaneously over a substantial part of the year. The cafeteria in the building requires kitchen cooling throughout the year.

3.2. Monthly Performance

Monthly heating performance factors are presented in Figure 5. In order to keep the figure readable, only sample error bars are shown for January-February and July-August each year. Accuracy is generally good when heating loads are high or when boundaries H3+ and H4+ are used. One notable feature of Figure 5 is that the monthly performance factors are highest in the winter months and lowest in the summer months. This is counter to the expectation that the heating performance factors will be higher when the heat pump entering fluid temperatures are higher.

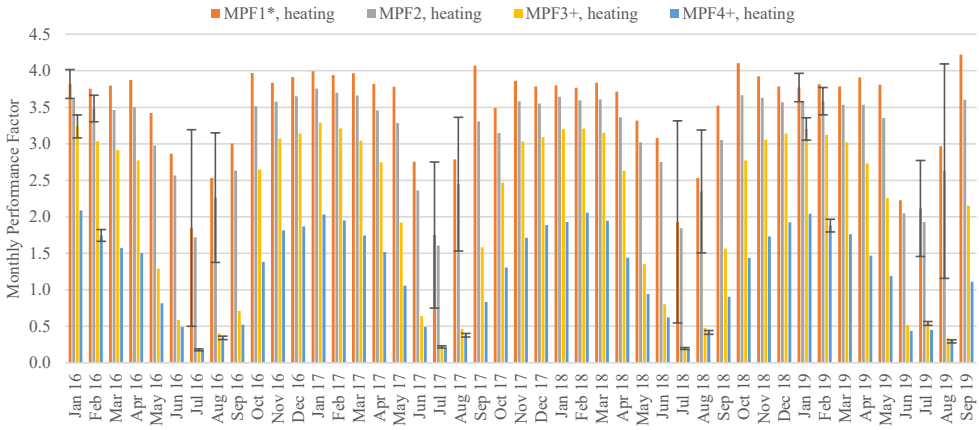

Fig. 5. Monthly heating performance factors with sample error bars, January 2016-September 2019. (The asterisk in MPF1* means that the heat pump internal electricity use is included).

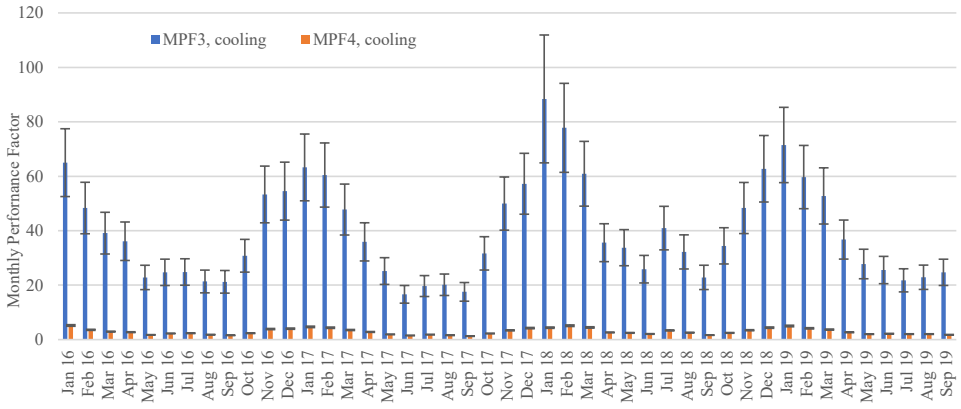

Fig. 6. Monthly cooling performance factors, January 2016-September 2019

Figure 6 shows very high MPFC3, which, in this system, is the same as MPFC2. Because the cooling is provided directly without a heat pump, the only power used at levels C2 and C3 is the source-side circulating pump. Furthermore, because the source-side circulating pump provides both cooling and the source fluid for

heating with heat pumps, its energy consumption is allocated between cooling and heating, thus further lowering the required input energy, and increasing the cooling MPFC3. However, the energy required to distribute the chilled water to the air handling units, accounted for in boundary C4, substantially reduces the cooling performance factors. It may also be noted that the cooling MPFs are higher in the winter months when the ground loop fluid temperatures are lower.

3.3. Seasonal performance

Table 3 summarizes the seasonal performance factors for each boundary. In addition to those presented above, combined SPF for heating and cooling taken together are presented in the last two rows. This avoids the problem of having to allocate pumping power between heating and cooling and, for more complex systems, may make more sense than attempting to determine heating and cooling SPF separately. The SPF calculated for each year are fairly similar, though the unusually hot summer of 2018 significantly increased the cooling load and also increased the cooling and combined SPF values.

One notable feature is the significant reduction in SPF going from boundary level 3 to 4. The only difference is the inclusion of pumping power to distribute chilled water and hot water to air handlers and panel radiators. An interesting, but inconclusive comparison can be made between this system and the ASHRAE Headquarters building GSHP system in Atlanta. [10, 11] This system is a distributed system with reversible water-to-air heat pumps. The reported system heating and cooling COPs for a 2 year-period [10] are roughly equivalent to SPFH4 and SPFC4 and are 3.6±0.3 and 4.2±0.6, respectively. (The ASHRAE system includes the fan energy to deliver the heating and cooling to the space. But, like the Studenthuset system, the ventilation fan energy is not included.) The Studenthuset GSHP system serves about four times the area of the ASHRAE GSHP system; the building energy signatures are significantly different, and the ground temperatures in Atlanta are warmer than in Stockholm. Yet, the ASHRAE system SPFH4 and SPFC4 are both considerably higher than the Studenthuset system. At the very least, this suggests that the pumping power used to distribute heating and cooling in the Studenthuset building is quite high. Whether it could be reduced by modifying the controls settings, or whether the high pumping power is “baked in” by the hydronic design is an open question at this point.

Table 3. Seasonal performance factors 2016-2019. The asterisk denotes that the heat pump internal electricity use is included.

Year	2016	2017	2018	2019 until Oct 15th
SPFH1*	3.8±0.2	3.8±0.2	3.8±0.2	3.8±0.2
SPFH2	3.4±0.2	3.5±0.2	3.5±0.2	3.5±0.2
SPFH3+	2.6±0.1	2.7±0.1	2.7±0.1	2.6±0.1
SPFH4+	1.5±0.1	1.5±0.1	1.6±0.1	1.5±0.1
SPFC2(3)	37±7	37±7	46±9	38±7
SPFC4	2.9±0.2	2.8±0.2	3.3±0.2	2.9±0.2
SPFCH2	5.0±0.2	5.1±0.2	5.6±0.2	5.5±0.2
SPFCH4+	1.8±0.3	1.7±0.3	2.0±0.3	1.8±0.3

3.4. Factors influencing performance

As discussed in Spitler and Gehlin [2] the system performance for both heating and cooling was more dependent on the heating and cooling provided than the ground heat exchanger exiting fluid temperature. This was demonstrated somewhat indirectly by plotting the overall daily performance factor vs. the total daily heating and cooling loads. Here, we have refined the analysis to calculate performance factors that are binned by the amount of heating and cooling provided.

First, Figure 7 shows the monthly average temperature exiting the ground heat exchanger and entering the heat pump, along with the monthly average air temperature. As expected, the fluid temperatures are relatively moderate compared to the air temperatures. The GHE exiting fluid temperatures are slightly higher in the summer of 2018 than other summers due to the increased cooling loads; but, otherwise, the temperature cycle is fairly stable.

Figure 8 shows the binned heating performance factors relative to the ground heat exchanger (GHE) exiting fluid temperature (ExFT). The general trend is that the heating performance factors decrease as the GHE ExFT increases, contrary to expectations based on thermodynamic considerations for the heat pump. BPFH3+ shows

a marked decrease between 10°C and 11.5°C. In this range, the building heating and cooling loads are low; the building heating loads go to zero at 12°C, and so the system heating performance becomes dominated by the domestic hot water heating. As can be seen, at 11°C and above, BPFH3+ and BPFH4+ are below one. This is due to the Legionella protection system, which consumes electricity to heat the water from 55°C to 62°C, and continuously circulates the water, dissipating about 3 kW heat to the building year-round. During the summer months, when there is little or no building heating needed, this energy is wasted, leading to performance factors less than one.

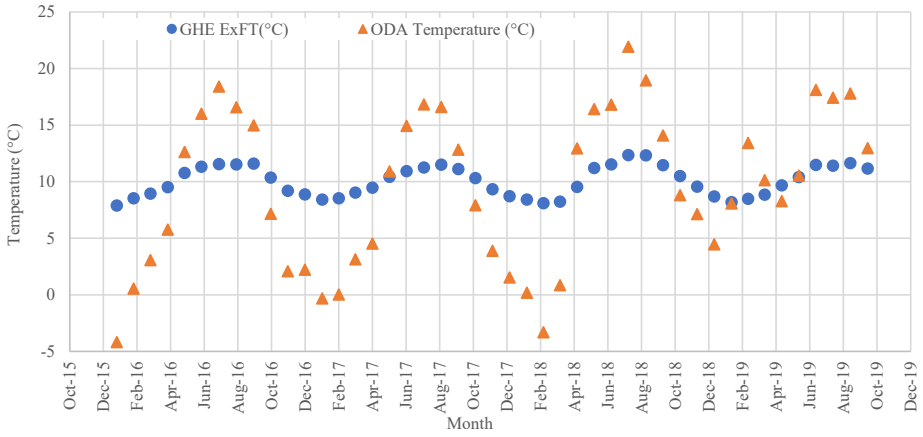

Fig. 7. Monthly average outdoor air temperatures (ODA) and borehole exiting temperatures January 2016 - September 2019

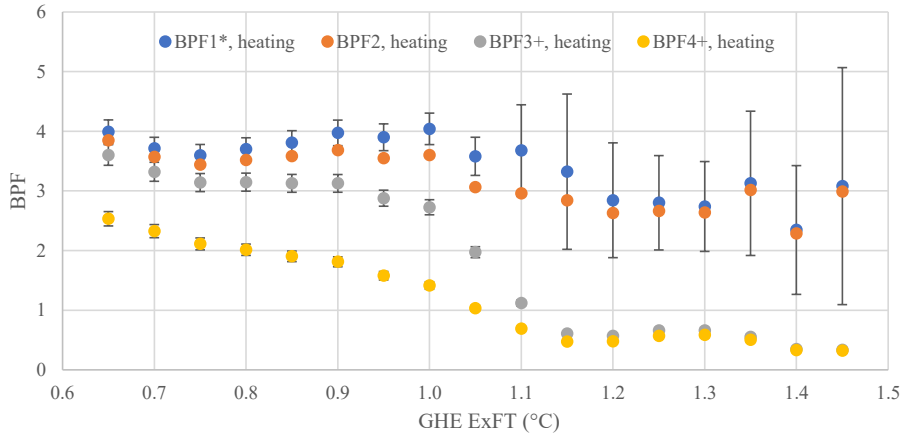

Fig. 8. Heating performance vs GHE Exiting fluid temperature (Error bars have been omitted on BPF2; they are similar, but between 5% and 35% lower than those shown for BPF1* (the asterisk denotes that the heat pump internal electricity use is included). 2016-2019.

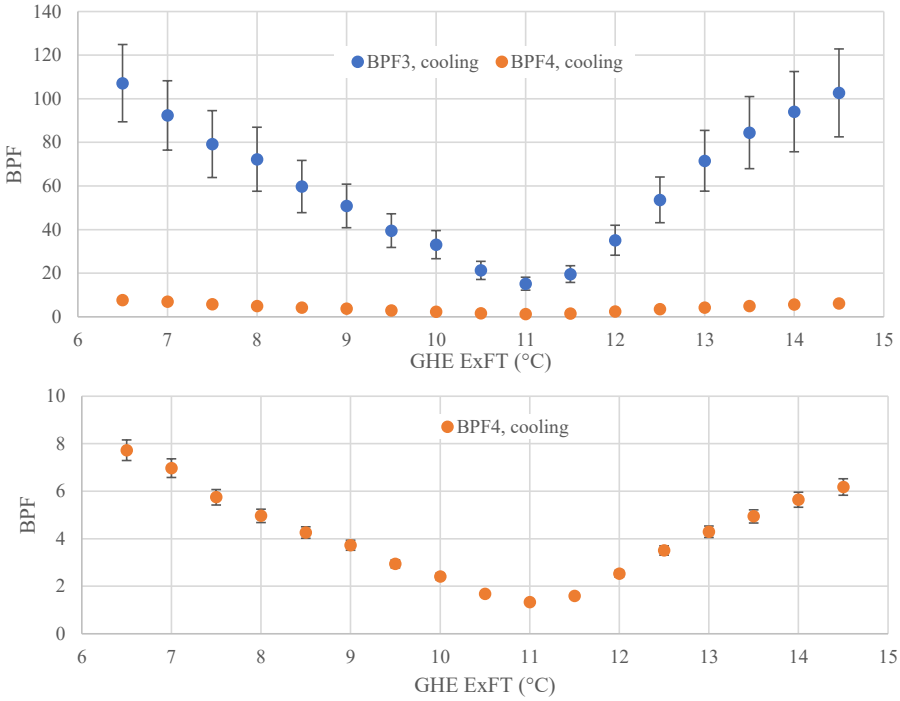

Fig. 9. Cooling performance vs GHE Exiting fluid temperature (°C). 2016-2019.

Figure 9 shows BPFC3 and BPFC4; the V-shaped trend is rather interesting. It is caused by a combination of effects. The cooling load is quite small below 11°C, and most of the pumping power is allocated to heating. Above 11°C, the cooling loads increase significantly. The pumping power also follows a V-shaped trend with a maximum of about 17 kW at both low and high GHE ExFT, and a minimum at 11°C of 11.5 kW. However, when plotted against the GHE ExFT, the pumping does not decrease near as much as the load and the result is the V-shaped profiles shown in Figure 9.

In Figure 10, the heating performance factors have been binned against the heating load. Likewise, in Figure 11, the cooling performance factors have been binned against the cooling load. With the exception of a slight wiggle at 30 kW of cooling provided, the performance factors increase monotonically with the load, demonstrating that the system performance is highly driven by the load. The decrease in the performance with decreasing load has been attributed [2] to cycling losses in the heat pump, parasitic losses within the heat pump (e.g. control hardware), pumping energy, and the use of electric resistance heating. For this system, there is a particularly strong influence of the Legionella protection and DHW recirculation systems, which use 3 kW continuously year-round to circulate hot water around the building.

Another factor is the source-side circulating pump. It is variable-speed, but the lower limit of flow is kept at 8 L/s and the pump uses about 1 kW. This relatively high lower limit often results in a very low temperature difference across the ground loop and continuous power consumption of 1 kW, even when the load is very low.

This sensitivity of the load is not unique to the Studenthuset building. Other systems with measured performance data, including a distributed GSHP system in the US [10, 11] and a central GSHP system in the UK [12] show similar trends.

Possible improvements to the system include lowering the minimum flow on the variable speed control and scheduling the operation of the Legionella protection system and DHW recirculation system. These actions should significantly decrease the energy consumption at low heating and cooling loads.

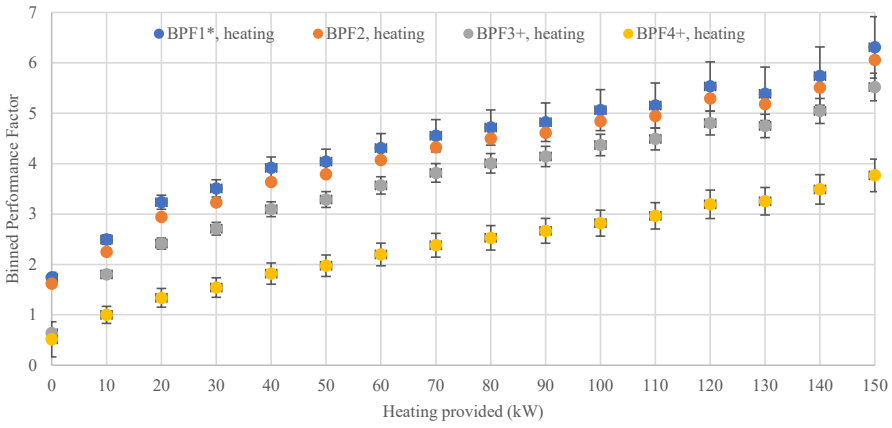

Fig. 10. Binned Performance Factors vs heating load, 2016-2019.
(The asterisk in BPF1* means that the heat pump internal electricity use is included).

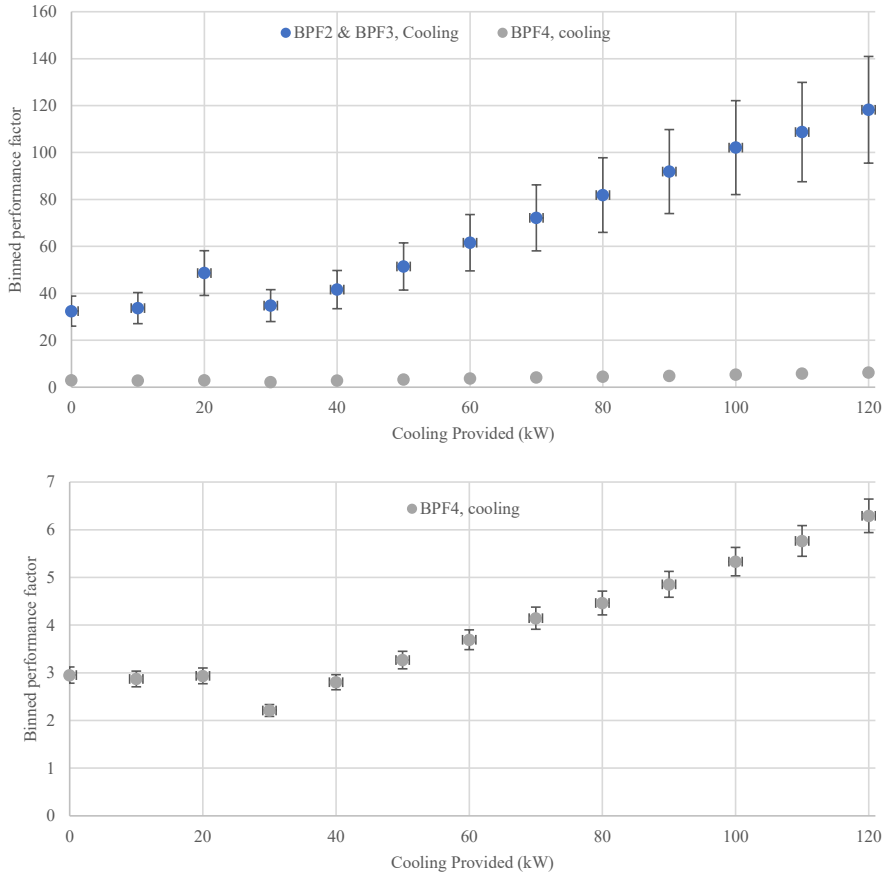

Fig. 11. Binned Performance Factor vs cooling load, 2016-2019

4. Conclusions

This paper has extended the previous one-year analysis [2] of the Studenthuset ground-source heat pump system to nearly four years. For the most part, the trends observed in the first year are still present. The system performance is now more clearly shown to be strongly related to the load – as the load increases, the system performance increases. This also means that the system has relatively poor performance at times when there is little heating or cooling load. A particularly warm summer in 2018 significantly increased the seasonal cooling load, but also increased the cooling performance.

It appears that reducing the minimum flow rate on the source-side (ground loop) circulation pump could improve the system performance at low loads. However, the distribution system that circulates hot water and chilled water from the heat pumps or ground loop to the air handlers and panel radiators consumes much more energy. Improvement of the distribution system could significantly improve the overall system performance. Design engineers, building owners and maintenance staff should take care to minimize energy usage by the distribution system.

Abstract

IEA HPT Annex 52, *Long-term performance measurement of GSHP systems serving commercial, institutional and multi-family buildings*, started in January 2018 and will close in December 2021. Within the annex, a large number of larger ground source heat pump (GSHP) systems in seven countries are monitored and analyzed from a long-term performance perspective. By the end of 2019, 40 GSHP performance-monitoring case studies, located in Sweden, the Netherlands, the UK, Finland, Germany, Norway and the USA, form part of the Annex 52 work. These case studies cover a range of building types, system applications and ground sources. Annex 52 offers unique experience and information on GSHP system performance, which will result in guidance on instrumentation, monitoring, uncertainty analysis, data analytics, performance analysis and suitable performance indices based on international experience. This paper gives an overview of Annex 52, including the active monitoring projects and the work and findings so far.

1. Introduction

The four-year international collaboration project IEA HPT Annex 52, *Long-term performance measurement of GSHP systems for commercial, institutional and multi-family buildings*, has now reached its midway point. As of the end of 2019, seven countries are participating in this annex (Sweden, the USA, Finland, Norway, Germany, the UK and the Netherlands). The aim of this IEA Annex is to monitor and analyze a large number of ground source heat pump systems in several countries from a long-term performance perspective. The emphasis is on heat pump and system performance, e.g. determining coefficients of performance, seasonal performance factors and other system efficiency indices. The results and experience from the many monitoring projects will be used in three annex subtasks. Within the first subtask, an annotated bibliography of previously published long-term monitoring projects reported will be compiled, together with a case study report summarizing all the included Annex 52 monitoring projects. The second and third subtasks will provide guideline documents on instrumentation, monitoring, analysis and key metrics for long-term performance of large ground source heat pump (GSHP) systems.

It is a well-known fact that many building heating and cooling systems consume excess energy due to problems that are only discovered after months or years, and that design decisions and control settings can have significant deleterious impacts on energy efficiency, and yet are poorly understood. Unless performance measurements are made, such problems may never be detected. Table 1 lists possible questions that may be answered by performance monitoring. This Annex is taking steps to standardize methods and analyses that will support widespread performance monitoring of ground-source heat pump systems.

Table 1: Possible questions to be answered by performance monitoring

Possible users	Questions to be answered
Prospective building owners	Is a GSHP system worth the extra investment?
Building owners	Is my system saving me the money that I expected?
Building owners	How does my system compare to other systems in the area serving similar buildings?
Building owners	How well does my system meet environmental criteria and building certification requirements?
Code-writing and regulatory bodies	How can we make informed decisions for energy policy, codes, and regulations?
Consulting (HVAC design) engineers	Do the systems I designed work as well as I expected? What should I do differently next time?
Consulting (HVAC design) engineers	How have other GSHP systems for similar applications in my area worked?
Building maintenance staff	Does my system need attention? Are there any failing components? Has the performance increased or decreased since last year? Is it likely to fail in the coming year?
Building energy managers	Is there room for further improvement in the system, or do we need to address other areas?
Controls engineers	How can setpoints be optimized? What are optimal setpoint values?
Commissioning agents	How does the system work compare to the intended design? Is the system constructed according to design documents?
Equipment manufacturers	How well do my products perform in the field? What market opportunities are there for new products and new features on existing projects?
Environmental Certification and Building Performance Certification Authorities	How can certification programs reward real energy efficient systems and not just planned efficiency or low building energy consumption, which may be due to low occupancy?
Handbook authors	What are best practices leading to highly efficient systems?
Researchers	How can simulation models be validated?

1.1. Performance indicators

The over-all performance of a GSHP system is affected by the performance of the source side ground circuit, as well as the heat pump (HP) unit performance and the load side circuit performance, including supplementary heating and cooling. Within Annex 52 we aim to identify and recommend performance indicators that will allow evaluation on all three levels, from a commissioning point of view as well as for fault detection, system optimization and future system development. Table 2 gives an overview of GSHP system performance indicators at various system levels.

A commonly used performance indicator for building heating and cooling systems is energy use intensity (EUI), typically expressed as annual energy usage of the building per unit area, e.g. kWh/m^2. EUI does not differentiate between the effects of the building envelope, its usage, and the performance of the heating and cooling system. Hence it gives little information about GSHP system performance. For GSHP systems, system coefficients of performance (COP) and seasonal performance factors (SPF) with various boundaries have occasionally been reported in the literature. Such measurements, whether termed COP or SPF, have the advantage of being able to focus solely on the actual system performance without comingling the effects of the building envelope and usage. Within the heat pump industry, certain terms (COP, SCOP, EER, SEER) are commonly used to refer to indices that are calculated based on physical testing of a heat pump unit under one or more conditions in a laboratory. Although these indices often have implications for codes and regulations, some researchers [1-3] have used “COP” or “SCOP” to refer to field measurements. The term “performance factor” is used more widely when referring to field measurements, but it has also been used [4] to refer to calculated values based on testing of heat pumps under multiple conditions in a laboratory. SPF (Seasonal Performance Factor) has also been used to refer to periods shorter than a year, e.g. Wemhoener et al. [5] present a graph with monthly SPF. Given the confusing situation, we plan to use the term “performance factor” with an indicator of the time period (seasonal, monthly, weekly, daily, or binned – SPF, MPF, WPF, DPF, BPF) with subscripts that correspond to the boundary conditions, e.g. H1, C4.

Table 2: GSHP system performance indicator matrix

	Is it as designed? (Commissioning)	Does it work well? (Fault detection)	Could it work better? (Optimization)	Could future systems work better?
Ground source	Do measured ground heat exchanger loads, flow rates and temperatures match design values?	What are the measured ground circuit (level 0) performance factors over seasons, months, days? Temperatures and pressure drop?	Could ground circuit pumps and pump control strategies be adjusted? Are there delay times in on-off mode? Are set-points optimal?	Can borehole thermal resistance be decreased? Could better hydraulic design and lower pressure drop be obtained?
Heat pump unit	Do measured HP entering fluid temperatures and flow rates, match design values?	What are the measured HP unit (level 1) performance factors over seasons, months, days? System Efficiency Index (SEI)? Temperatures and pressure drop?	Could HP unit controls be changed (e.g. control curves and set points) Could the HP be changed?	Could sizing be better? Could internal control be improved?
System level	Do measured temperatures, flow rates, energy signatures, seasonal heating and cooling loads and supplemental heating and cooling match design values?	What are the measured system (level 2-5) performance factors over seasons, months, days? Temperatures and pressure drop? Simultaneous heating and cooling?	Are operation schedules and control set-points for supplementary heating and cooling optimal?	Could better hydraulic design and lower pressure drop be obtained? Could components be improved?

2. Annex 52 achievements

In its first two years, Annex 52 has gathered more than 60 international experts from research institutions and industry at four international experts' meetings and a number of national workshops. The focus has been on selecting and setting up GSHP monitoring case studies in all participating countries and surveying previously published large-scale GSHP long-term performance studies and performance indicators. Based on this work, guideline documents and recommendations are under way. A summary of the Annex 52 outcomes so far follows.

2.1. Bibliography

In partial fulfillment of Annex 52 subtask 1, the participants have compiled an annotated bibliography containing 65 publications describing 55 buildings where long-term performance monitoring of larger GSHP systems has been performed and that contain some form of SPF measurement. A further 18 references describe monitoring of larger GSHP systems that do not go as far as determining any SPF. Spitler and Gehlin [6] present a comprehensive review of this performance measurement literature for large GSHP systems. The authors conclude that nomenclature for performance indicators used by different authors is inconsistent, reflecting a lack of consensus on how to evaluate, express and present performance for complex large-scale GSHP systems. Another conclusion is that existing performance data is far too limited to be useful in setting performance expectations.

2.2. System boundary schema

As a starting point for Annex 52 the system boundary schema developed within the EU project SEPEMO [7] has been used for calculation of COP and SPF. The SEPEMO schema is used for SPF calculations of ground, air and water source heat pumps in the EU renewable energy directive. However, several other similar schemas have been published in the literature. Spitler and Gehlin [6] identified five other system boundary schemas different from the SEPEMO schema. For the most part, these schemas are aimed at small monovalent or bivalent heat pump systems and have limitations when accounting for the complexity of larger GHSP systems used in commercial, institutional and multi-family residential buildings. Though performance

evaluation for most of the case studies included in Annex 52 is still in the beginning stages, it is evident that the SEPEMO boundary schema used for SPF calculation is insufficient for covering the complex nature of large-scale GSHP systems.

Therefore, as part of subtask 3 the Annex 52 group has proposed a new system boundary schema, consisting of six defined boundaries and an indicator for use of supplemental heating or cooling (Figure 1). This system boundary schema is better suited for large and complex GSHP systems of the kind that are the focus of Annex 52. The system boundary schema may be used for seasonal performance factors (SPF), shorter time intervals, e.g. daily, monthly (DPF, MPF), or binned performance factors (BPF). The system boundary schema is an extension of the SEPEMO schema, such that every SEPEMO boundary matches one of the Annex 52 boundaries (Table 3). The proposed schema is now being tested on the 40 included case studies within Annex 52.

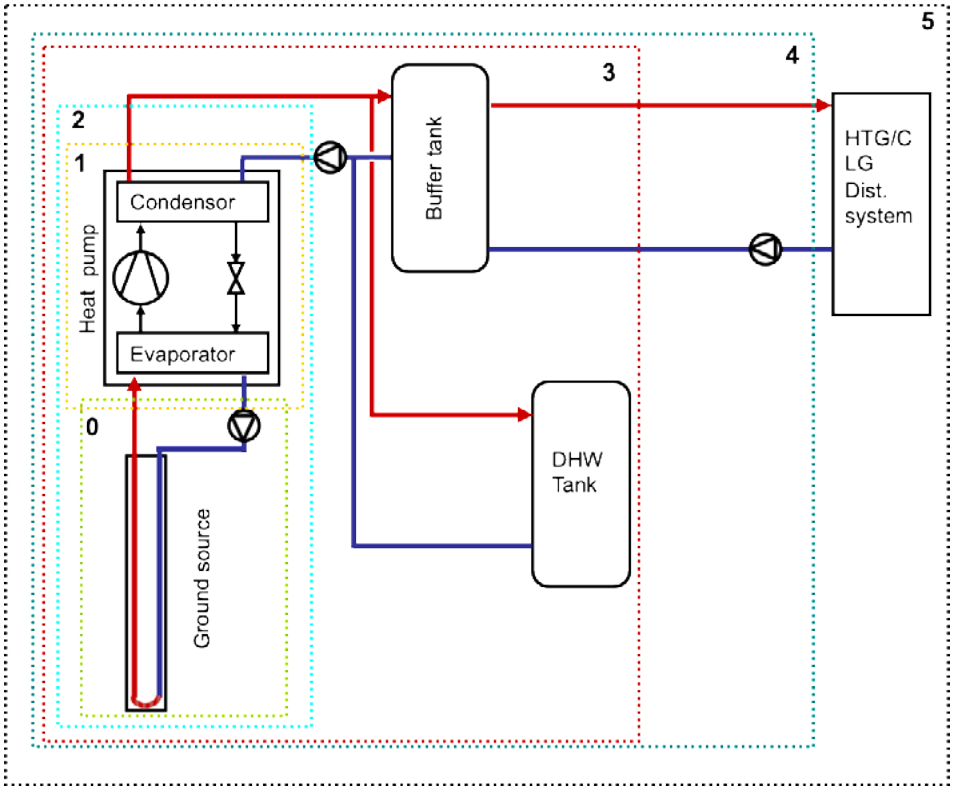

Fig. 1. Proposed Annex 52 system boundary schema. Auxiliary heating and cooling could be added at any boundary level, which will then be indicated with a "+" superscript.

Table 3: System boundary schema comparison of the SEPEMO scheme and the proposed Annex 52 schema for SPF and COP. (Mapping corresponds with having auxiliary heating (H) or cooling (C) only at the same levels as SEPEMO. For the proposed schema, the "+" superscript indicates auxiliary heating/cooling within the boundary).

Boundary description	Boundary levels											
	0	0+	1	1+	2	2+	3	3+	4	4+	5	5+
Ground Source (CP + GHE)	X	X			X	X	X	X	X	X	X	X
Heat pump unit including internal energy use, excluding internal CP			X	X	X	X	X	X	X	X	X	X
Buffer tank (including CPs between HP and BT)							X	X	X	X	X	X
CP on load-side (between BT & building H/C distr. system)									X	X	X	X
Building H/C distribution system											X	X
Auxiliary heating or cooling		X		X		X		X		X		X
Equivalent in the SEPEMO boundary schema			H1/C1		H2/C2	H3					C3	H4/C4

2.3. Case studies

As part of Annex 52 subtask 1, 40 GSHP monitoring case studies, covering a range of applications, located in seven countries, are included in the annex work. Locations and types of ground sources for the 40 case studies are summarized in Figure 2 and Table 4. These case studies, in various stages of completion, will be reported with consistently defined performance indicators in a comprehensive case study report at the closing of Annex 52. Results from several of the Annex 52 case studies have already been published in reports, conference papers and journal papers. These are indicated with an asterisk in Table 4.

Naicker and Rees [8-9] present seasonal system performance factors for the GSHP system serving the Hugh Aston building in Leicester in the UK. Seasonal performance factors are presented for SEPEMO levels C1 and H1, and combined cooling and heating SPF, referred to as SPF1, SPF2, and SPF4, are also defined corresponding to SEPEMO levels H1, H2 and H4. The authors show that cycling losses increase with decreasing cycle time, and that SPF2 and SPF4 are affected by the pumping controls that start the circulating pumps three minutes before the compressors. Several approaches to improving the system performance are identified.

Spitler and Gehlin [6] analyze one year of monitoring data for the mixed-use commercial GSHP system for the student union building Studenthuset at the university of Stockholm in Sweden. SPF values for SEPEMO boundaries H2, H3 and C2 are calculated. The authors show that the system provides space heating consistent with the design values, and that the cooling provided is about four times higher than anticipated in the design. Measured COPs are more affected by the amount of heating and cooling provided than by the entering fluid temperature to the heat pumps. Heating COPs are higher at lower entering fluid temperatures, which correspond to higher run-time fractions for equipment and less influence of “parasitic” loads such as pumps and unit control boards. The Legionella protection system and domestic hot water (DHW) recirculation system run all the time, causing the COP to approach 1 at times in the summer. In addition, the minimum flow rate set point in the borehole circuit leads to excess flow and excess energy consumption by the circulating pump.

The journal papers by Naicker and Rees [8-9] and Spitler and Gehlin [6] provide two sets of high-quality open access measurement data, which may be used by researchers and developers in their future work. Providing at least one set of open access reference monitoring data for a large commercial GSHP system has been one of the important goals of HPT Annex 52.

Results from long-term performance monitoring of two distributed heat pump systems at the ASHRAE Headquarters building in Atlanta in the USA were published by Southard et al. [10, 2] and Spitler et al. [11]. An air-source variable-refrigerant flow heat pump system and a ground-source heat pump system were analyzed and seasonal heating and cooling system coefficients of performance were calculated for the two systems. Because the distributed heat pumps delivered heating and cooling with fans integrated in the heat pump units, and the electrical energy was measured for all heat pumps and the source-side circulating pump together, the coefficients of performance correspond to SEPEMO levels H4 and C4.

The industrial high-temperature borehole storage in Emmaboda in Sweden was operated without heat pumps over several years [12-13]. In 2018 heat pumps were installed. This will improve the possibilities to cool industrial processes and provide improved thermal comfort in the facility. System performance before and after heat pump installation will now be compared.

Boon et al. [14] describe a retrofitted groundwater loop heat pump system at Grangetown nursery school in Cardiff, UK, and its three years of field monitoring. Seasonal performance factors corresponding to SEPEMO level H4 were calculated to be 4.5 over the measurement period.

A first performance evaluation of the early operation of the Rosenborg groundwater heat pump system in Stockholm, mainly focused on the ground source performance, is presented by Abuasbeh and Acuña [15].

Two GSHP systems for multi-family buildings in Stockholm were analysed by Börjesson [16]. One of the buildings was built in 1939 and has been retrofitted with a GSHP system in two steps in 1970 and 2011. This building has supplementary heating with district heating. The other building and its GSHP system were built in 2011 and has supplementary heating from electric heating. Seasonal performance factors over 8 years of operation, corresponding to SEPEMO level H2 and H3 were calculated for the first building and level H2, H3 and H4 were calculated for the second building.

2.4. On-going guideline preparation

Within the Annex 52 subtask 2, instrumentation and measurement guidelines are currently in preparation. The instrumentation guideline document will cover GSHP system-related instrumentation hardware and its installation and associated error and uncertainty, as well as data management with recommendations on measurement intervals and data storage. A draft document has been compiled and discussed; an updated version will be presented in the spring of 2020. Another related useful tool for quantitative evaluation of

monitoring data from GSHP systems is a guide to uncertainty analysis that has been prepared as an aid to the Annex 52 case studies and future performance monitoring studies. This document will be an integrated part of the final instrumentation guideline.

In parallel with the instrumentation guideline, there is on-going work on defining recommended key performance indicators for various system boundaries and performance objectives (Tables 1 and 2). These recommended performance indicators will affect the instrumentation guideline recommendations on instrumentation points.

3. Conclusions

Annex 52, *Long-term performance measurement of GSHP systems for commercial, institutional and multi-family buildings,* aims to provide tools to improve the state of the art, based on wide international experience from 40 case studies evaluated as part of the annex. These tools include an improved boundary schema with complementary performance indicators, guidelines on instrumentation and monitoring, guidelines on analysis and key metrics, a thorough bibliography and a unique case study report with long-term performance evaluation of 40 GSHP systems worldwide, using a harmonized evaluation scheme. The results from Annex 52 will contribute significantly to harmonization and system development of such tools. With these new tools, we hope to prepare the way for widespread long-term performance monitoring to become a useful tool for a variety of end users in the GSHP market, such as the audiences listed in Table 1.

At half-term, Annex 52 has already fulfilled two of its goals – the annotated bibliography of previously published large-scale GSHP performance measurements, and two sets of open access reference data. Updates on the Annex 52 work and results are continuously posted on the Annex web site [17].

Effectiveness-based air flow rate optimization for a residential heat pump in seasonal performance conditions

Minsu Park[a], Min Soo Kim[b*]

[a]LG Electronics Corp., 128 Yeouidae-ro, Yeongdeungpo-gu, Seoul 07736, Republic of Korea
[b]Seoul National University, 1 Gwanak-ro, Gwanak-gu, Seoul 08826, Republic of Korea

Abstract

The conventional rating performance of a residential heat pump system is being replaced by the seasonal performance due to increased demands for the energy saving. In order to achieve the satisfactory seasonal performance, the current system should be modified according to the part load characteristics. Moreover, operating conditions of actuators must be optimized for each test condition to acquire the utmost system efficiency. Fan speeds of both indoor and outdoor units are one of the most significant variable since they are individually controllable and the operating ranges of them are broad. Hence, in this study, effectiveness-based simulation model is introduced to accurately predict the optimum air flow of the system for each seasonal performance condition. The heat exchanger performance is predicted by the modified effectiveness, which can be obtained from the developed non-dimensional correlation. The compressor performance is estimated by the semi-empirical efficiency models. From the verification result, the developed model can estimate the optimum air flow rate within an error of 10% for seasonal performance conditions.

1. Introduction

The amount of energy consumed by HVAC system is the large part of total power supply and thus demands for the high efficiency system have been constantly increased. Heat pump is considered as one of the most efficient device so many researches have been conducted for the performance improvement. Conventional researches have concentrated on the rating performance but seasonal performance is being more important due to the rising usage of an inverter compressor. Therefore, new performance index is required to represent the overall performance in various part load conditions, so European Union introduced the new energy label for SEER and SCOP [1]. As a result, consumers are not interested in the rating efficiency any more but consider the energy grade for seasonal efficiency and thus manufacturers are now focusing on improving seasonal performance. Regarding SEER and SCOP, part load efficiency is significant for seasonal performance so it is inevitable to optimize current system according to part load characteristics [2].

Regarding a compressor, it is required to secure better performance in part load conditions, so the accurate estimation of the efficiency is essential for various operating conditions. For this reason, many researchers tried to estimate compressor efficiencies with various methods. Ishii et al. numerically examined the net efficiency for various geometry [3] and Yang et al. established a model for volumetric and isentropic efficiency with neural network method [4]. Dutra and Deshamps developed an induction motor model for motor efficiency [5]. However, stated models are not appropriate to be applied for any compressor since they are only

* Corresponding author. Tel.: +82-2-880-8362; fax:.
E-mail address: minskim@snu.ac.kr.

valid for the certain compressor. Therefore, semi-empirical efficiency models are developed for the compressor installed in the reference system shown in Table 1.

Regarding a heat exchanger, it is essential to reduce air side thermal resistance for better performance but this enhancement generally augments air side pressure drop [6]. As a result, COP can be deteriorated due to the increased fan power consumption, especially at the low load conditions. Thus, it is required to consider both air side hA and pressure drop for each part load condition. In other words, the optimum air flow rate of each heat transfer condition should be defined to maximize the heat exchanger performance. Lee et al. introduced the simulation-based solution with utilizing genetic algorithm and identified the big difference between the optimized and non-optimized air flow rate under seasonal performance conditions [7]. However, new dataset will be required if specifications of the system are changed. Thus, the author established the simulation model to easily obtain required performance data but it still takes considerable time since iteration processes are included. The calculation time can be drastically increased as iteration loops should be repeatedly conducted for various indoor and outdoor air flow rates. Furthermore, correction factors should be appropriately selected for each correlation to accurately calculate the heat exchanger performance if geometries are changed. The model that has many iteration loops or needs updates for changeable specifications will not be appropriate for a commercial system considering the practical capability of a MiCom in the system.

Hence, this study investigates the non-iterative and universal solution to optimize both indoor and outdoor air flow rates for seasonal performance conditions. The developed model can instantly predict the optimum air flow rate and its accuracy is validated by experiments.

2. Model description

2.1. Heat exchanger model

The modified effectiveness is newly proposed to calculate both sensible and latent heat transfer rate for various heat exchanger geometries. In case of a heat exchanger of the refrigerant cycle, the actual and the maximum heat transfer rate can be expressed as the following Eqs. (1) and (2) [8]. Only two-phase heat transfer is considered for the refrigerant side since the heat transfer mainly occurs at that region. The temperature at the halfway point of a single path is considered as the $T_{ref,sat}$ and the effectiveness for dry condition can be expressed as Eq. (3) for dry condition.

$$Q_{actual} = C_c\left|T_{c,i} - T_{c,o}\right| = \dot{m}_{a,ID} C_{p,a,ID}\left|T_{a,ID,i} - T_{a,ID,o}\right| \tag{1}$$

$$Q_{max} = C_{min}\left|T_{h,i} - T_{c,o}\right| = \dot{m}_{a,ID} C_{p,a,ID}\left|T_{ref,sat} - T_{a,ID,i}\right| \tag{2}$$

$$\varepsilon_{dry} = \frac{Q_{actual}}{Q_{max}} = \frac{\Delta T_a}{\left|T_{ref,sat} - T_{a,i}\right|} \tag{3}$$

Table 1. Specifications of the reference system

Model		AS-W126M, LG Electronics
Performance	Rating capacity [kW]	3.5 for cooling, 4.0 for heating

Indoor Unit	Heat exchanger	Fin and tube, Φ7, 3 Rows, 680 mm
	Fan	Cross flow, BLDC motor
Refrigerant		R410A, 1.0 kg

Table 2. Specifications of heat exchangers

	#1	#2	#3
Fin type	Slit	Slit	Corrugated
Number of rows	3	3	2
Number of steps	16	24	24
FPI	21	22	18
D_o [mm]	7.35	5.20	7.35
L [mm]	680	740	814
P_R [mm]	12.7	10.0	18.2
P_S [mm]	21	14	21

In case of wet condition, the effectiveness cannot be acquired by the temperature difference due to the latent heat, so the effectiveness is defined as the ratio of the actual to the maximum enthalpy difference of air [9]. In order to obtain h_{max}, the enthalpy of the outlet air is assumed to be the smallest when the air wet bulb temperature is equal to the evaporating temperature. The effectiveness can be expressed as Eq. (4) for wet condition.

$$\varepsilon_{wet} = \frac{h_{actual}}{h_{max}} = \frac{\Delta h_a}{h_{a,i} - h_{a,min}} \tag{4}$$

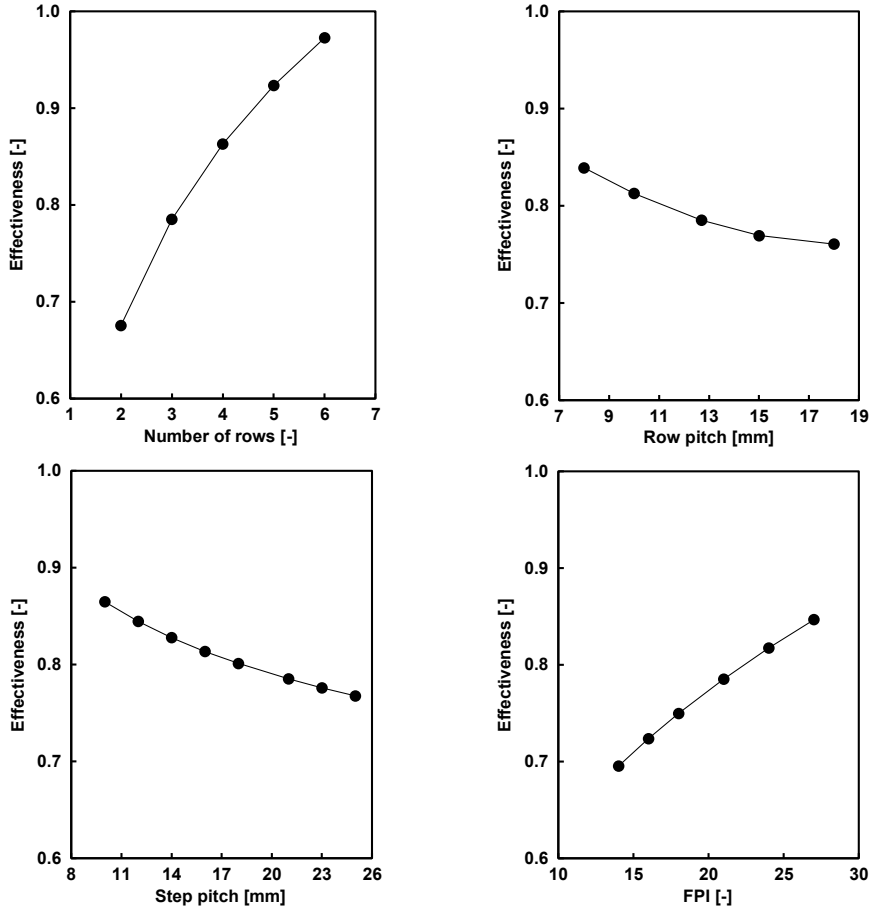

Fig. 1. Variation of the modified effectiveness for various heat exchanger geometry

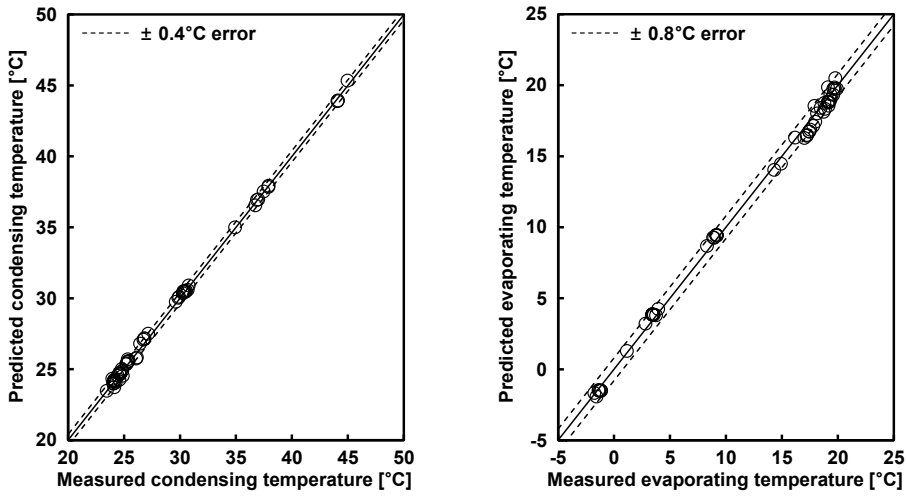

Fig. 2. Validation for saturation temperatures

Heat exchangers were selected as described in Table 2 and experimental data were obtained for each heat exchanger to establish the correlation between the effectiveness and various geometries of the heat exchanger. Key factors are selected by data analysis and the effect on the effectiveness is examined for each factor. Consequently, a non-dimensional correlation for the modified effectiveness which represents both ε_{dry} and ε_{wet} is developed as Eq. (5). α is 1.00 for the corrugated fin and 1.06 for the slit and louvered fin, while β is -0.02 for condensation and 0.02 for evaporation. The root mean square (RMS) error of the developed model is 2.7% for condensation and 5.3% for evaporation. Hence, this correlation can accurately predict the modified effectiveness for heat exchangers which have various geometries. Fig. 1 shows the variation of the effectiveness for number of rows, row pitch, step pitch and FPI, respectively.

$$\varepsilon = 0.43\alpha(0.2644\ln R + 0.4761)\left(\frac{P_r}{P_f}\right)^{0.3}\left(\frac{P_r}{P^*}\right)^{-0.35}\left(\frac{P^*}{P_s}\right)^{0.02\left(\frac{P_r}{D_c}\right)^{3.6}} PLR^{\beta}(1-0.00025\mathrm{Re_D}) \quad (5)$$

Capacity can be fixed for each seasonal performance condition since the inverter compressor will be operated to match the part load. Thus, heat transfer rate of the indoor heat exchanger can be the input and the heat transfer rate of the outdoor heat exchanger can be calculated by Eqs. (6) and (7). Temperature and enthalpy difference of air side can be acquired by Eqs. (1) and (8), respectively. As a result, saturation temperatures of the refrigerant can be attained without an iteration process from the modified effectiveness. The RMS error of the predicted condensing temperature is only 0.19°C while 0.41°C for evaporating temperature as shown in Fig. 2.

$$Q_{OD,c} = Q_{ID}(1 + 0.18PLR^{1.3}) \quad (6)$$

$$Q_{OD,h} = Q_{ID}/(1 + 0.08PLR^{1.16}) \quad (7)$$

$$Q_e = \dot{m}_a(h_{a,i} - h_{a,o}) \quad (8)$$

In addition, in order to estimate the power consumption of both indoor and outdoor fans, the empirical polynomial equations are established from the pressure to volume flow rate data provided by the manufacturer.

Table 3. Compressor coefficients

V_0	V_1	V_2	V_3	V_4	M_0	M_1	M_2	M_3	M_4
1.1160	-0.0764	0.2934	0.0006	-0.0351	0.6944	-0.0001	0.0171	-0.1619	-0.0010

2.2. Compressor model

In order to determine the optimum air flow rate, compressor power should be accurately calculated since it is the largest part of the power consumption. If experimental data is attainable for the whole operating range, map-based model will be effective. However, it is unavailable to conduct the experiment when rotational speed of a compressor is very low. Furthermore, the excessive DSH should be maintained at the compressor suction according to the compressor performance standards. Hence, map-based model is inapposite for part load conditions and thus efficiency-based model is applied for the compressor. Semi-empirical correlations are developed as the following Eqs. (9) to (13) for isentropic, volumetric and mechanical efficiency. Regarding Eqs. (12) and (13), several coefficients are applied to reflect various specifications of a compressor and coefficients for the reference system are indicated in Table 3. RMS error of the developed correlation is 5.6% for η_{isen}, 3.1% for η_{vol} and 6.3% for η_{mech} including motor and drive efficiencies.

$$\eta_{isen,c} = -0.0782\Theta^2 + 0.4121\Theta + 0.3297 \tag{9}$$

$$\eta_{isen,h} = -0.0261\Theta^2 + 0.2060\Theta + 0.5905 \tag{10}$$

where

$$\Theta = \frac{T_{dis,ideal} - T_{a,OD,i}}{2\pi N \cdot 3600 \cdot V_{disp} \cdot PR} \tag{11}$$

$$\eta_{vol} = V_0 + V_1 PR^2 + V_2 PR + V_3 \rho_{suc}^2 + V_4 \rho_{suc} \tag{12}$$

$$\eta_{mech} = M_0 + M_1 N^2 + M_2 N + M_3 PR + M_4 T_{a,OD,i} \tag{13}$$

3. Experiments

3.1. Experimental setup

Experiments are conducted in the calorimeter consists of the indoor and the outdoor chambers to verify the established simulation model. The wind tunnel is installed in the indoor chamber to measure the capacity of the indoor unit by air-enthalpy method. Temperature and humidity are steadily maintained by air handling units, so that deviations of every air temperature are less than ± 0.1°C from each set value. The air flow rate of the indoor unit is acquired by the differential pressure sensor at the nozzle.

Table 4 shows test conditions of EN 14825 and SCOP A, E and F are excluded since these conditions are insignificant on SCOP. Experiments are carried out with various indoor air flow rates and outdoor fan speeds for each test condition to determine the optimum air flow rate. Compressor speed is controlled to make the capacity correspond to the part load for each condition and EEV is adjusted to maintain DSH at the evaporator outlet as 1°C for all conditions. In D conditions of both SEER and SCOP, COP will be degraded by the following Eq. (14) since the capacity substantially exceeds the part load even though the compressor operates at the lowest rotational speed [1].

Table 4. Test conditions

		PLR [%]	Outdoor DBT / WBT [°C]	Indoor DBT / WBT [°C]
SEER	A	100	35 / 24	27 / 19
	B	74	30 / 20	27 / 19
	C	47	25 / 16	27 / 19
	D	21	20 / 12	27 / 19
Heating	Rating	100	7 / 6	20 / 15
SCOP	B	54	2 / 1	20 / 15
	C	35	7 / 6	20 / 15
	D	15	12 / 11	20 / 15

$$COP_d = COP(1 - C_d(1 - Q_{rating}/Q_{measured})) \quad (14)$$

3.2. Data reduction

The measurement data is obtained at the complete steady-state according to the standard [10] and both capacity and COP are calculated by the following Eqs. (15) to (18). The latent heat is not considered if the air speed is significantly high since condensation does not occur in the evaporator.

$$Q_{a,c} = \dot{m}_{a,ID}(h_{a,ID,i} - h_{a,ID,o}) + KA_{WT,surf}(T_{a,ID,i} - T_{a,ID,o}) \quad (15)$$

$$Q_{a,c,SH} = \dot{m}_{a,ID}\, C_{p,a,ID}(T_{a,ID,i} - T_{a,ID,o}) + KA_{WT,surf}(T_{a,ID,i} - T_{a,ID,o}) \quad (16)$$

$$Q_{a,h} = \dot{m}_{a,ID}\, C_{p,a,ID}(T_{a,ID,o} - T_{a,ID,i}) + KA_{WT,surf}(T_{a,ID,o} - T_{a,ID,i}) \quad (17)$$

$$COP = Q_a/W \quad (18)$$

3.3. Uncertainty analysis

Uncertainty of the acquired data is shown in Table 5 and its propagation is indicated in Table 6. In order to analyze the uncertainty of the cooling capacity and COP, the uncertainty of the air enthalpy should be examined. However, it cannot be directly measured by sensors but can be calculated by temperatures or humidity. Generally, it can be obtained by measured dry bulb and wet bulb temperature through the complicated calculating process which is not appropriated for the uncertainty analysis. Therefore a linear formula is developed as Eq. (19) within the measurable range, so the propagated error of the cooling capacity and COP can be calculated as the following Eqs. (20) to (22) for every test condition [11]. If the condensation does not occur, it is recommended to only consider sensible heat to reduce the error since the uncertainty of the air enthalpy difference is crucially larger than that of the temperature difference. As a result, the uncertainty is 2.0 ~ 4.3% for cooling COP and 1.8 ~ 2.6% for heating COP which are deserved to be reliable.

$$h_a = -0.0437\, T_{DB} + 3.160 T_{WB} - 4.508 \quad (19)$$

$$\frac{U_{h_a}}{h_a} = \sqrt{\left(\frac{\partial h_a}{\partial T_{DB}}\right)^2 + \left(\frac{\partial h_a}{\partial T_{WB}}\right)^2} \quad (20)$$

$$\frac{U_{COP_c}}{COP_c} = \sqrt{\left(\frac{U_{\dot{m}_a}}{\dot{m}_a}\right)^2 + \left(\frac{U_{\Delta h_a}}{\Delta h_a}\right)^2 + \left(\frac{U_W}{W}\right)^2} \quad (21)$$

$$\frac{U_{COP_h}}{COP_h} = \sqrt{\left(\frac{U_{\dot{m}_a}}{\dot{m}_a}\right)^2 + \left(\frac{U_{\Delta T}}{\Delta T}\right)^2 + \left(\frac{U_W}{W}\right)^2} \quad (22)$$

Table 5. Uncertainty analysis

4. Result analysis

The optimum indoor and outdoor air speeds of each seasonal performance condition are obtained by the established simulation model and validated by measured data. In order to obtain the optimum air flow rate via simulation, wide range of air speed is given and then COP is promptly calculated for each air speed without any iteration process. The optimum air speed can be ascertained for each seasonal performance condition from the results. Detailed simulation results for both indoor and outdoor heat exchangers are indicated in Table 7 and it is obvious that each operating condition has its own optimum air speed that can achieve the best performance. The optimum air speed has a positive correlation with the capacity but the tendency is slightly different for indoor and outdoor heat exchanger. The indoor heat exchanger is more influenced by the cooling capacity while the outdoor heat exchanger is more affected by the heating capacity, which identifies that the air flow rate of the evaporator is less influential for the performance.

In order to examine the stated correlation between the optimum air speed and the capacity, distribution of the power consumption should be firstly considered. The power consumption of the compressor is more than 80% of the total at the full load condition, so it can be advantageous to increase the air flow rate to reduce the pressure ratio of the compressor. However, at the low load condition, it will be reduced under 60% and hence the power consumption of both fans is about 30% instead. Therefore, COP can be significantly decreased when the air speed is not well optimized. For instance, COP will be deteriorated by 10% in SEER D condition if the indoor air flow rate is 75% of the optimum value but it will decline by only 1% in SEER A condition. In fact, in order to achieve the remarkable seasonal performance, it is essential to operate the system at the optimum air speed. Secondly, the suitable air side temperature difference should be secured for the thermal comfort of occupants, so UA of the indoor heat exchanger is generally smaller than that of the outdoor heat exchanger. In addition, both sensible and latent heat exist at the evaporator, the air flow rate can be less influential since the

Table 7. Verification results

Test condition		Optimum indoor air flow rate [CMM]			Optimum outdoor air flow rate [CMM]		
		Predicted	Measured	Error	Predicted	Measured	Error
SEER	A	24.0*	15.5	+ 54.8%	39.4*	32.6	+ 20.9%
	B	18.5*	15.5	+ 19.4%	32.0	32.2	- 0.6%
	C	13.0	12.5	+ 4.0%	24.6	25.9	- 5.0%
	D	10.3	10.0	+ 3.0%	20.9	19.5	+ 7.2%
SCOP	B	14.4	14.5	- 0.7%	23.4	23.7	- 1.3%
	C	11.7	11.5	+ 1.7%	16.0	17.2	- 7.0%
	D	10.3	10.0	+ 3.0%	13.5	15.0	- 10.0%

* Above the permissible sound pressure level

reduced temperature difference between the fin surface and the moist air will decrease the latent heat which has the exceedingly large enthalpy difference. Consequently, the decreasing tendency of the optimum air flow rate according to the capacity is differently observed for indoor and outdoor heat exchanger as well as cooling and heating operation. Therefore, the optimum air flow rate should be separately investigated by considering the heat transfer circumstance of the heat exchanger.

Simulation results are validated by the experimental results and described in Table 7. In some cases, the air flow rate cannot reach the predicted optimum value even though fan motor is operated at its maximum speed. Practically, the air flow rate should be regulated to satisfy the noise regulation, so maximum speed of the motor is designed around the limit value. Thus, results cannot be obtained for the air flow rate which exceeds the maximum speed nevertheless the optimum COP is not identified within the experimental data. As a result, the modeling shows an unusual large error for those test conditions. However, it can precisely predict the optimum air flow rate with the RMS error of 4.9%, 2.7% for the indoor air flow rate and 6.2% for the outdoor air flow rate. Furthermore, if the real-time capacity can be secured during heat pump operation, the optimum air flow rate of both indoor and outdoor units will be instantly obtained for the current operating condition. In fact, the system can be operated with the optimum air flow rate all the time, which implies the most practical energy saving.

5. Conclusion

In this study, effectiveness-based simulation model is established to accurately predict the optimum air flow rate for various operating conditions. The non-dimensional correlation which can reflect various heat exchanger geometries is introduced for the modified effectiveness, so COP can be ascertained for various air flow rate and load conditions. The correlation can predict the condensing and evaporating temperature within the RMS error of 2.7% and 5.3%, respectively. Furthermore, the optimum air flow rate of various seasonal performance test conditions can be predicted within the RMS error of 4.9% for the permissible operation range of both fans. If the system is available to calculate its real-time capacity, the utmost COP can be always secured by predicting the optimum air flow rate for the calculated capacity.

NEDO R&D Project for Innovative Thermal Management

Tetsushiro Iwatsubo[a*], Yuka Ogasawara[a], Toshihiko Ota[a], Masanori Kobayashi[a]

[a]New Energy and Industrial Technology Development Organization (NEDO), 212-8554 Japan

Abstract

A national R&D project "Research and Development Project for Innovative Thermal Management Materials and Technologies" in NEDO is introduced in this paper. In this project, technology developments are conducted to Reduce (which technologies for reducing heat usage; thermal insulation, heat shield and thermal energy storage), Reuse (which technologies for reusing heat; heat pump technologies) and Recycle (which technologies for reusing heat by converting it; thermoelectric energy conversion, waste heat power generation) unutilized thermal energy effectively, including total thermal management based on the combination of these technologies, and realize a future energy-efficient society. This paper focuses on high temperature heat pumps and its new refrigerants.

Keywords: R&D Project; Thermal Management; Unutilized Thermal Energy; Industrial Heatpumps; New Refrigerant;

1. Introduction

In July 2018, the Cabinet of Japan approved the new Strategic Energy Plan, and the new plan emphasizes the strengthening of efforts to ensure continued, concrete results towards 2030. Towards 2050, the new plan seeks to achieve energy transitions and decarbonization, in light of the global momentum in this direction and in enforcement of the Paris Agreement, and to pursue all tenable options toward this end.

In Japan, about 30% of primary energy, mainly fossil resources such as oil, coal and natural gas, are lost when they are converted into electricity and fuel [1], and at the final consumption, it is used only a small portion, so most of primary energy is considered not to be used effectively but discarded as heat. NEDO refers to such artificially discharged heat as "unutilized thermal energy", and it is the key for realizing thorough energy efficiency to effectively reduce, reuse and recycle this huge amount of unutilized thermal energy discharged into this environment, and it can be said to be a frontier.

In this paper, it is introduced that an overview of a national R&D project "Research and Development Project for Innovative Thermal Management Materials and Technologies", which aims to realize thorough energy efficiency promoted by New Energy and Industrial Technology Development Organization (NEDO). Above all they focus on R&Ds of new high-temperature heat pumps and their refrigerants that make use of heat efficient in industrial fields by reusing unused thermal energy for process heating instead of boilers.

2. Surveys of actual exhaust heat and R&D target

Although it is expected that unutilized thermal energy will be used for thorough energy efficiency, the temperature zone, amount, and location vary. Therefore, in order to grasp the actual state of unutilized thermal energy, NEDO conducted a large-scale questionnaire survey and estimated exhaust heat in industrial field, in "Research and Development Project for Innovative Thermal Management Materials and Technologies" [2]. It is believed that such data on temperature and quantity of exhaust heat are valuable for introduction

* Tetsushiro Iwatsubo. Tel.: +81-44-520-5281; fax: +81-44-520-5187.
E-mail address: thermal-energy@nedo.go.jp.

consideration not only on high temperature heat pumps introduced below, but also on applications of relatively low temperature industrial heat pumps and absorption chillers that have already been established technically. However, such large-scale surveys of actual exhaust heat in industrial fields had not been conducted since the survey conducted from 1997 to 2000 [3]. Figure 1 shows the estimated amounts of nationwide unutilized thermal energy, by sector and temperature based on the survey result from 1,273 factories of 15 industries. The nationwide estimation of the amount of unutilized thermal energy (exhausted as gas) was based on results of questionnaires, approximation calculated by the correlation between energy inputs to factories and unutilized thermal energy as exhaust gas by industry, and FY2015 energy consumption statistics of manufacturing industries.

The total amount of exhaust gas heat in these 15 industries was 743 PJ / year, and the 76% (565 PJ / year) was occupied by exhaust gas heat of less than 200 ° C. As shown in Fig. 1(a), it can be seen that a lot of exhaust gas from steel industry, non-ferrous metal industry, and transportation equipment industry, with melting and heat treatment processes, is in high-temperature of 500 ° C or higher, and exhaust gas from clean-up industry and other manufacturing industries, with incineration processes, is concentrated from 150 ° C to 249 ° C. On the other hand, when comparing exhaust gas calorific value of 15 industries estimated in 2015 with the result of 2000, as shown in Figure 1(b), it decreased by about 14% from 2000, and it was speculated about 10% energy efficiency was achieved for 15 years.

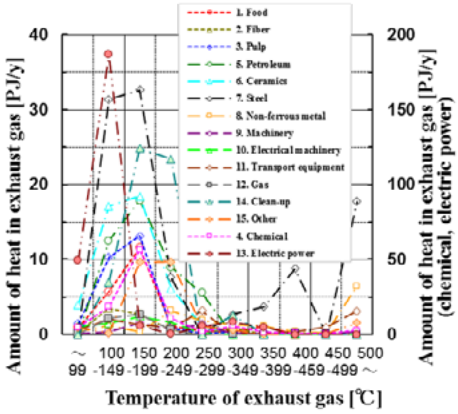

Fig. 1(a). Estimation of amount of heat in exhaust gas from industry by temperature range

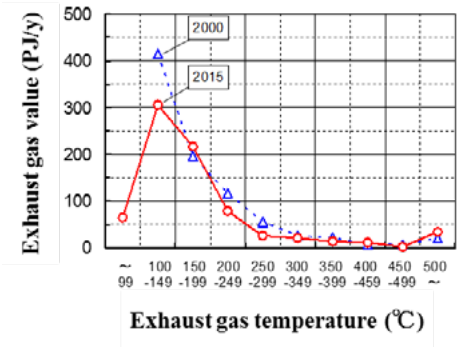

Fig. 1(b). Comparison with survey results between 2000 and 2015

Based on the above, NEDO is promoting an R&D project to effectively reduce (heat insulation, heat shield and thermal storage), reuse (heat pumps) and recycle (thermoelectric generation abd heat power generation) of unutilized thermal energy mainly below 200 ° C or above 500 ° C, with thermal management technologies, led by Dr. Haruhiko Ohara, the project leader, who also serves as the Deputy Director-General of the Planning Headquarters of the National Institute of Advanced Industrial Science and Technology (AIST),

with industry-academia collaboration of the Thermal Management Materials and Technology Research Association (TherMAT) described in Fig. 2. As the oucomet of this R&D and penetration of these technologies, NEDO and they aim to achieve domestic fossil fuel reduction effect of about 6 million kL per year or more in crude oil equivalent and CO_2 reduction effect of over 17 million t-CO_2 per year in 2030 alone. In order to NEDO also aims to realize these effects by reducing or utilizing unutilized waste heat, which is above 500 ° C, mainly with heat insulation and thermoelectric generation technologies, and which is below 200 ° C, mainly with heat pumps, thermal storage and heat power generation technologies. In this way, this R&D project is intended for a wide range, but here it is introduced that an R&D on high temperature heat pumps and its refrigerant, which are the core of this R&D project and can show high energy efficiency effect.

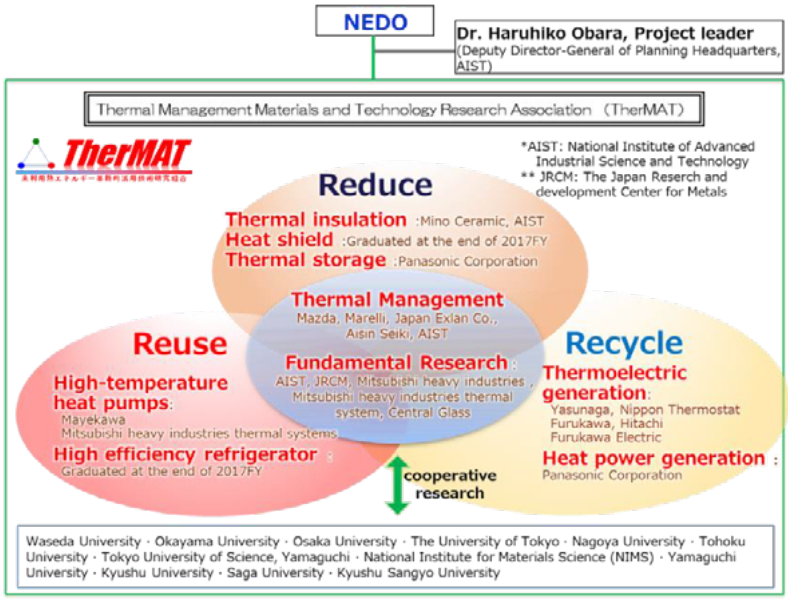

Fig. 2. Organizational chart of "Research and Development Project for Innovative Thermal Management Materials and Technologies"

3. R&D of high temperature heat pumps and refrigerants in NEDO

Currently, boilers using fossil resources are often used as heat sources for industrial heating applications, and a large amount of unutilized thermal energy is discharged from each heating process. By reusing this waste heat as a heat source, it is expected to regenerate it to a higher temperature and replace the heat sources from conventional boilers with high temperature heat pumps, for which NEDO has been promoting the R&D of that. In this project, it aims to develop high temperature heat pumps which can supply high-temperature heat about from 160 ° C to 200 ° C with high efficiency (e.g. COP: 3.5 or higher), recovering from waste heat of 80 ° C or 100 ° C which is discarded from industrial manufacturing processes, and as the result of penetrating them as alternatives to steam boilers, can contribute to use primary energy efficiently and reduce CO_2 emissions. In addition, refrigerants used in the heat pumps are selected, developed and evaluated as compounds which have small GWP (Global Warming Potential) and are suitable for high-temperature applications, in this project.

3.1. Development of industrial high-efficiency and high-temperature heat pump capable of supplying maximum 200 ° C

In this project, Mayekawa Mfg. Co., Ltd. and Mitsubishi Heavy Industries Thermal Systems, Ltd., who are the members of TherMAT, are developing heat pump systems with having the goal that can meet the supply temperature range up to 200 ° C, and achieve COP: 3.5 or higher by heating from 100 ° C to 200 ° C at the end of 2022.

Mayekawa Mfg. Co., Ltd. got the analysis based prospect of achieving COP4.10 by heating from 80 ° C to 160 ° C and the intermediate target (COP3.5) using the developed integrated analysis simulator. Also the ultrahigh-speed turbo compressor was developed, and results by fluid analysis and structural analysis showed achieving the adiabatic efficiency target of 70% or more. In addition, the correlation model necessary for the design was created by the trial model tests of the high-temperature and high-pressure heat exchanger, and the basic design of the heat pump prototype was completed. Based on these, they designed and manufactured a prototype heat pump using R600 refrigerant with a maximum heating temperature of 200 ° C and a heating

capacity of 300kW, and started performance verification tests. (Fig. 3) For the purpose of further improving efficiency, they evaluated HFO refrigerants as working media, and they clarified that it was non-flammable, and low GWP, and the rotation speed of the compressor was expected to be lower than that of R600 refrigerants. Based on the above, they have started the development of an oil-free turbo compressor with this working medium.

Fig. 3(a). High temperature heat pump prototype unit

Fig. 3(b). Developed oil-free and ultra-high speed turbo compressor

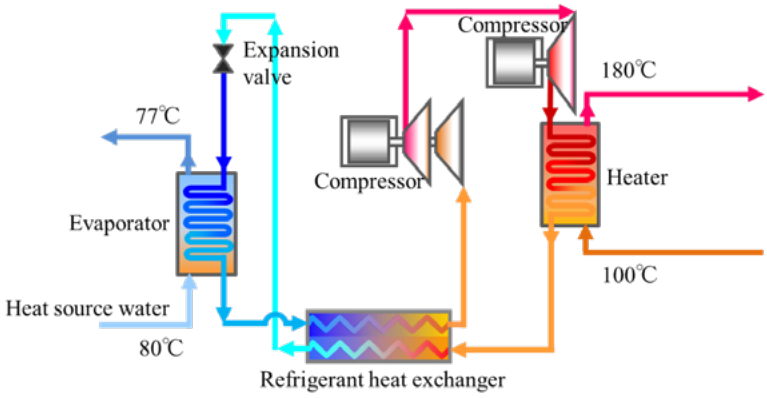

Fig. 3(c). Primary prototype testing machine flow chart of the high temperature heat pump

Mitsubishi Heavy Industries Thermal Systems, Ltd. selected the optimum heat pump cycle as the result of basic heat pump analyses at 160 ° C and 200 ° C. They also decided the refrigerant adopted for the 160 ° C hot water output heat pump, completed their basic plan, and got the prospect for realizing over COP 4.0. In addition, drop-in operation tests using refrigerant candidates in high temperature ranges were performed on an element verification test machine modified an existing product, and the validity of elemental technologies was evaluated. (Fig. 4) At the same time of these R&Ds, they extracted industrial processes that are expected to have high effect including energy efficiency with introduction of high-temperature hot water output heat

pumps, and grasped the actual operating conditions including heat balance and energy consumption in each process.

Fig. 4. Drop-in test with low GWP refrigerant

3.2. R&D of refrigerants suitable for high-temperature heat supply heat pumps

In order to be applied to turbo heat pumps with 500kW or more that can be introduced into industries such as machinery and chemical industries, Mitsubishi Heavy Industries, Ltd., Mitsubishi Heavy Industries Thermal Systems, Ltd., Central Glass Co., Ltd. and AIST, who are the members of TherMAT, in collaboration with Kyushu University, Saga University and Kyushu Sangyo University, have been exploring, developing, evaluating physically and selecting several low GWP refrigerants, that meet the requirements for the temperature zone when industrial heat pumps will be used.

By FY2017, they selected refrigerants that were promising for using at 160 ° C hot water output heat pumps. Specifically, among the compounds for which some thermophysical property data are known, three compounds were selected as new refrigerant candidates, and their performance (normal boiling point and critical temperature), thermal stability, safety (toxicity and flammability), environmental impact (GWP <20) were evaluated, and also thermodynamic properties and transport properties data (PVT properties, thermal conductivity and viscosity) were obtained. In addition, they conducted synthesis studies using cheaper catalysts, confirmed the high selectivity and long life of the catalyst and revealed the low toxicity as the result of subacute toxicity tests.

New refrigerant candidates suitable for use for 200 ° C hot water output heat pump have not been studied yet, including other applications, and had no REFPROP FLD files. Therefore, they have developed a method for preliminary toxicity test and synthetic method with high yield for new refrigerants candidate corresponding to 200 ° C, and they evaluated five screened candidate refrigerants from points of view of thermal stability, basic thermophysical properties, safety and environmental impacts, and as the result of that candidate refrigerants were narrowed down to two. They developed equation of state based on sound of speed in gas phase, PVT property measurements and vapor pressure measurement for the refrigerant candidate, and confirmed that it was almost the same as the actual measurement value of physical property. Also, they have also found a catalyst with high selectivity, high conversion and long life in the synthesis process.

3.3. Next steps

Based on above R&D, materials can be selected by analyzing thermodynamic characteristics and heat exchange characteristics of the 200 ° C output heat pump cycle using new refrigerant candidates, and evaluating elastomer compatibility suitable for the refrigerant candidate. Then, toward the final goal, they will conduct element verification tests of high temperature heat pumps using new refrigerant candidates suitable for 200 ° C output machines, confirm the each component performance of heat pump cycles, together with evaluation of the soundness, evaluate overall performance of the heat pumps, and determine basic specifications.

On the other hand, toward introduction of the heat pumps after the end of R&D, it can be difficult to see the effect or value when they apply to actual heat utilization equipment in factories. Especially it will be even more

difficult to conduct verification to grasp the energy efficiency effect in the actual environment using the existing systems. Therefore, it will be proceed with activities of model cases studies, assumed actual heat utilization facilities, and based on the results of this studies, calculation and quantitatively evaluation of the effect or value including energy efficiency, cost merit and heat pump system configuration post introduction. As the result of the activities, "visualization" of introduction effect will be progressed and it will be possible to share the installation image of heat pumps in industrial heating processes with customers, which will be able to lead to acceleration of the introduction. It is planned to construct equipment utilizing systems with high temperature heat pumps including attached facilities, proceed with model case verifications that examine optimal applied processes and clarify economic effects, and studies on "visualization" of introduction effect with TherMAT and all Japan in this R&D project. Through these activities, the newly developed industrial high-efficiency and high-temperature heat pumps will be properly arranged and used for process heating instead of boilers, thereby promoting energy efficiency in factories and contributing to solving energy and environmental problems in the future.

4. Conclusion

"Energy efficiency" is the primary expectation for the realization of "3E + S" (simultaneously achieving Energy Security, Economic Efficiency and Environment, with coming Safety always at first) in Japan and global long-term decarbonization, but most of primary energy is still discharged as unutilized thermal energy without being effectively used, even though various measures have been taken so far. Among energy forms such as fuel, electricity, and hydrogen that are expected to be used in the future, the last remaining form is heat, and decarbonization of all sectors that use this heat can be the key to construct the sustainable recycling society. Now all the relevant people are required to promote to implement technologies for effectively reducing or recovering a large amount of unutilized thermal energy discharged into the environment including high-temperature heat pumps, to the society with economic rationality, realize significant energy efficiency of the entire society and a "circular economy", and there can be no doubt that this R&D project has been a driving force for it.

Abstract

In order to replace the inefficient and polluting boilers, an ammonia-water absorption heat pump prototype is proposed for rural residential heating. The prototype can be driven by the combustion of biogas that is widely available in rural areas. Experimental investigations are carried out to analyze its performance under different working conditions. During the experiment, the prototype works with an electric oil heater which simulates the biogas burner in real applications, and uses conduction oil as the heating medium. Experimental results indicate that at the ambient temperature of -5 °C, the prototype can provide 25 kW heating capacity and the supply water temperature is 50 °C, with the coefficient of performance and primary energy efficiency of 1.37 and 1.14, respectively. By introducing the intermediate process, 2.39 kW exhaust heat is recovered, and the exhaust heat temperature is reduced to 41.3 °C. Moreover, the primary energy efficiency of the proposed system is still greater than 1 even when the ambient temperature is reduced to -10 °C, showing an obviously better performance than that of the conventional boiler.

1. Introduction

In China, buildings consume a large amount of energy, which occupies about 24% of the total energy consumption [1], and this number is expected to gain further enhancement considering the improving living standard [2], especially in rural areas where over 40% of the nation's whole population live in. Among the building energy consumption, residential heating systems account for over 20% [3]. At present, most of these heating systems are coal-fired boilers in rural areas of China, which produce a huge amount of aerosol and contaminant that is the main source of air pollution. Even worse, the primary energy efficiencies (PEEs) of the boilers are very low, ranging from 0.8 to 0.9. In order to meet the demand of energy conservation, emission reduction and environmental protection, more efficient and environmental friendly heating technologies haven been proposed to replace the boiler systems. Among these, absorption heat pump (AHP) is outstanding because of its higher primary energy efficiency. Conventional AHP systems use high-grade combustion heat of fossil fuels or waste heat of the industrial areas as the driving force, recover additional low-grade heat from the ambient (mainly including air and ground), and produce intermediate-grade heat for water heating, ranging from 40 °C to 100 °C.

The single-effect AHP systems applied for residential heating have been studied extensively. Some articles analyzed systems that are driven by the heat network, and a ground-source AHP [4] was analyzed for residential heating. The results showed that it was more efficient than the compression heat pump (CHP). Further studies [5] demonstrated that the AHP system has an energy efficiency that is 54% higher than that of the conventional

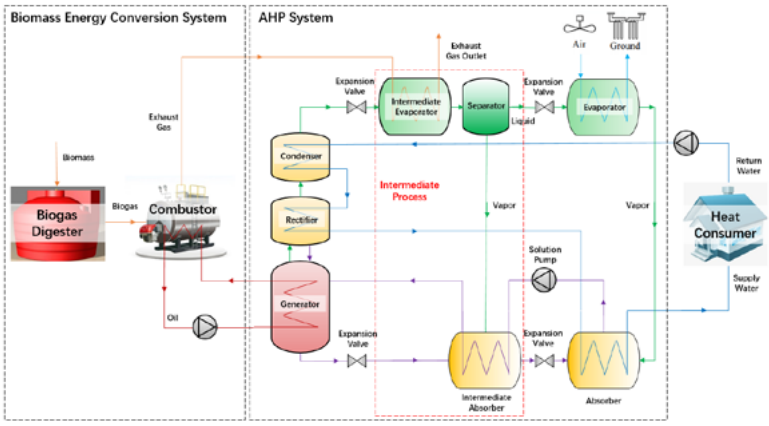
heating systems based on boilers. Wu et al. [6] proposed a water-source AHP system to provide 45 °C water for district heating. Experimental study indicated that as the evaporation temperature is -10 °C, the COP is 1.2. Nitkiewicz et al. [7] compared the performance of a CHP, an AHP, and a gas-fired boiler. Results showed that the heating plant using ground-source AHP system had a much lower eco-indicator and environmental impact than those of the CHP and boiler. Li et al. [8] used an AHP to utilize heat from a heat network, and found that both the heating capacity and PEE were enhanced by recovering the low-grade renewable energy. Besides, the coal and power consumption was reduced significantly, and thus the operating cost became relatively lower. Other papers focused on directly gas-fired systems, and an AHP system that could provide hot water above 57 °C was proposed [9], and theoretical studies showed that the COP was 1.74 as the ambient temperature was about 20 °C. At the similar ambient temperature, an AHP prototype [10] could provide 45 °C hot water and the COP was 1.63. Baig et. al. [11] tested the performance of an AHP prototype. It was shown that when the ambient temperature was -5 °C, the PEE was above 1, which was higher than that of the conventional boiler. However, as the ambient temperature went down to -5 °C, the PEE decreased sharply below 1.

Although the traditional single effect AHP system is an efficient district heating method, its performance decreases obviously under low ambient temperature, which limits its application in cold areas [12]. Besides, no matter it is directly gas-fired or utilizes heat from the heating network based on gas boiler (combustor), there is no effective recovery method of flue gas waste heat.

In this paper, an ammonia-water absorption heat pump prototype is proposed for rural residential heating. The prototype can be driven by the combustion of biogas that is widely available in rural areas. Experimental investigations are carried out to analyse its performance under different working conditions. During the experiment, the prototype works with an electric oil heater which simulates the biomass burner in real applications, and uses conduction oil as the heating medium. Intermediate process is introduced, and the prototype can utilize both the low-grade ambient heat and waste heat from biomass combustion through the evaporator and intermediate evaporator, respectively.

2. System Structure

The rural residential heating network based on the proposed AHP system is shown in Fig. 1. The driving heat is generated by the combustion of biogas that comes from the biogas digester, and heat conduction oil is used as the heating medium to transform heat from the combustor to the generator. Return water from the heat consumer is heated in sequence through the rectifier, condenser and absorber, with its temperature increases gradually, and then the heated water is supplied to the heat consumer. A higher PEE is obtained because of the ambient heat, including air- and ground-source, recovered in the evaporator, and waste heat of exhaust gas recovered in the intermediate evaporator [13].



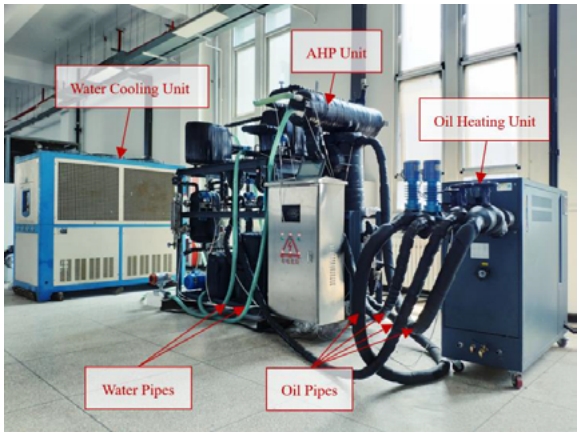


Fig. 1. Residential heating network based on AHP system.

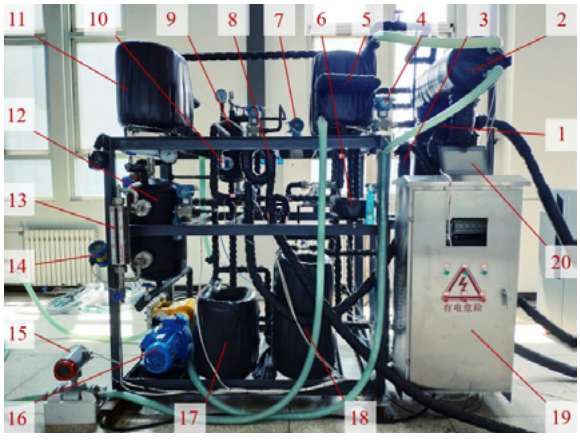

The proposed AHP system has the intermediate process. Exhaust gas from the biomass combustor enters the intermediate evaporator and the waste heat is recovered in the intermediate evaporator, where partial ammonia evaporation happens. The ammonia two-phase flow enters the separator, and the liquid and vapour

flows to the evaporator and intermediate absorber, respectively. The vapour is absorbed by the weak solution from the generator, and the heat from the intermediate absorption process is recovered by the pressurized strong solution. The above process occurs at the intermediate pressure between the system high pressure and low pressure. The additional intermediate pressure can reduce the degradation of system performance due to the large pressure difference at the low ambient temperature. In addition, the introduction of intermediate processes has two additional benefits: lower waste heat discharge temperature and improved internal heat recovery.

Based on the previous simulation studies [40], an experimental prototype system of residential heating is designed and built, as is shown in Fig. 2(a). The system contains three units: the oil heating unit, the water cooling unit and the AHP unit. The oil heating unit is an electric oil heater (simulating the biogas combustor), which heats the oil to the target temperature and delivers it to the generator of the AHP unit through the oil pipes; the water cooling unit is a water chiller (simulating the heat consumer), which cools the supply water down to the target return water temperature and delivers it to the AHP unit through the water pipes. The structure of the AHP unit is shown in Fig. 2(b).

Fig. 2. Experimental prototype system of residential heating.

3. Calculation Method

3.1. Calculation of the generation heat Q_G

The generation heat Q_G is defined as the enthalpy difference between heat conduction oil inlet and outlet of the generator. It is calculated based on Eq. (1):

$$Q_G = m_{OG} \cdot c_{p,O} \cdot \Delta T_{OG} = \rho_O \cdot V_{OG} \cdot c_{p,O} \cdot \left(T_{OG,in} - T_{OG,out}\right) \tag{1}$$

where m_{OG} and V_{OG} are the mass and volume flow rates of the heat conduction oil through the generator; ρ_O and $c_{p,O}$ are the linear mean values of its density and specific heat, considering that they both change with temperature.

3.2. Calculation of the recovered exhaust heat Q_{WH}

The recovered exhaust heat Q_{EH} consists of two parts: waste heat recovered in the solution preheater Q_{SP} and waste heat recovered in the intermediate evaporator Q_{IE}. They are calculated based on Eqs. (2) ~ (4):

$$Q_{SP} = m_{OIE} \cdot c_{p,O} \cdot \Delta T_{OSP} = \rho_O \cdot V_{OIE} \cdot c_{p,O} \cdot \left(T_{OSP,in} - T_{OSP,out}\right) \tag{2}$$

$$Q_{IE} = m_{OIE} \cdot c_{p,O} \cdot \Delta T_{OIE} = \rho_O \cdot V_{OIE} \cdot c_{p,O} \cdot \left(T_{OIE,in} - T_{OIE,out}\right) \tag{3}$$

$$Q_{EH} = Q_{SP} + Q_{IE} = \rho_O \cdot V_{OIE} \cdot c_{p,O} \cdot \left(T_{WH,in} - T_{WH,out}\right) \tag{4}$$

where m_{OIE} and V_{OIE} are the mass and volume flow rates of the heat conduction oil through the intermediate evaporator; $T_{OSP,in}$ and $T_{OSP,out}$ are the oil inlet and outlet temperatures of the solution preheater, and $T_{OSP,in}$ is equal to $T_{WH,in}$; $T_{OIE,in}$ and $T_{OIE,out}$ are the oil inlet and outlet temperatures of the intermediate evaporator, and $T_{OIE,out}$ is equal to $T_{WH,out}$.

3.3. Calculation of the heating capacity Q_{HC}

In the experimental prototype, the return water passes through the condenser, rectifier and absorber, and are heated to the target temperature. Therefore, the heating capacity Q_{HC} consists of three parts: condensation heat Q_C, rectification heat Q_R and absorption heat Q_A. They are calculated based on Eqs. (5) ~ (8) [14]:

$$Q_C = m_W \cdot c_{p,W} \cdot \Delta T_{WC} = \rho_W \cdot V_W \cdot c_{p,W} \cdot \left(T_{WC,out} - T_{WC,in}\right) \tag{5}$$

$$Q_R = m_W \cdot c_{p,W} \cdot \Delta T_{WR} = \rho_W \cdot V_W \cdot c_{p,W} \cdot \left(T_{WR,out} - T_{WR,in}\right) \tag{6}$$

$$Q_A = m_W \cdot c_{p,W} \cdot \Delta T_{WA} = \rho_W \cdot V_W \cdot c_{p,W} \cdot \left(T_{WA,out} - T_{WA,in}\right) \tag{7}$$

$$Q_{HC} = Q_C + Q_R + Q_A = \rho_W \cdot V_W \cdot c_{p,W} \cdot \left(T_{SW} - T_{RW}\right) \tag{8}$$

where m_W and V_W are the mass and volume flow rates of the circulating water; ρ_W and $c_{p,W}$ are its density and specific heat; $T_{WC,in}$ and $T_{WC,out}$ are the water inlet and outlet temperatures of the condenser; $T_{WR,in}$ and $T_{WR,out}$ are the water inlet and outlet temperatures of the rectifier; $T_{WA,in}$ and $T_{WA,out}$ are the water inlet and outlet temperatures of the absorber; T_{SW} and T_{RW} are the supply water and return water temperatures, T_{SW} is equal to $T_{WA,out}$, and T_{RW} is equal to $T_{WC,in}$.

3.4. Calculation of the heating efficiency COP and PEE

The experimental prototype has two heating efficiency indexes: the coefficient of performance COP and the primary energy efficiency PEE, which are calculated based on Eq. (9) and (10):

$$\mathrm{COP} = \frac{Q_{HC}}{Q_G + W_P} \tag{9}$$

$$\mathrm{PEE} = \frac{Q_{HC}}{Q_G / \eta_C + W_P / \eta_E} \approx \frac{Q_{HC}}{Q_G + Q_{EH} + W_P / \eta_E} \tag{10}$$

where W_P is the pump work; η_C is the efficiency of the combustor; η_E is the efficiency of electricity generation, which is around 33% [2]; Q_G / η_C is the calorific value of the natural gas, and is approximately

equal to the combustion heat plus flue gas waste heat: $Q_G / \eta_C \approx Q_G + Q_{EH}$ [13].

4. Results and Discussion

4.1. Performance under basic working condition

The performance of the experimental prototype system is studied under the basic working condition: the ambient temperature is about -5 °C, the oil inlet temperature is 180 °C, and the return water temperatures is 35 °C. Summary of experimental performance under the basic working condition is shown in Table 1. In the basic working condition, the return water passes in sequence through the condenser, rectifier and absorber, and its temperature increases to 40.0, 46.2 and 50.6 °C, respectively, when the flow rate is kept at 1.4 m^3/h. It is also shown that by introducing the intermediate process, 2.39 kW exhaust heat is recovered, and the exhaust heat temperature is reduced to 41.3 °C, which is lower than the dew point of the exhaust gas, indicating that the exhaust heat recovery is improved. Besides, the pressurized strong solution of 46.5 °C is first heated to 127.6 °C by recovering the intermediate absorption heat, and then it is further heated in the solution preheater into the two-phase flow, indicating that the internal heat recovery is improved. Moreover, the energy input and output of the AHP unit are 26.59 and 25.43 kW, respectively. Therefore, the heat loss is about 1.16 kW that is only 4.4% of the total energy input, indicating that the experimental prototype is in good energy balance. It is shown that when the evaporation temperature is -5 °C, the experimental prototype system can provide 25 kW heating capacity to heat the water from 35 °C to above 50 °C, and the COP and PEE are 1.37 and 1.14, respectively.

Table 1. Summary of experimental performance under basic working condition

	Components	Energy input (kW)		Energy output (kW)	
		Value	Uncertainty	Value	Uncertainty
Energy Transfer	Generator	18.13	±0.41	/	/
	Rectifier	/	/	6.45	±0.31
	Condenser	/	/	10.14	±0.47
	Evaporator	5.57	±0.35	/	/
	Intermediate Evaporator	1.54	±0.21	/	/
	Absorber	/	/	8.84	±0.42
	Solution Preheater	0.85	±0.05	/	/
	Solution Pump	0.50	±0.03	/	/
	Total	26.59	±0.57	25.43	±0.69
Performance Parameters	Parameters	Value		Uncertainty	
	Heating Capacity	25.43 kW		±0.69 kW	
	Recovered Exhaust Heat	2.39 kW		±0.07 kW	
	Supply Water Temperature	50.6 °C		±0.3	
	Exhaust Heat Temperature	41.3 °C		±0.3	
	COP	1.37		±0.05	
	PEE	1.14		±0.03	

4.2. Influence of the oil inlet temperature

The oil inlet temperature T_{OI} is an important working condition parameter of the absorption heat pump system, because of its effects on the generation process and system performance. Low T_{OI} cannot provide sufficient driving force for system operation, while high T_{OI} will cause huge exergy destruction in the heat transfer process. Some research shows that there is an optimal T_{OI}, and when the value continue goes up, the system performance will not improve or even degrade. This is also observed in this study, as is shown in Fig. 3. When T_{OI} increases from 165 to 186 °C, both COP and PEE increase rapidly at first till reach 1.61 and 1.32, respectively, and then remain nearly constant. The turning point happens when T_{OI} is about 175 °C.

For the exhaust heat temperature, it raises along with T_{OI}, but basically keeps between 39 and 42 °C. Moreover, the supply water temperature increases linearly from 54 to 59 °C when T_{OI} increases from 165 to 186 °C, and is expected to continue to raise when T_G further increases. Therefore, in order to obtain the target supply water temperature, the oil inlet temperature can be appropriately increased above the optimal value, at the cost of slightly reducing the COP.

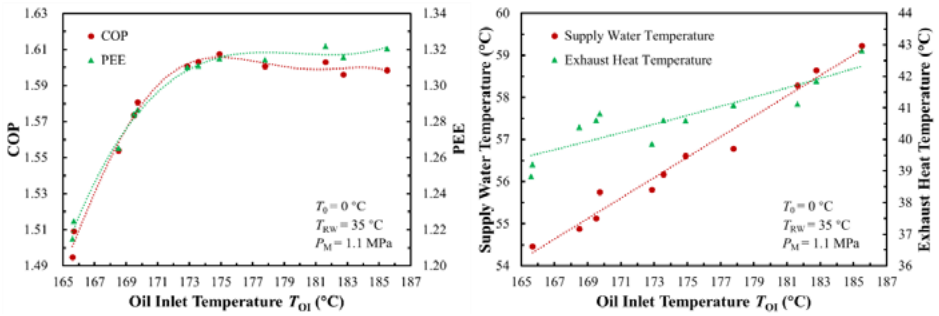

Fig. 3. Influence of the oil inlet temperature on the system performance

4.3. Influence of the ambient temperature

The ambient temperature T_0 has a huge influence on the evaporation process and thus the system performance. It is shown in Fig. 4 that as T_0 decreases from 5 °C to -10 °C, the heating capacity reduces from 30 kW to 22 kW, and the COP decreases from 1.60 to 1.25. The proposed system has a much higher primary energy efficiency than that of the conventional boiler, and it is higher than 1 even when the ambient temperature T_0 is reduced to -10 °C.

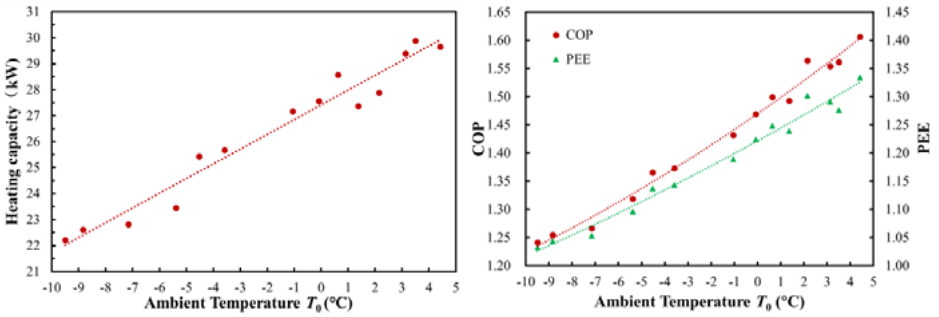

Fig. 4. Influence of the ambient temperature on the system performance

4.4. Influence of the return water temperature and water flow rate

The return water temperature T_{RW} has effects on almost all the processes of the AHP system, including the condensation, rectification, generation and absorption processes. If T_{RW} is high, the ammonia vapour becomes difficult to condense in the condenser and rectifier, and the system high pressure will increase, which has a negative effect on the generation process. Even worse, it also obstructs the absorption process since the absorption heat is hard to carry away. In the previous analysis, T_{RW} is fixed at 35 °C, which is a common return water temperature for most residential heating systems. However, it changes as the working condition deviates from the set state, such as the ambient temperature suddenly drops. Fig. 5 indicates that the system is quite sensitive to the return water temperature when the water flow rate V_W is fixed. It is shown that the COP drops linearly from 1.57 to 1.27, as T_{RW} increases from 30 to 40 °C. At the same time the supply water temperature T_{SW} raises from 46.6 to 52.3 °C. On the other hand, if the return water temperature T_{RW} is fixed, the COP will increase and the supply water temperature T_{SW} will decrease, as the water flow rate V_W raises, as is shown in Fig. 6. Therefore, if T_{RW} deviates from the set value, V_W can be adjusted accordingly to stabilize the system performance. More specifically, enlarge V_W if T_{RW} increases, and reduce V_W if T_{RW} decreases.

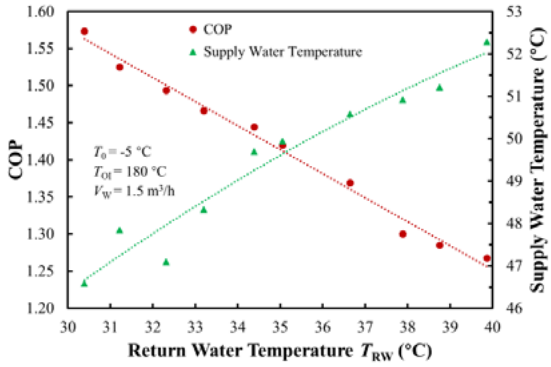

Fig. 5. Influence of the return water temperature on the system performance

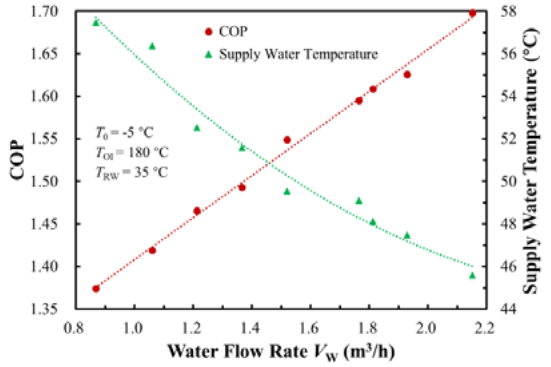

Fig. 6. Influence of the water flow rate on the system performance

4.5. Influence of the return water temperature and water flow rate

The intermediate pressure P_M is a key parameter of the proposed system, and its value influences both the waste heat recovery of the intermediate evaporator and the solution heat recovery of the intermediate absorber. Fig. 7 shows that as the intermediate pressure increases, the waste heat outlet temperature raises from 39 °C to 45 °C, indicating that the waste heat recovery is limited. It is probably because the enhanced intermediate pressure raises the intermediate evaporation temperature and thus increases the waste heat outlet temperature. On the other hand, a higher intermediate pressure causes a higher solution heat recovery outlet temperature of the intermediate absorber, indicating that the internal heat recovery is improved.

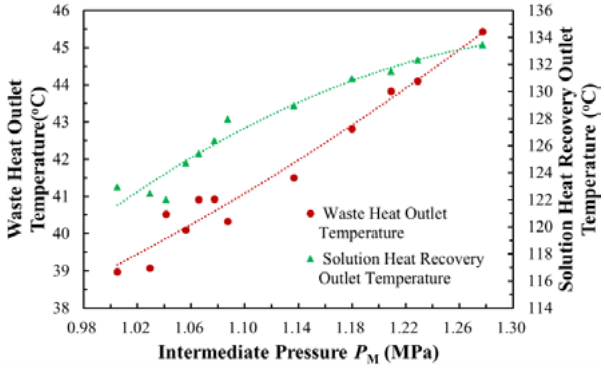

Fig. 7. Influence of the intermediate pressure on the system performance

5. Conclusions

In order to replace the inefficient and polluting boilers, an ammonia-water absorption heat pump prototype is proposed for rural residential heating. The prototype can be driven by the combustion of biogas that is widely available in rural areas. Experimental investigations are carried out to analyse its performance under different working conditions. During the experiment, the prototype works with an electric oil heater which simulates the biomass burner in real applications, and uses conduction oil as the heating medium. Several conclusions are drawn as following.

- When the ambient temperature is -5 °C and the oil inlet temperature is 180 °C, the experimental prototype system can provide 25 kW heating capacity to heat the water from 35 °C to above 50 °C, and the COP and PEE are 1.37 and 1.14, respectively.
- By introducing the intermediate process, 2.39 kW exhaust heat is recovered, and the exhaust heat temperature is reduced to 41.3 °C, which is lower than the dew point of the exhaust gas, indicating that the exhaust heat recovery is improved.
- When the oil inlet temperature increases, both COP and PEE increase rapidly at first, and then remain nearly constant. The turning point happens when the oil inlet temperature is about 175 °C.
- As the ambient temperature decreases from 5 °C to -10 °C, the heating capacity reduces from 30 kW to 22 kW, and the COP decreases from 1.60 to 1.25. The proposed system has a much higher primary energy efficiency PEE than the conventional boilers, and it is higher than 1 even when the ambient temperature is reduced to -10 °C.
- The COP drops and the supply water temperature raises as the return water temperature increases. On the other hand, the COP increases and the supply water temperature decreases as the water flow rate raises. Therefore, if the return water temperature deviates from the set value, the water flow rate can be adjusted accordingly to stabilize the system performance.
- As the intermediate pressure increases, the waste heat outlet temperature raises from 39 °C to 45 °C, indicating that the waste heat recovery is limited. On the other hand, a higher intermediate pressure causes a higher solution heat recovery outlet temperature of the intermediate absorber, indicating that the internal heat recovery is improved.

Abstract

Absorption cycles cogenerating cooling and power are flexible systems able to adapt to the irregularity of the user's needs. To facilitate their integration in industrial processes and mobility applications, this work investigates the performance and control of a water-ammonia based cogeneration system operating at low-grade heat (< 200 °C). Through a complete model of a cogeneration cycle implementing an accurate description of an expander, the optimal performance of power and/or cooling production are explored according to the needs and the available temperature sources. Simulations show that power and cooling productions can respectively reach the performances of Kalina and absorption cycles for determined operating conditions. They also highlight the critical features of an expander in a combined production cycle. The model is then imported in a dynamic solver to investigate the transient behavior of a cogenerating system. Such complex systems present significant inertia when starting or switching from one production mode to another (between cooling and power). This study provides some insight on the most critical elements of the cycle.

The literature depicts various architectures of combined cooling and power (CCP) production. A first overview of the systems studied was proposed by Ayou *et al.* (2013). Two main families stand out: the cogeneration architectures in series [2]–[4] and those in parallel [5]–[7]. The architectures in series are generally more efficient for simultaneous co-generation of cold and electricity while the architectures in parallel enable more flexibility in term of production. Parallel architectures are also easier to implement

E-mail address: haitrieu.phan@cea.fr.

because only two levels of pressure are present. Independently of the architectures, the cold can be produced using the principle of the absorption chillers [3], [5], [6] or that of the ejectors [2]. The combination of both technologies was also considered in several studies [7], [8]. Electricity is produced by the expansion of the working fluid in an expander (volumetric type or turbine) coupled to a generator. The development of expanders notably benefits from the recent study of organic fluid Rankine cycles (ORC) [9].

As cogeneration systems are quite complex cycles, only a few experimental investigations have been conducted so far and they usually simulate hard-provisioning components with simplified equivalents [5]. In return, the numerical approach is widely used to explore the performance of innovative architectures. Concerning cooling production, the physical models that describe the various components of thermodynamic cycles have already been well investigated and have led to numerous numerical studies of both absorption and compression machines [10]. Concerning power production, expander models need further investigation due to complex phenomena and a wide range of existing technologies.

Lemort *et al.* (2009) developed a first scroll expander model. This semi-empirical model considers the physics related to the transformation of the fluid from the inlet to the outlet of a scroll. In CCP systems coupling an absorption cycle with an expander, the expanded gas in the expander is most often ammonia containing traces of water. Hence, there is a real interest in adapting this model to work with ammonia. Based on experimental data, Mendoza et al. (2014) developed a simplified version of Lemort's model with ammonia as working fluid. The model is later included into a CCP cycle (Mendoza et al., 2014) and the performance of a scroll expander is then calculated for three different working fluids.

As a continuous of the literature work, the present study aims to optimize the performance of CCP cycles. A parallel architecture of the expander integrated into an ammonia-water absorption chiller has been studied. Numerical models of the cycle were developed with a detailed model of a scroll-type expander. Tests were also conducted on an ORC system and an absorption-chiller machine, giving experimental data for calibration of the model parameters and boundaries. The simulation results were then analyzed, giving us information about the key factors affecting the cycle performance. Finally, the transient behavior of the cogenerating system has been investigated through dynamic simulations. This illustrates the stability of the system and gives insights on typical response times to control the operation of the cycle.

2. Cycle description

The CCP cycle considered in the present study is shown in Figure 1. It consists of a water-ammonia absorption cycle in parallel with an ORC cycle, the one using part of the desorbed ammonia as a working fluid and a scroll expander for power production.

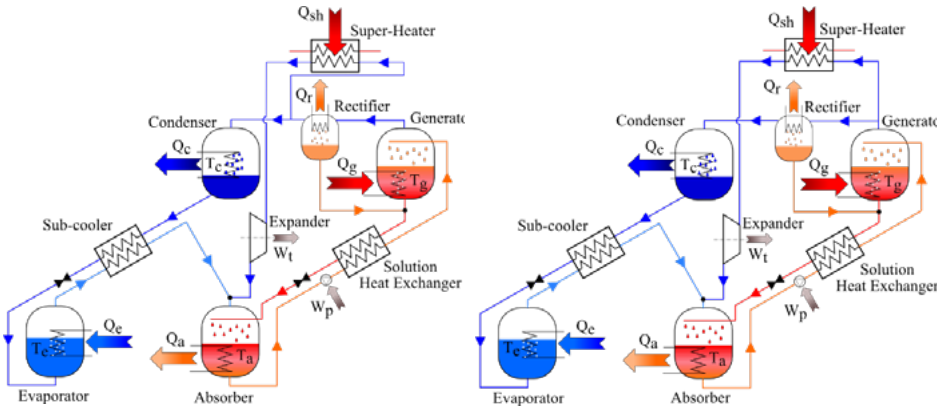

Fig.1. Scheme of the CCP cycle with two different configurations

On the solution circuit loop, a first line of ammonia-rich solution flows from the absorber to the generator through pressurization by a pump. A second line with an expansion valve brings the poor solution back to the absorber. An economizer preheats the rich solution with the poor solution coming out of the generator.

Upstream of the production lines, a rectifier maximizes the ammonia content of the gas produced at the generator in order to obtain better performance for cooling production. In Configuration A (Figure 1), the rectification is effective for both the cooling and the power production lines, while in Configuration B the ammonia expended to produce power is not rectified as the switch valve directing the flow between the two production lines is positioned before the rectifier. The two variations of the cycle exist in different architectures founded in the literature [5], [6].

To produce power, a superheater raises the temperature of the fluid to ensure that it remains in a gaseous state throughout the expansion. In the scroll expander, the fluid is then trapped and expanded in expansion chambers. By deforming, the chambers cause the rotation of a shaft that is coupled to a generator to produce electricity.

To produce cooling, a heat exchange with an intermediate temperature source (usually the ambient) condenses the ammonia flowing from the generator. A valve expands the ammonia to low temperature so it can take calories at the evaporator for cooling production. Finally, a sub-cooler allows the ammonia to be pre-cooled before it is expanded, by using the ammonia coming out of the evaporator.

The flows from the two production lines mix and are finally absorbed into the poor solution through cooling by a source of intermediate temperature (the same as the one used in the condenser).

3. Experimental devices

Two different devices provide data to setup the following numerical models: the scroll expander model is parametrized according to tests performed on an ORC test rig, and an absorption cycle is characterized to setup the other components in the model of the complete CCP cycle.

3.1 Organic Rankine Cycle

Scroll expanders ensure the continuous expansion of a fluid in closed chambers. This solution is therefore very relevant for small power applications with moderate flow rates [12]. A 1 kW Air Squared® scroll expander (model E15H022A-SH) was mounted on an existing ORC test rig [13]. A preheater has also been added to the initial device to increase the range of test conditions. In detail, a Hydra-Cell pump ensures the circulation and pressure elevation of the fluid. A preheater and an evaporator transfer up to 18 kW of thermal energy to it. Then the gaseous fluid expands in the scroll expander by driving a generator. Finally, a series of three condensers, fed by the same cold source, liquefy the fluid before it returns to the pump.

As ammonia cannot be directly tested in the installation, another pure fluid serves to characterize the scroll expander. The choice is an HFC commonly used in the heat pump industry: R245fa. This refrigerant have already demonstrated its ability to produce energy by expansion in an expander [14], [15]. Thanks to adaptation laws between fluids described by [14], the characterization completed with R245fa allows to project the scroll behavior when operating with ammonia.

3.2 Absorption chiller

To characterize the other components in the studied CCP cycle, tests are performed on an existing water/ammonia absorption chiller device. This experimental cycle produces up to 5 kW of cold (at temperature from -10°C to 20°C) from a heat source at low-grade temperature (70°C to 130°C) and a source at intermediate temperature (15°C to 45°C). The operating pressures vary between 8 and 20 bar on the high-pressure side and from 2 to 6 bar on the low-pressure side. Details of the design of the device and its detailed description were the subject of a previous paper [16]. In short, the operation of the device is identical to that of the CCP cycle studied and presented above, without the electricity production line parallel to the cooling production. The tests carried out on the device make it possible to estimate the pinches of temperature, pressure drops, and efficiencies associated with the various components presented in the CCP cycle.

The two following models were implemented in the ‘Engineering Equation Solver’ (EES) environment to be solved. The calculated values of specified thermodynamic states come from EES’s database for pure ammonia and water/ammonia mixtures.

4. Numerical models

4.1 Expander scroll modelling

Lemort's semi-empirical model [11] has been used in many studies to explore the different operating conditions of a scroll expander [14], [17]. It quantitatively estimates the performance of an expander with a

limited number of operating conditions (flow rates, pressures and temperatures) at the inlet. In detail, the model decomposes the flow of fluid through the scroll into seven distinct thermodynamic transformations. It also considers the mechanical and thermal exchanges of the scroll with its environment. The equations specific to each transformation and balance are detailed in the reference publication [11].

Table. 1: Scroll properties determined from experimental data with R245fa.
The bold values identify the corrections for operation with ammonia.

	A_{in} (mm²)	$AU_{in,n}$ (W/K)	$AU_{out,n}$ (W/K)	AU_{amb} (W/K)	BVR	A_{leak} (mm²)	τ_{loss} (N.m)
R245fa	28	12	31,4	7,5	2,7	5,7	0,2
Ammonia	28	**6**	**14,7**	7,5	**1,9**	**1**	0,2

The design of the expander, the working fluids and the operating conditions are inputs of the model Table.1 lists the parameters related to the nature of the expander. A_{in} is the flow cross-section of the fluid at the expansion inlet. $AU_{in,n}$, $AU_{out,n}$ and AU_{amb} are the heat exchange coefficients of a fictitious isothermal wall with, respectively, the fluid before expansion, the fluid after expansion and the ambient. The Built-in Volume Ratio (BVR) characterizes the volume expansion rate. A_{leak} represents the total leakage area related to the flow of fluid through the expander that does not produce work. Finally, τ_{loss} is a mechanical friction coefficient. All these parameters are determined by minimizing the differences between experimental measurements and model calculations. The scroll response (power generation, output temperature and flow rate) was experimentally measured through 30 tests performed on the previously introduced ORC test bench for different temperature and flow rate conditions over the operating range of the expander. The same tests were simulated with the model by imposing four input parameters: the scroll speed, the temperature of the inlet fluid and the pressures upstream and downstream of the expander. The difference between the numerical and experimental results is quantified by the error:

$$\varepsilon = \sum \left[\left(\frac{T_{out,exp} - T_{out,num}}{\overline{T_{out,exp}}} \right)^2 + \left(\frac{\dot{W}_{exp} - \dot{W}_{num}}{\overline{\dot{W}_{exp}}} \right)^2 + \left(\frac{\dot{m}_{exp} - \dot{m}_{num}}{\overline{\dot{m}_{exp}}} \right)^2 \right] \quad (1)$$

T_{out}, $\dot{W}$ and $\dot{m}$ are respectively the expansion outlet temperature, the power output and the fluid mass flow rate. The *exp* and *num* indices distinguish experimental quantities from numerically calculated quantities. A genetic algorithm is used to minimize the error ε and determine the value of the parameters listed in Table 1. To assess the accuracy of the model, a comparison is made between the experimental measurements and the recalculated numerical values based on the newly determined parameters (see Figure 2). It shows that the differences are less than 10% for 26 of the 30 configurations studied, what tends to validate the numerical approach.

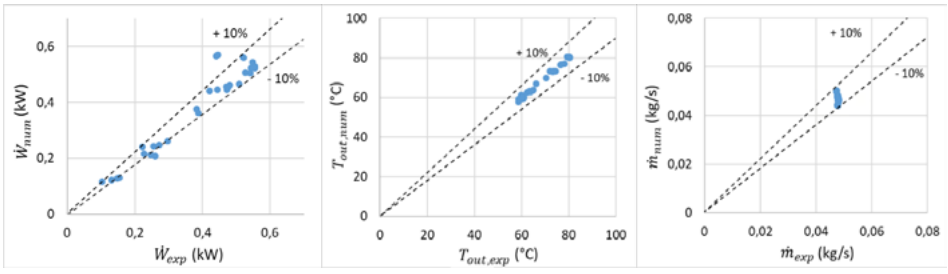

Fig.2. Comparison of numerical (vertical axis) and experimental (horizontal axis) results of $\dot{W}$, T_{out} and $\dot{m}$

The heat exchange coefficients of the model depend on both the properties of the scroll and the working fluid. In order to preserve the validity of a model calibrated on a type of scroll expander for different fluids, [14] uses the intrinsic properties of the fluids to recalculate the heat exchange coefficients. Thus, the values of the exchange coefficients $AU_{in,n}$ and $AU_{out,n}$ determined for R245fa take the values of 6 W/K and 15.7 W/K

respectively with ammonia. The study of an expander designed to operate with ammonia also requires adapting its geometry to be compatible with the properties of the fluid. Thus, since the expansion rate of ammonia is significantly higher than that of R245fa, the BVR is reduced to 1.9 in the scroll expander model.

To evaluate the performance of the expander, its efficiency is defined as follows:

$$\eta_{expa} = \frac{\dot{W}}{\dot{m} . \Delta h_{is}} \quad (2)$$

With Δh_{is} the enthalpy variation of the fluid in the scroll in the case of an isentropic transformation (ideal).

4.2 Modelling of the combined cooling and power cycle

A numerical model was developed based on the prototype of absorption cycle presented previously [16]. For each component, the energy and mass conservation equations were formalized. The experimentally set values of pinch, pressure drop, and efficiency configure the heat exchanger model. Finally, it is assumed that the fluids are saturated at the outlet of each exchanger (except for an imposed superheating of 5 °C at the evaporator outlet). From this configuration, the model predicts the performance and thermodynamic states of the system for given operating conditions (temperature or power of the sources and solution mass flow rate).

To complete the development of the CCP cycle, the scroll expander model is integrated into the parallel absorption chiller model of the cold production circuit (see Figure 1). In addition, a superheater modelled as an adjustable power supply to the fluid precedes the scroll. In order to control the share of cold and electricity production, the split ratio r_s divides the refrigerant flow between the two production lines. It is equal to the ratio of the mass flow rate of ammonia passing through the evaporator to the mass flow rate of ammonia produced at the generator.

To estimate the cold production efficiency of the CCP cycle, the COP is defined as follows:

$$COP = \frac{Q_{evap}}{Q_{gen} . r_s} \quad (3)$$

With Q_{evap} the thermal power exchanged at the evaporator and Q_{gen} that at the generator.

5. Results and analysis

A first analysis focuses on the operation of the scroll expander under the operating conditions of the CCP cycle and define a newly criteria to assess the quality of expanders. We then explore the performance of the complete cycle and carry out a comparative study between the two configurations of the cycle presented in Figure 1. Finally, a transient study of the cycle introduces the dynamical behavior of this complex system.

5.1 Scroll performance under operating conditions of the CCP cycle

In a conventional absorption cycle, the flow of ammonia produced at the generator matches 20-30% of the flow of rich solution [10]. Tests on the absorption chiller device estimate a maximum flow rate of fluid through the expander of about 0.01 kg/s. Figure 3 shows the power production of the scroll with ammonia as a function of flow rate. In order to highlight the sensitivity of the scroll performance to the low flow rate imposed by the CCP cycle (~ 0.01 kg/s), the study focuses on the influence of the following sensitive parameters: the pressure variation in the expander ΔP and the leakage area A_{leak}. We note that for a leakage area equivalent to that determined for the expander installed on the ORC test rig (solid curves), energy production is nil or very low for flows below 0.01 kg/s. Indeed, in this configuration, the internal leakages are too large compared to the ammonia flow and the scroll is not being driven. This effect is even more important as the pressure differential in the scroll is high (bold curves).

With a leakage area reduced to 1 mm², the critical flow rate required to produce power is reduced to about 0.003 kg/s (dotted curves). As the leakage area is directly related to the volume efficiency of scroll expanders, this result illustrates the need to design highly efficient expanders for the development of small capacity CCP cycles. The reduced leakage area is retained for the rest of the study (A_{leak}= 1 mm²).

The characterization of leaks in expanders operating with ammonia is of major concerns as there are essential in the development of CCP cycle, Kalina cycle [18] or ORC operating with ammonia. Considering a critical leakage area being the limit for A_{leak} above the one there is no power generation, it is relevant for expander constructors to evaluate this critical area easily from the foreseen operating conditions. The equations that governs the leaks in Lemort's model involve numerous parameters [11].

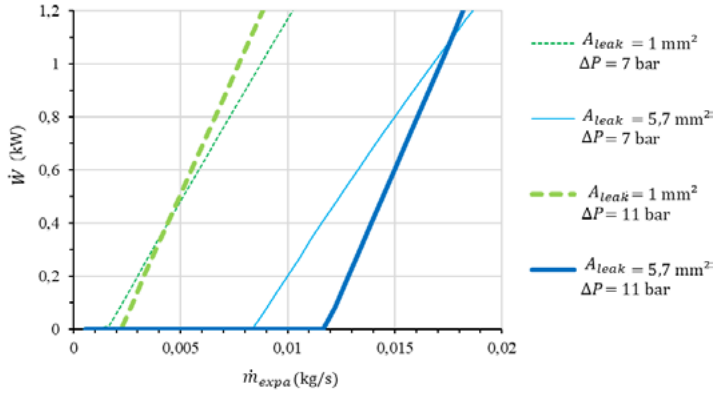

Fig. 3. Power produced by the scroll expander as a function of the leakage area and the pressure variation in the expander

A sensitivity analysis stated that mostly the leakage area, the upstream pressure and the fluid nature influence the leakage mass flow rate. Considering ammonia as operating fluid, an evaluation of the leaks evolution, with variations of the two remaining parameters, enable to identify an analytical law to predict the critical mass flow rate:

$$A_{leak,c} = k\frac{\dot{m}_{expa}}{P_{in}} \tag{4}$$

With k a constant consistent with speed unit and proper to the fluid. A regression of the mean square deviation between the law and the numerical prediction gives a value of k = 612.3 m/s for ammonia as working fluid. Finally, the prediction of the analytical law (equation 4) fits with the numerical calculation of a critical leakage area with less than 3.7 % of relative error (see Figure 4).

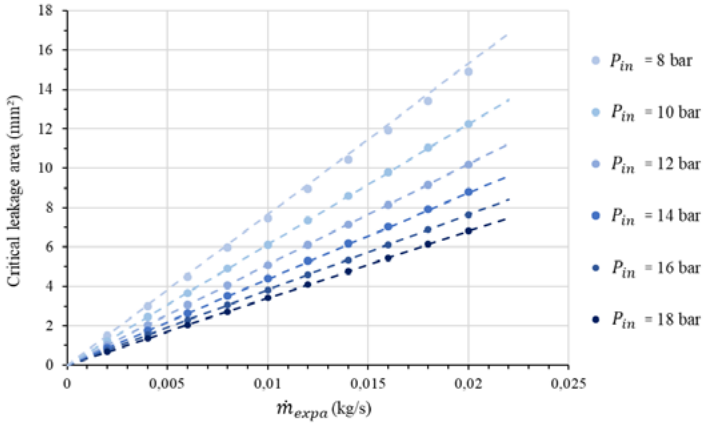

Fig.4. Numerical and analytical calculations of the critical leakage area of a scroll expander as a function of the ammonia mass flow rate and the pressure differential through the scroll.

The numerical data are computed for an inlet temperature of the fluid in the turbine of 110 °C and an outlet pressure of 4 bar. Nonetheless, sensitivity calculations show that the leakage mass flow rate varies less than 11 % for an input temperature between 90° and 160°C, with a slight leakage decrease when the temperature increases. Moreover, the outlet pressure doesn't act on the leakage numerical calculation unless it is greater than about 53 % of the inlet pressure, what is very rarely the case in ammonia absorption chiller. Thus, the

scope of validity of the analytical law to estimate a critical leakage area (equation 3) cover a large range of CCP cycles empowered by low-grade temperature source (90°C to 160°C).

5.2 Impact of the rectification of ammonia for power production

To compare the two configurations of cycles previously introduced, this study analyses the action of the rectifier on the cycle performance. By lowering the temperature of the gas produced at the generator, the rectifier will condense the remaining traces of water in the ammonia and redirect them to the poor solution. Thus, the rectifier limits the water content in the ammonia, but also reduces the flow rate in the downstream production lines. To quantify the overall influence of the rectification on cycle efficiencies, Figure 5 shows, for both configurations, the expander efficiency (equation 2) and the COP (equation 3) of the cold production as a function of the mass fraction of ammonia in the evaporator. For the comparison, the cycle inputs are set as follow: the sources of hot, intermediate and cold temperatures are set respectively to 110°C, 27°C and 18°C; the rich solution flow rate is set at 0.028 kg/s; the superheater imposes an increase of temperature of 15°C between the generated ammonia and the inlet of the scroll.

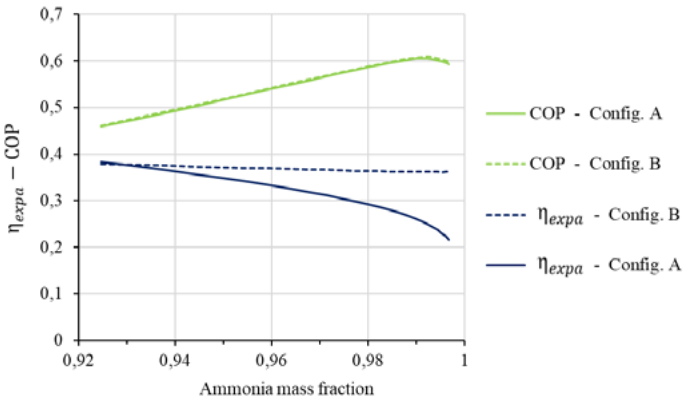

Fig.5. Expander efficiency and COP of the cooling production as a function of the mass fraction of ammonia at the evaporator

The results confirm the relevance of the rectifier to improve the performance of cooling production as the COP increases to an optimum corresponding to an ammonia content of 99.2%. In addition, it can be observed that the COP is logically relatively unaffected by the cycle configuration since in both configurations the rectifier is always upstream of the cold production line.

Focusing on power production, the rectification of ammonia before it passes through the expander (configuration A) results in a significant decrease of the expander efficiency. For instance, an optimal rectification for cooling production (99.2% ammonia content) leads to a 34% reduction of the efficiency. This trend does not occur when the ammonia entering the expander is not rectified (configuration B). The decrease of the expander efficiency is then limited to 5% and is due to the reduction of the high pressure of the cycle, which is related to the rectification rate occurring on the cooling production line. Finally, this result makes it possible to establish that the loss of performance attributable to the presence of water vapor in the working fluid is less significant than that due to the reduction in flow rate caused by the rectification.

Note that other constraints (serial CCP cycle, combined generator-rectifier, etc.) may favor the choice of a less optimal configuration (type configuration A). Then the quantified comparison presented in this study can be used as a reference to arbitrate between different architectural options.

5.3 Transient analysis of varying production of power and cooling

A dynamic model of the CCP cycle based on the previously used steady one is developed in the dynamic solver Dymola®. The objective is to foresee typical response times and potential instability of the cycle when changing the operation mode to adapt the production of cooling and power to the user needs. Those data would latter benefit to configure an efficient predictive control of the system. Some simplifications were made to the dynamic model to accelerate the calculation time of the simulations and to gives the possibility to explore various scenarios. Hence, the rectification and the sub-cooler system are not present in the dynamic modelling

and the expander is modelled via an isentropic efficiency and an imposed rotational speed of 60 Hz as if connected to a national electrical grid.

Figure 6 illustrates for two transient scenarios the typical response times of the power and cooling productions to a change of control of the three-way valve dividing the ammonia flux in the production lines. In the first setup, the split ratio r_s starts at a steady value of 0.5, corresponding to a simultaneous production of cooling and power. From $t = 0$, the operating control changes to reach $r_s = 0$ (i.e. power production alone). In the second setup, the split ratio r_s starts at a steady value of 0 and from $t = 0$, the operating control changes to reach $r_s = 1$ (i.e. cooling production alone). To match the behavior of classic automated valves, the valve switching time t_v is set to 20 seconds in the first scenario and 30 seconds in the second one.

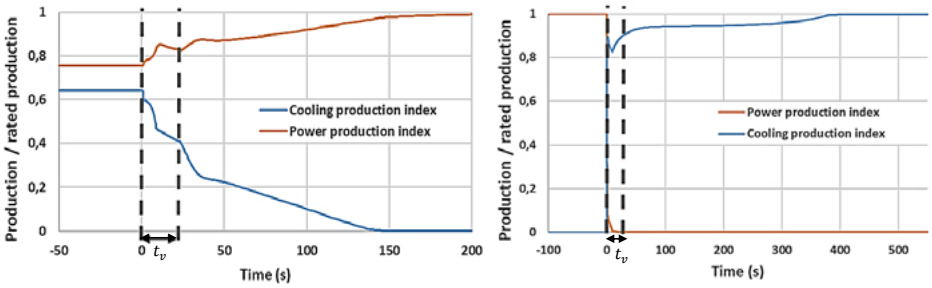

Fig.6. Evolution of the productions of cooling and power after a change of the controlling inputs. From a mix of both productions to power production alone (left) and from a power production alone to cooling production alone (right)

The first important observation is that there is no important instability of the system when switching from a production mode to another. The dynamic simulations predict that the transitions are not systematically instant, but they are always smooth enough to guarantee the stability of the system.

When switching from a mix production mode to a power alone production mode, a transient phase occurs before the cooling production stops and the power production reaches its nominal value. This is mainly the consequence of the condenser and evaporator inertia. Both heat exchangers partly contain liquid ammonia when cooling production is operating, so when the valve closes before the condenser, this ammonia will take time to evaporate as the system low pressure decreases. The symmetrical increase of power production is a consequence of the lowering low pressure that implies an increase of the pressure ratio at the expander ends. In the present simulation, this transient state last about two minutes and this time will be directly correlated to the volumes of the heat exchangers.

In the second scenario, when switching to power production alone to cooling production alone, the power production stops instantaneously as there is no storage of ammonia before the expander and the flow is immediately null. The initialization of cooling production is instant too, but it takes about 6 minutes to reach the optimal cooling production as the heat exchangers takes time to reach their liquid/vapor equilibrium.

6. Conclusion

Among the CCP cycle architectures under development, those in parallel are the most versatile and easiest to implement but they have not been widely investigated. To contribute to the development of these systems, a complete numerical model of the parallel CCP cycle was developed and configured through the characterization of two experimental devices: an ORC test rig to characterize a scroll expander and an absorption cycle to evaluate the rest of the system.

Early results highlighted the importance of using a detailed expander model to quantify the intrinsic physics of the flows in the scroll. Indeed, under the operating conditions of a small capacity machine, low flow rates require the use of expanders of high volume efficiency. Moreover, an analysis focusing on the role and position of the rectifier in the cycle highlights its influence on the performance of power production. This result introduces a new criterion for cycle architecture optimization. Finally, dynamic simulations of a combined cooling and power cogeneration system predict that the transition between production modes are quite stable and the transition times are longer when stopping cooling production than when stopping power one.

Abstract

Recent advances have introduced ionic membranes that can provide high water permeability in heating, ventilation, and air conditioning (HVAC) applications. These materials can be useful in many applications to help provide more efficient building technologies and higher indoor air quality through devices such as ionic liquid heat pumps (ILHPs), ionic liquid desiccants (ILDs), and energy recovery ventilators (ERVs). Water transmission mechanisms behind the water transport is not well understood, since different ionic membranes provide transmission in different ways. Water transportation can be a function of ionomer structure via the building blocks of the backbone, or from the functional groups on the side chains or from subtle features in membrane design and composition. In this work, we studied the permeation properties of different advanced ionic membranes. Membranes that show high water selectivity, and permeabilities exceeding 2*10-5 g/(s*m^2*Pa) are presented. High performance membranes are identified for optimum applications for different HVAC systems.

1. Introduction

Building operation consumes more than 40 percent of the total energy used in the United States and building heating and cooling loads comprise the largest fraction [1]. Demand for cooling energy is exacerbated in hot and humid climates. High humidity poses a serious limitation to the design and operation of buildings, promoting mold and dust mites and often associated with increased disease transmission. Consequently, dehumidifying air in building ventilation systems is normally a requirement to mitigate the effects of high humidity, improve indoor thermal comfort, and meet indoor design conditions.

For over a century, the vapor-compression system (VCS) has been the de facto technology of choice in heating, ventilation, and air conditioning (HVAC), especially for dehumidification and cooling. Despite its success, research, policy, and economics all encourage change considering its many inherent shortcomings. From an energy standpoint, the inability of the VCS system to decouple latent and sensible loads leaves condensation, an energy intensive process, as the only means for dehumidification. The heart of the VCS system lies in the refrigerant, whose chemistry has evolved in response to policy and environmental concerns. From chlorofluorocarbons (CFCs) and hydrochlorofluorocarbons (HCFCs), banned under the Montreal Protocol in 1987, to hydrofluorocarbons (HFCs), such as R-134a with a global warming potential (GWP) 1430 times that of carbon dioxide (CO_2), environmental concerns associated with VCS can no longer be overlooked [2]. These concerns, coupled with potential excess greenhouse gas (GHG) emissions resulting from the inefficiencies inherent in the system, place research on future HVAC technologies at the cornerstone of any effort aimed at mitigating climate change.

Researchers are pursuing alternatives to these conventional practices, especially for cooling and dehumidification. Advancements in artificial membranes enable new possibilities in this area. While traditionally used for industrial separations, such as reverse osmosis and gas separation, membranes provide a means to selectively transfer water vapor from one fluid to another [3], [4]. Polymeric, non-porous reinforced membranes are made from ionically functionalized polymer materials. These materials have ionically conductive groups embedded in the repeating unit of the polymer that aid in the transportation of water through the membrane. The methods for this mass transfer are being researched, and a few of the HVAC applications and transport methods are discussed in the following section.

2. Technology Description

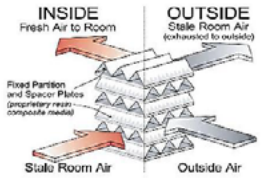

Fig. 1. Schematic of an ERV

In this paper, we explain the importance of pervaporation in heating, ventilation and air conditioning. The term ‘pervaporation’ is derived from a three-step process: (a) Sorption of permeating components at the feed side into a membrane, (b) Transport of components across a membrane by diffusion according to Fick’s law and (c) Evaporation or desorption at the permeate side into vapor phase. The driving force for transport of different components is provided by a chemical potential difference between the liquid feed/retentate and vapor permeate at each side of the membrane. The main advantage of a pervaporation technique versus conventional approaches in a heat and mass exchange application is its fundamental capacity to save energy and water. Pervaporation systems eliminate aerosols or air contamination by liquid water and therefore avoid any entrained contaminants evolved from dissolved solids in the feed water stream carried over to air streams. Pervaporation systems are modular, scalable, simple to operate and can be started up and shut down rapidly. The objective for these pervaporative systems and membranes are to reduce the total energy load for the systems. This is done by latent cooling i.e. reducing the relative humidity in the air to be treated. Energy recovery ventilators (ERV) and pervaporative cooling of water are also discussed.

Ionic liquids, as the name implies, are synthetic ionic salts that remain liquid under normal operating conditions. These fluids are mainly useful for their water desiccation properties, as they can adsorb or desorb water vapor to help control the relative humidity of the air in its container. With membranes, they are mainly utilized in flat sheet or shell and tube contactors that utilize fluid flows of air and desiccant in crossflow patterns. These systems can dehumidify gas streams with relatively high efficiency. Additionally, these contactors can be paired with a heat pump system to regenerate the desiccant so that the system can be operated in a loop. The synthetic ionic liquids can be engineered such that the waste heat from the heat pumps can be utilized to regenerate them.

ERVs will use an assembly of corrugated sheet membranes to allow heat and mass transfer between the outgoing exhaust air stream and incoming makeup air. A schematic of an ERV is shown in Fig. 1. In this figure “outside” makeup air is contacted with “inside” exhaust air and heat and moisture are exchanged. This passively conditions the air before entering the air-conditioner and reduces energy load of the HVAC system.

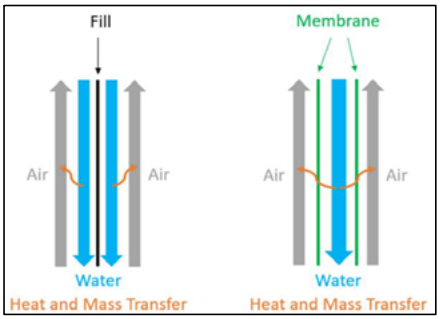

Fig. 2. Schematic of a cooling tower fill and our proposed membrane based evaporative condenser

Pervaporation can also be used as a substitute to evaporative cooling. Unlike conventional cooling tower fills (shown in the left side of Fig. 2), in which the cooling water and the ambient air are in direct contact, in the proposed concept, (shown in right side of Fig. 2) the membrane acts as a selective barrier between the two phases: the liquid-phase feed and the vapor-phase permeate. It allows the desired component(s) of the liquid feed to permeate (transfer) through it by vaporization. The driving force for the separation is the difference in the partial pressures of the components on the two sides and not the volatility difference of the components in the feed.

3. Experiment & Results

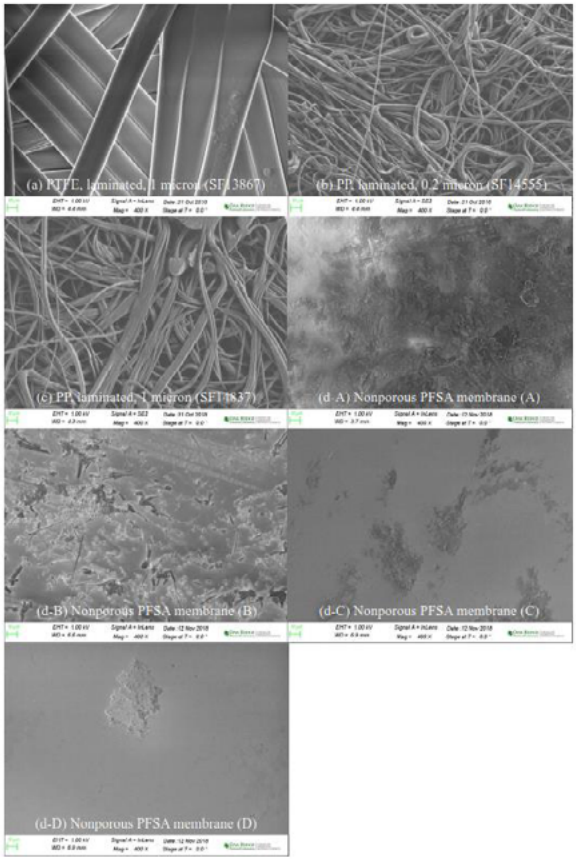

Fig. 3. Microstructures of membranes tested

In this section we discuss moisture vapor transmission results of four PFSA (perfluoronated sulfonic acid) nonporous membranes with different acidity and three commonly used porous membranes. The four PFSA nonporous membranes are the acid form of the perfluorinated sulfonic ionomer membrane (PFSA), which is an ion-conductive polymer, with an electrically neutral semi-crystalline polymer backbone (hydrophobic polytetrafluroethylene) and a randomly tethered sidechain with a pendant ionic group (hydrophilic), SO_3^-, that is associated with a specific counterion (e.g., $SO_3^- + H^+ \rightarrow SO_3H$). Two of porous membranes are unlaminated polypropylene membranes with the pore size of 0.2 μm (model number: SF14555) and 1.0 μm (model number: SF14837), respectively. They have a thickness of 150~250 μm and a porosity of 60% approximately. Another is a laminated PTFE membrane with the polypropylene (PP) support (model number: SF13867). It has a pore size of 1.0 μm, a thickness of 150~220 μm, and a porosity of 80~90% approximately [5], [6]. The test index, type, and properties of the investigated membranes are listed in Table 1. Moreover, the microstructures of the tested membranes are photographed using the transmission electron microcopy technology, as shown in Figure 5.

Table 1. Properties of the tested membranes.

Model Number	A	B	C	D	SF13867	SF14555	SF14837
Membrane Test Index	1	2	3	4	5	6	7
Dense/Porous	Non-Porous	Non-Porous	Non-Porous	Non-Porous	Porous	Porous	Porous
Wettability	Hydrophilic	Hydrophilic	Hydrophilic	Hydrophilic	Hydrophobic	Hydrophobic	Hydrophobic
Pore size (μm)	N/A	N/A	N/A	N/A	1.0	0.2	1.0
Porosity (%)	N/A	N/A	N/A	N/A	80-90%	60%	60%
Thickness (μm)	~25	~25	~25	~25	150-220	150-250	150-250

The water vapor transmission rate (WVTR) of the membranes were measured with the wet cup and dry cup method described by ASTM E96 (ASTM 1995), as well as some modified methods such as upright wet cup fulfilled with water, reversed wet cup, and upright wet cup filled with liquid desiccant. The basic procedure of the test is sealing a tested membrane to the open mouth of a permeability cup which contains a certain amount of water or desiccant inside. During the test, the permeability cup is placed on the top of a scale in an air-conditioned chamber with controlled air temperature and humidity. Periodic weighing is documented by the data acquisition system to determine the rate of water vapor movement through the membrane from the cup inside to the controlled chamber or vice versa.

Figure 4: Cup configurations: (a) wet cup with air gap, (b) dry cup using solid desiccant, (c) wet cup without air gap, and (d) reversed wet cup

The first method we used is wet cup method. The wet cup is shown in Figure 4(a), with distilled water inside, and an air gap existing between the membrane and distilled water. The second method is the dry cup method containing a certain amount of anhydrous calcium chloride ($CaCl_2$) as shown in Figure 4(b). The membrane and the solid desiccant do not contact with each other. The wet cup method is typically used to simulate regions of high humidity and the dry cup is more reflective of drier climates. The third method is the wet cup without air gap method. This method is very similar to the conventional wet cup method. The only difference is that the distilled water is filled in the permeability cup and the membrane is bonded and contacted with the water tightly without any air gap, as shown in Figure 4(c). The fourth one is the reversed wet-cup method. This method is also very similar to the wet cup method. The only difference is that the permeability cup is reversely placed in the chamber so that the distilled water inside the cup contacts with the membrane directly as shown in Figure 4(d). By inverting the cup, there is a greater pressure driving force across the membrane making the test more reflective of conditions with a signifigant pressure driving force.The last two methods we used are the liquid desiccant methods (not pictured), which use an aqueous solution of calcium

chloride ($CaCl_2$) with a mass concentration of 40% with air gap (e) or without any air gap (f). The test conditions are listed in Table 2.

Table 2. Summary of test conditions

Cup method	B	A	C	D	E	F
Membrane Test Index	1-7	1-7	2,3,4	1-7	1-7	1-7
Air gap	Yes	Yes	No	No	Yes	No
$T_{chamber}$ (°C)	24.5	24.5	24.5	24.5	24.5	24.5
$RH_{chamber}$ (%)	80.8%	80.8%	80.8%	80.8%	80.8%	80.8%
$Pv_{chamber}$ (Pa)	2495	2495	2495	2495	2495	2495
Materials inside cup	$CaCl_2$	Distilled water	Distilled water	Distilled Water	$CaCl_2$ Solution	$CaCl_2$ Solution
Pv_{cup} (Pa)	0	3076	3076	3076	1260.5	1260.5
Pv_{diff} (Pa)	2495	581	581	581	1234.5	1234.5

With the above experimental apparatus, the water vapor permeance of the seven membranes were tested at several different conditions, including wet cup with air gap, wet cup without air gap, reversed wet cup and dry cup (using solid desiccant) with air gap. These experiments were used to generate weight change data, with respect to time. Figures 5 and 6 provide examples of the results of these experiments.

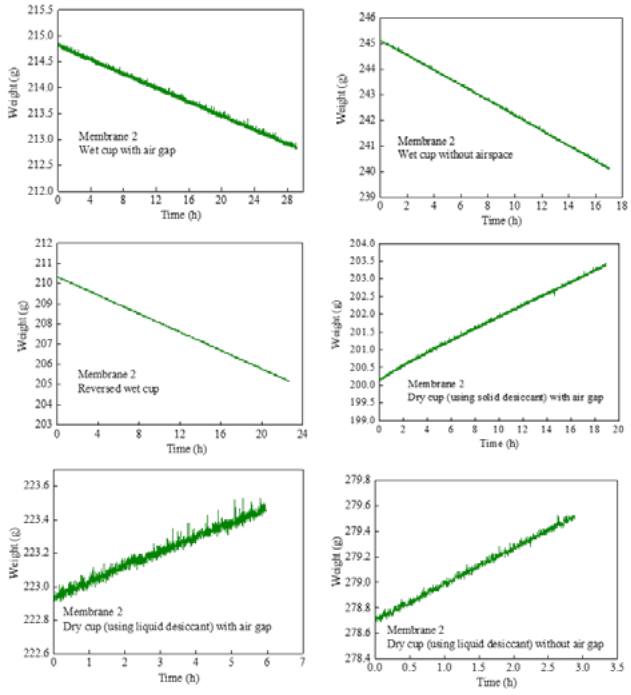

Fig. 5. Example weight change with time for a non-porous membrane (membrane 2)

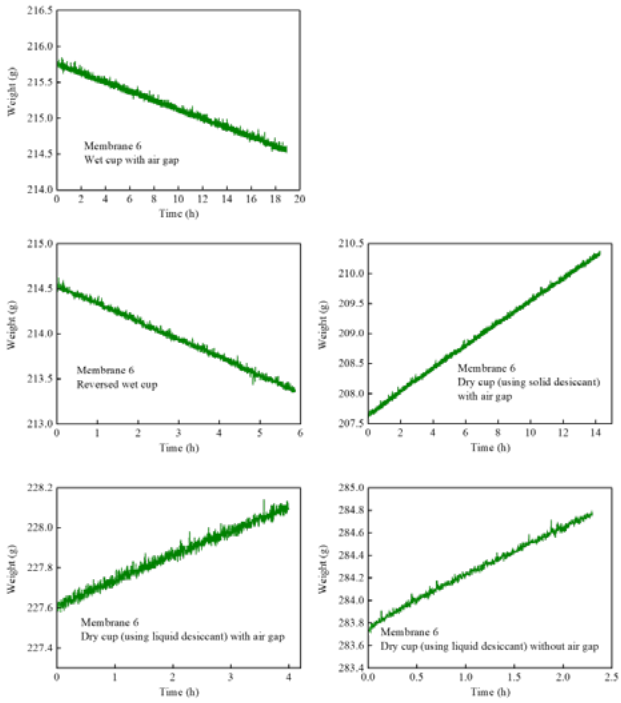

Fig. 6. Example weight change with time for a porous membrane (membrane 6)

The water vapor transmission rates of the membranes were derived for each membrane using figures similar to Figure 5 and 6. These rates were normalized to the surface area of the membrane and the pressure difference across the membrane (the driving force of permeation) to calculate the water vapor permeance, as reported in Table 3.

Table 3. Measured water vapor permeance of seven membranes (10^{-5} g/m^2-s-Pa)

Cup Test Method	Non-Porous Membrane				Porous Membrane		
	1	2	3	4	5	6	7
A	0.8474	1.080	1.118	1.118	0.9810	1.010	0.9684
C	N/A	4.689	4.465	4.396	N/A	N/A	N/A
D	3.150	3.638	3.482	3.654	3.155	3.168	3.133
B	0.5796	0.6138	0.7546	0.6589	0.8110	0.6993	0.7773
E	0.7899	0.6594	0.8163	0.8372	0.9047	0.9267	0.8412
F	2.696	2.090	2.944	2.767	2.824	3.259	3.267

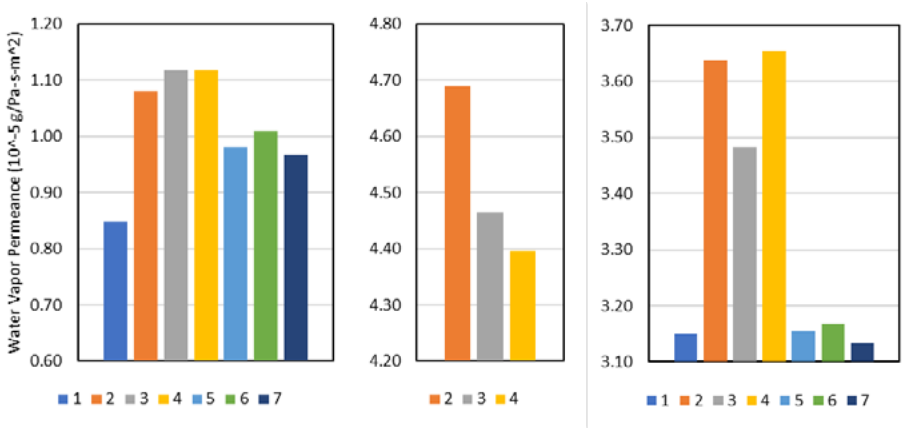

Fig. 7. Water vapor permeance of different membranes measured with (left to right) wet cup with air gap, wet cup without air gap, and reversed wet cup methods

The wet cup testing methods are the most reflective of the conditions seen in ERVs, evaporative cooling towers, and ILD modules. As seen in Fig. 7, Membrane 2 had on average the best performance during the wet cup tests. Membrane 4 was a close second, however, taking economic considerations into account, (Membrane 2 is commercially produced while Membrane 4 is currently only produced for R&D purposes), Membrane 2 was selected as the transport element in the experimental heating and cooling devices. While Cup Test Methods E and F could have provided insight into the interaction between the membranes and a liquid desiccant, the tests did not produce conclusive results. The results of Cup Test Method B, which is more commonly used with low permeation materials [7], was not analyzed further in this study.

4. Pervaporative HVAC Devices using Membrane 2

4.1. Ionic Liquid Desiccant based dehumidifier

A new membrane-based liquid desiccant air dehumidification (MLDAD) technology utilizes the membrane technology and ionic liquid desiccants (ILDs) to prevent carryover and corrosion in LDAD [8]. The semi-permeable membrane separates the air and liquid desiccant but allows a good mass transfer between them. Therefore, solution droplets cannot enter the air stream to corrode the metal ductwork and degrade the air quality. The ILDs are synthesized salts in the liquid phase. They are non-corrosive to metal and non-crystallizable so that the solution side corrosion issues can be avoided and the reliability of the MLDAD system can be improved. The performance of the dehumidifier at different conditions are as shown in Figures 8 through 10.

The high humidity upstream air was dehumidified by the MLDAD to the decreased humidity downstream. The analysis of these figures was only performed at steady-state, roughly 5 minutes after the test began and after the inlet (upstream) humidity stabilized. Startup conditions varied, depending on the air flow rate. The primary variable effecting the dehumidification power of the system was found to be the ambient (upstream) relative humidity. When comparing Figures 9 and 10, the high inlet humidity (94.0% RH, Figure 9) increased the absolute humidity drop across the module to over twice the absolute humidity drop under the inlet conditions of Figure 10. At low upstream absolute humidities and low airflow, as in Figure 8, the MLDAD module does not provide significant latent cooling – the average absolute humidity drop across the membrane is about 1 g/m^3.

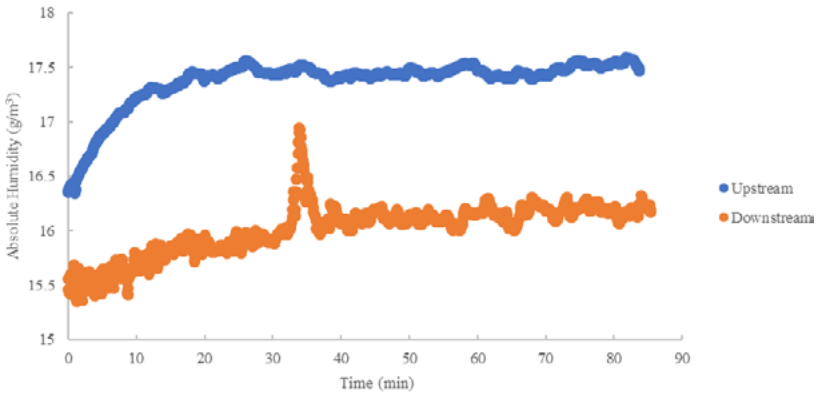

Fig. 8. Dehumidification of air at 0.28 m³/min (10 CFM), average inlet (upstream) RH of 53.0% and an average outlet (downstream) of 50.0% RH (30.5°C). Note that the spike in AH between 30 and 40 min was caused by a leak in the system. This leak was resolved during the test and these data points were disregarded in the analysis.

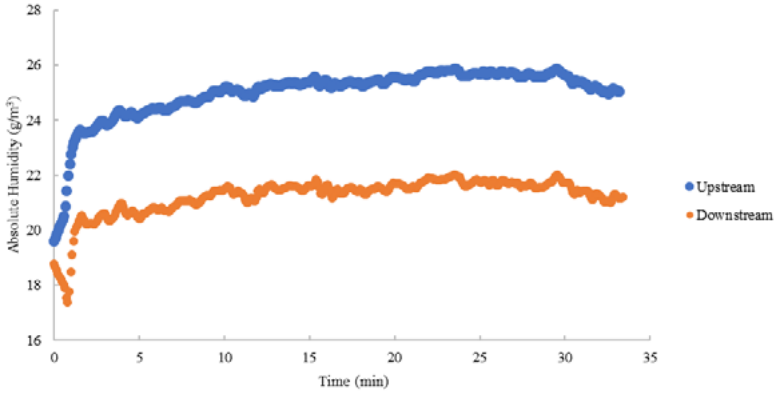

Fig. 9. Dehumidification of air at 0.85 m³/min (30 CFM), average inlet (upstream) RH of 94.0% and an average outlet (downstream) RH of 78.5% (26.8°C)

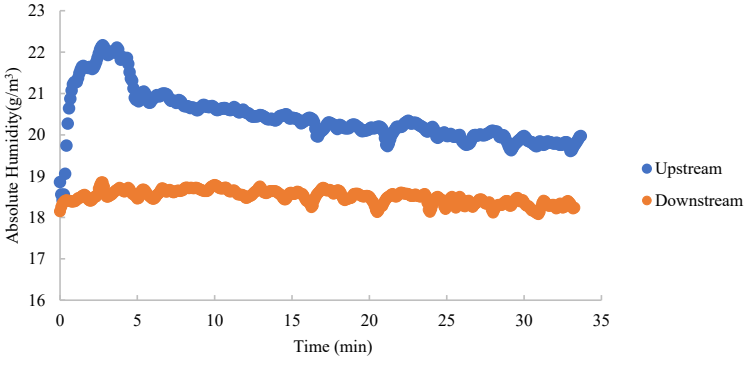

Fig. 10. Dehumidification of air at 0.85 m³/min (30 CFM), average inlet (upstream) RH of 70.3% and an average outlet (downstream) RH of 63.3% (28.8°C)

4.2. Membrane based cooling towers

Pervaporative membrane tubes or flat sheets can also be used in manufacturing advanced evaporative cooling devices. These devices can be used to provide cooling to water downstream of the condenser side of chiller. They can also be used to cool large datacenters and other electronics cooling applications. In Figure 11, we show an evaporative cooling prototype made of pervaporative membranes. It is 40.6 cm (16") in height, 30.5 cm (12") in width and 15.2 cm (6") in depth. The small scale evaporative cooling device made of pervaporative membranes was tested using inlet water at 35°C (95°F) and water flow rate between 9.5 and 37.9 LPM (2.5 and 10 GPM). Figure 12 compares the heat transfer capacity of pervaporative cooling device at different flow rates of water. The test data shows a significant enhancement of pervaporation cooling performance due to an increase in water flow rate; the heat rejection is nearly directly proportional to the flow rate. This shows that advanced pervaporative cooling towers are feasible and scalable, especially when coupled with energy efficient water pumps.

Figure 11. Membrane Evaporative Cooling Module

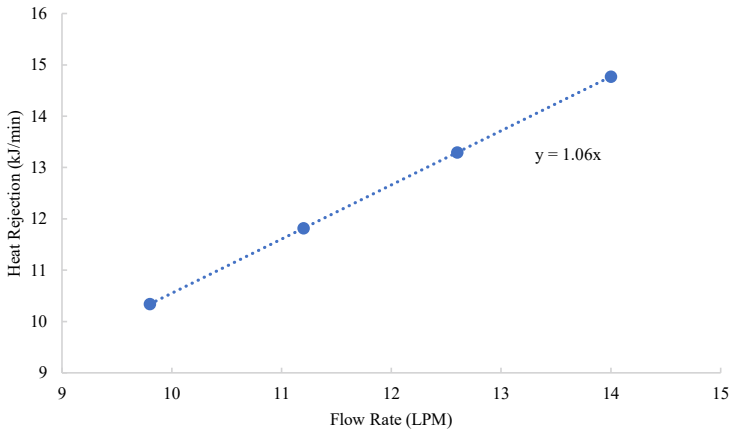

Figure 12. Heat rejection characteristics of membrane evaporative cooling module & linear fit where "y" is the heat rejection in kJ per min and "x" is the flow rate in liters of water per minute

5. Conclusions

Pervaporative membranes show strong potential for energy efficient heating and cooling. As presented in this paper, proof-of-concept laboratory protoypes have been developed for membrane based liquid desiccant air dehumidification and pervaporative membrane heating and cooling towers. The MLDAD system was able to provide dehumidification while preventing the potential for corrosion, seen in previous systems. Membrane based cooling towers were found to be a scalable source of evaporative cooling. However, as HVAC membrane

technology is considerably young, when compared to traditional vapor compression air conditioning, there is still significant research and development to be made in the field. In order to be competive with conventional technology, the next steps to commercialization is cost and longevity research. However, the technologies described in this paper are at different stages and have their own research needs.

Specifically, measured performance is needed on commercial products for a range of inlet temperatures and humidities. In-the-field monitoring can also show how performance varies with inlet condition, and also how it deteriorates with time. Membrane liquid desiccant dehumidifiers require manufacturing methods that ensure leak-free modules, which can be checked with accelerated life testing of the conditioner and regenerator. Membrane prototypes for evaporative cooling and humidification have shown the feasibility of this process. It is also unclear whether membranes, with their added cost, will be preferred to wicked surfaces. Across all systems membrane fouling may present a problem. However, using lessons learned from the fouling issues in industrial membrane processes, the magnitude of this problem can be mitigated. The HVAC applications are also expected to see fewer contaminants than traditional industrial membrane processes, further decreasing the significance of this issue.

The outlook for these membrane devices is uncertain. Advances in membrane technology over the previous few decades have enabled these unique devices for HVAC applications, which could potentially lead to more energy efficient products. But more research and development are needed if these products are to compete against the inexpensive and established air conditioning technologies.

6. Nomenclature

Table 4. Acronyms and abbreviations, defined.

Term	Definition	Term	Definition
AH	Absolute humidity (g/m^3)	ILD	Ionic liquid desiccant
CFC	Chlorofluorocarbons	ILHP	Ionic liquid heat pump
CFM	Cubic feet per minute	LDAD	Liquid desiccant air dehumidifier
ERV	Energy recovery ventilation	LPM	Liters per minute
GHG	Greenhouse gas	PFSA	Perfluorosulfonic acid
GPM	Gallons per minute	PP	Polypropylene
GWP	Global warming potential	PTFE	Polytetrafluoroethylene
HCFC	Hydrochloroflurocarbon	RH	Relative humidity
HFC	Hydroflurocarbon	VCS	Vapor compression system
HVAC	Heating, ventilation, and Air Conditioning	WVTR	Water vapor transmission rate

Abstract

R290 (propane) is a flammable refrigerant having an A3 classification according to the ASHRAE Standard 34. Because of its extremely low Global Warming Potential (GWP), several regions around the world use or consider using it for air-conditioning and refrigeration applications. On the other hand, the R290 application is currently limited to small charged self-contained air-conditioning and refrigeration products in most of the world due to its high flammability and safety implications. The possibility of increasing R290 charge limits set by relevant safety standards (IEC/UL-60335-2-40 and IEC/UL-60335-2-89) is being evaluated in the working groups of these standards.

To properly address A3 refrigerants in safety standards, the Air-Conditioning, Heating, and Refrigeration Technology Institute (AHRTI) undertook a research project to investigate R290, specifically to carry-out leak and ignition testing under whole room scale conditions.

This paper summarizes the results of A3 refrigerant R290 leak and ignition tests for a packaged terminal air-conditioner (PTAC). A mock-up full scale motel room was built with a wall mounted PTAC installed. The testing simulated refrigerant leaks from the evaporator with ignition sources present. Two different R290 charge levels (114g and 217g) were tested. The tests also included using the PTAC circulation fan to disperse leaked refrigerant in the test room as a mitigation method. The tests demonstrated that the ignition severity depended on the charge level and the fan operating state. In all ignition events observed, the highest temperatures were recorded close to floor level indicating flames were low in height. The results were also compared to existing test results of A2L refrigerants R32 and R452B under the same test setup.

Keywords: Low GWP, refrigerant, flammability

1. Introduction

The global industry is transitioning to environmentally friendly low global warming potential (GWP) refrigerants. To date, most of promising low GWP refrigerants are flammable. Implementation of these refrigerants in the field requires revisions of relevant safety standards and codes. To advance the understanding of flammable refrigerants safety, AHRTI launched a research project to conduct whole room scale testing. The objective was to conduct refrigerant leak and ignition testing under whole room conditions to understand the potential ignition and event severity associated with the use of A2L and A3 refrigerants [1, 2]. The whole room testing was conducted by AHRTI's contractor UL at its test facility in Northbrook, IL.

The overall testing consisted of scenarios that represented refrigeration and air conditioning applications. The refrigeration applications included reach-in coolers testing. Air conditioning scenarios included (i) motel

* Corresponding author. Tel.: +1-703-600-0305.
E-mail address: xwang@ahrinet.org.

room with PTAC unit; (ii) motel room with mini-split unit. For simplicity, this paper provides a high-level summary of the PTAC tests. More detailed information is contained in the project final reports [1, 2].

2. Test Setup and Procedures

Refrigerants R290, R32 and R452B were tested for the PTAC. Their information is listed in Table 1. One can observe that R290 has significantly lower LFL than the two. Therefore, its allowable charge amount is much less than A2Ls.

Table 1. Refrigerant properties

Parameter	R290	R32	R452B
Safety Classification per ASHRAE Standard 34 [3]	A3	A2L	A2L
Lower Flammability Limit (LFL, % volume)	2.1%	14.4%	11.9%
Lower Flammability Limit (LFL) kg/m³ at 101.3 kPa	0.038	0.307	0.310
Upper Flammability Limit (UFL, % volume)	9.5%	29.3%	22%
Laminar Burning Velocity (cm/s)	44	6.7	<4.0
Composition (% mass)	R290 (100%)	R32 (100%)	R32/R1234yf/R125 (67%/26%/7%)

A full scale motel room was built to simulate real application. To avoid over-pressure and damage to the test room from ignition events, six deflagration vents were created at the top section of two walls. Four of them had dimensions of 0.6m x 1.2m (2ft. x 4ft.), and two had dimensions of 0.6m x 0.9m (2ft. x 3ft.). They were covered by plastic sheets. The plastic sheets provided air seal environment inside the test room and could be blown or melted open due to pressure/temperature rise should an ignition event occur.

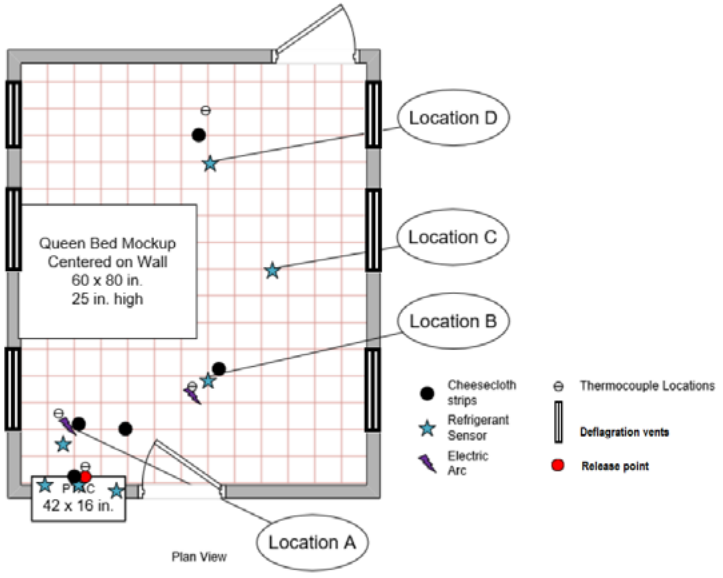

Fig. 1. Schematic of test room setup and instrumentation plan [2]

The plan view of the test setup is shown in Figure 1. The room dimensions were 3.95m x 4.81m x 2.42m (13ft. x 15ft. 9in. x 7ft. 11in.). The enclosed volume was 46.0 m³ (1620 ft³). The floor area was 19.0 m² (205 ft²). A mockup bed was located in the room. A PTAC was mounted such that the base of the unit was 0.4 m (16 inches) above the floor at the minimum distance from the side wall. An 8mm (¼ inch) O.D. copper tube

was placed in the center of the evaporator coil at 0.6 m (24 inches) above the floor. The tube was angled directly out from the face of the evaporator towards the front grill as shown in Figure 2. When used, the unit fan was operated on low speed. The fan volume flow rate was determined to be 5.7 m³/min (200 CFM). The measurements were made with a calibrated vane anemometer at several locations across the exhaust outlet and integrated with area to determine volume flow rate.

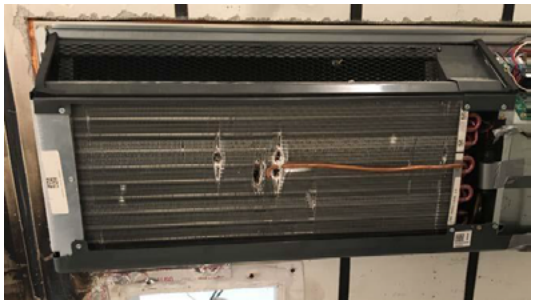

Fig. 2. PTAC discharge tube location [2]

The locations of the instrumentation, and ignition sources were located in clusters at locations A, B, C and D shown in Figure 1. These locations were chosen according to the expected refrigerant flow path. The leaked refrigerant gas concentration in the test room was measured by oxygen sensors (Apogee SO-220 electrochemical sensor). High speed video cameras installed at different angles to document the test events. Cheesecloth strips were used to indicate whether the refrigerant ignition would cause a secondary fire. A total of 32 Type K thermocouples were used to measure the temperature at different locations and heights within the room. The thermocouple response time was approximately 3 seconds. Their readings do not reflect actual flame temperatures. The instantaneous temperatures of the flames are higher than what the thermocouples recorded because thermocouples have response time delay, and the flames have fast movements.

During the test, the refrigerant in liquid phase was released into test room with several viable ignition sources present. The refrigerant release system is illustrated in Figure 3. Its two main components are a pressurizer tank and a release tank that are equipped with accessories such as control valves and temperature and pressure measurement. Both tanks contained R290 and were submerged in heated water tanks to achieve desired pressure and temperature conditions. The pressurizer tank ensures the release tank to release liquid refrigerant to the test room at a constant rate. The refrigerant release rate was controlled by a control valve that continuously adjusts its opening according to the feedback from the mass flow meter. The solenoid valve was used to start and stop the refrigerant flow during testing.

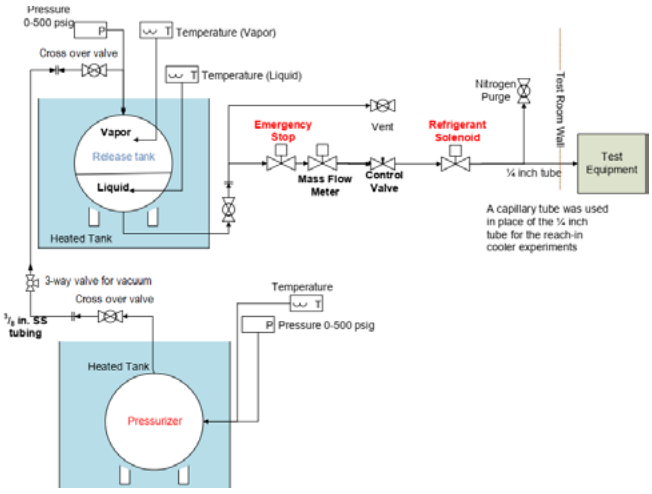

Fig. 3. Schematic of the refrigerant release mechanism setup [2]

The ignition sources used in the scenario tests are electric arcs. The electric arcs were created by a step-up gas tube transformer. The electric arc transformer was continuously energized for several minutes during the tests. The energy of the electric arc in one-half 60 Hz cycle was 0.147 joules (147 mJ). This ignition energy is nearly 300 times the commonly accepted minimum ignition energy of propane/air mixtures at 0.46 mJ [2].

The general procedure for testing was to get the refrigerant release system ready, initiate the data acquisition prior to release of the refrigerant, discharge the target quantity of refrigerant at the target flow rate, and energize the electric arcs at 5 seconds after the completion of the discharge.

The R290 test matrix is shown in Table 2. Two tests were conducted with the circulating fan off. One test was planned with the fan running before the discharge began.

Table 2. R290 test matrix

Fan State	Planned Discharge (g)	Planned Discharge Rate (g/s)
Off	114g	21.4
Off	217g	21.4
On	217g	21.4

The R290 charge levels used in the testing had their bases in either existing or proposed limits for A3 refrigerants. In the absence of recommended limits for A3 refrigerants, the formulas for A2L refrigerants were used on the assumption that limits for A3's would follow the same formula. This approach allowed the project to assess safety factors for refrigerant charge quantity and mitigation criteria including mitigation response time and airflow rate for mixing and threshold for performing a certain safety test for commercial refrigerators. Table 3 and the notes below the table contain the determination of the charge limits used in this test series. The R290 discharge rate was based on the finding that the mass flow rate of liquid propane is 49% of the R-32 liquid mass flow rate at the same saturation temperature and orifice size [2]. The value was selected so that comparisons are possible between the A2L and propane refrigerant tests in the 9007-01 [1] and 9007-02 [2] programs.

Table 3. PTAC Charge Limit Determination [2]

Charge Limit	A3 (R290)	A2Ls	Mitigation Requirement
m_1 per UL 60335 2-40 Nov 2017	$3 \times LFL$ (114g)	$6 \times LFL$ (R-32: 1.81kg, R-452B: 1.85kg)	No mitigation required
m_1 per IEC 60335 2-40 Edition 6	$4 \times LFL$ (152g)		
m_{max} per UL 60335 2-40 Nov 2017	217g (notes 1,3)	$0.5 \times LFL \times h_a \times A$	Air circulation
m_{max} per IEC 60335 2-40 Edition 6	325g (notes 2, 3, 4)	$0.75 \times LFL \times h_a \times A$	Air circulation

Notes:
1. Nov. 2017 draft of UL 60335-2-40 [4]: $m_{max} = 0.5 \cdot LFL \cdot h_a \cdot A = 217g$
2. IEC 60335-2-40 Edition 6 [5]: $m_{max} = 0.75 \cdot LFL \cdot h_a \cdot A = 325g$
3. Using A2L equations for A3. A3 equations in development.
4. 325g not tested because 217g ignited with air circulation

3. Test Results [1, 2]

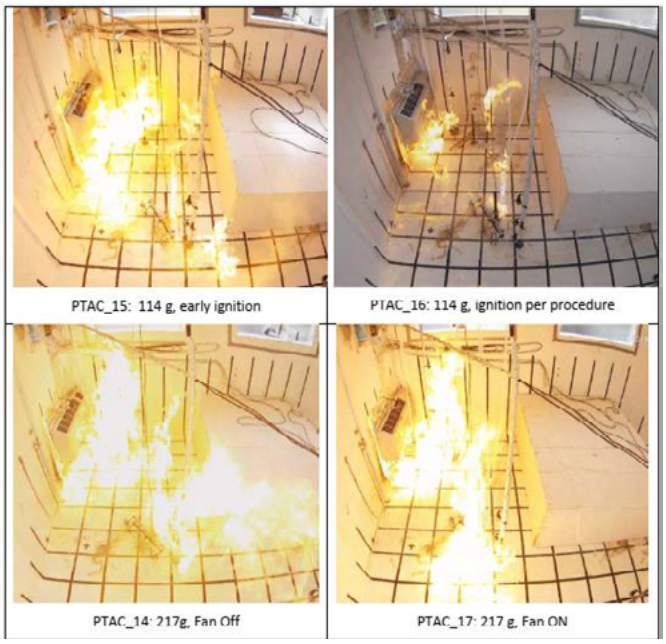
The PTAC ignition tests are summarized in Table 4. Three ignition tests (PTAC_14, 16 and 17) were performed following the plan outlined in Table 2. In PTAC_15 test, the electric arcs were energized ~1 s instead of planned 5 s after completion of the discharge. This test was repeated as PTAC_16. While PTAC_15 was incorrect in its procedure, the largest number of deflagration vents were burst in this test due to the higher concentrations existing immediately after completion of the discharge.

R290 tests all resulted in ignition even in the case that the fan was running continuously before the start of the discharge of 217g R290. The severity depended on the charge level. Without fan running, the highest temperatures were recorded close to floor level indicating flames were low in height (C-08, 8 inch above floor at location C). With the fan running, the highest temperature was measured at 60 inches above the floor at location B (B-60). Temperatures at the ceiling level were due to buoyant transport and not direct flame impingement. Temperatures and refrigerant concentrations over time at measured locations were not presented in this paper for simplicity. Readers are encouraged to read the report for details. Since all three planned tests resulted in ignition, testing at higher charge level was terminated.

Table 4. PTAC R290 ignition test results

Test Code	Fan State	Measured Discharge (g)	Measured Discharge Rate (g/s)	Max Temp (°C)	Max Temp Location	Max Ceiling Temp (°C)	Number of Vents Burst /Melted	Arc Delay Time (s)
PTAC_14	Off	214	18.3	463	C-08	216	3/3	4.3
PTAC_15	Off	111	20.9	534	C-08	277	4/1	0.9
PTAC_16	Off	110	20.4	371	C-08	99	2/1	5.7
PTAC_17	On (200cfm)	215	20.4	383	B-60	117	3/1	5.7

Estimates for the maximum flame size were made from the videos and are shown in Figure 4. The photos demonstrate the effect of timing the electric arcs. PTAC_15 was an invalid test and the comparison to PTAC_16 shows the effect of early ignition before the propane was able to mix and diffuse. PTAC_15 is considered an invalid test because its igniter timing was too short compared to the test plan, but still contains informative data about ignition timing. Comparison of PTAC_14 (Fan off) and PTAC_17 (Fan ON) both with 217 g discharges shows a small effect from the action of the fan in reducing the size of the flames. PTAC_17 (Fan on) resulted in bursting three deflagration vents compared to two bursts in the PTAC_14 test (Fan off)



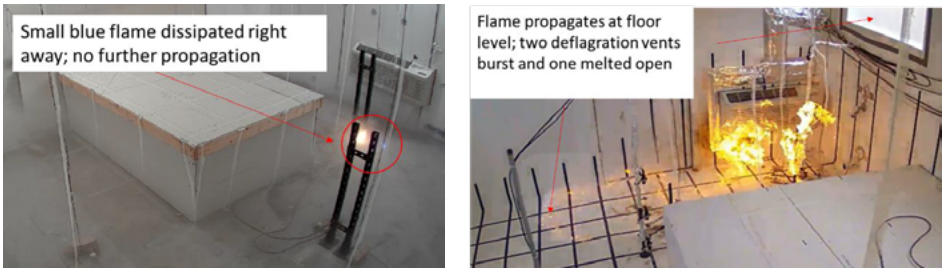


Fig. 4. PTAC Estimated maximum flame sizes

For comparison purpose, Figure 5 shows test results for both A2L refrigerant R452B and A3 refrigerant R290 using UL-60335-2-40 m1 charge level specified in Table 3. The R290 test parameters were listed as PTAC_16 in Table 4. The R452B test was conducted under the same room dimension and similar test procedure. 1.9 kg of R452B was actually released during the test (the target amount was 1.85kg). The R452B release rate was ~47g/s due to the density difference from R290 as noted before. The ignition source and ignition timing used for R452B test were also different from the R290 test. The ignition sources were electric arcs (same as R290 tests) with tea candles.

For R452B test, the ignition sources were energized approximately 27 second after the completion of the release. A small refrigerant flame was observed near location A (in front of the PTAC). The flame was quickly distinguished with no further propagation. The total flaming time for the refrigerant flame was 3 seconds. The cheesecloth was not ignited. The same test was performed using A2L refrigerant R32 at around 1.8kg with same release rate as R452B. The ignition sources were energized approximately 15 second after the completion of the R32 release. No ignition was observed. For R290 PTAC_16 test, the flame propagated along the floor indicating a flammable region had formed at the floor level.

(a)R452B, 1.9 kg, 47.4 g/s, no mitigation (b)R290, 110 grams, 21 g/s, no mitigation

Fig. 5. PTAC Test R452B vs R290

4. Discussion

The PTAC testing was designed to assess the R290 charge levels according to the then current proposed "Preliminary Comment Draft" of 3rd Edition UL 60335-2-40 (dated Nov 22, 2017) which was based on the 6th Edition of IEC 60335-2-40. According to the draft UL 60335-2-40, the charge limit for R290 is 114g regardless the room size for direct systems; however, the IEC standard 60335-2-40 Edition 6.0 allows higher charge. The IEC standard allows R290 charge up to 152g without room size restriction. Charge higher than 152g is correlated to the room area and equipment installation height for an unventilated room.

The PTAC AC tests indicated that the flammable cloud can form at floor level and be ignited at the current charge limit of 114g without room size restriction defined in UL 60335-2-40. The testing also demonstrated that the maximum allowable charge (325g) per the test room area (19m2) calculated using IEC 60335-2-40 would have caused R290 to build up flammable region around the unit vicinity at floor level and caused ignition when the ignition sources were present.

Both IEC and UL 60335-2-40 specify requirements for equipment using A2L refrigerants with incorporated circulation airflow which includes an incorporated fan to be either continuously operated or initiated by a refrigerant detection system. This concept is to ensure circulation airflow prevents refrigerant stagnation so that the equipment can use higher refrigerant charge than those without this feature. At present, neither the IEC nor UL 60335-2-40 has specified such requirements for A3 refrigerants that would allow higher A3 refrigerant charge quantity. IEC has established a WG (SC61D/WG16) to develop additional requirements for A3 refrigerants including the incorporated airflow concept. This project used the existing requirements for A2Ls in terms of determining charge quantity, minimum airflow rate for R290 tests to assess these requirements applicability to A3 refrigerants. The PTAC testing demonstrated that ignition can even happen while the PTAC fan is kept constantly on at low speed setting during the refrigerant release. This indicates that 1) the safety factor in the calculation of refrigerant quantity may not be enough; and 2) the mitigation using air flow may require a higher air flow rate than the A2L refrigerants to mitigate A3 refrigerants for floor mounted products.

The test results demonstrated that R290 was much easier to be ignited, and the ignition events were more severe compared to A2L refrigerants R32 and R452B at m1 charge level.

It should be stressed that testing scenarios were designed according to the existing requirements or proposed requirements in the IEC Standards 60335-2-40 and its equivalent North American version UL 60335-2-40. However, the R290 discharge rates were based on the finding that the mass flow rate of liquid propane is 49% of the R-32 liquid mass flow rate at the same saturation temperature and orifice size [2]. These values were selected so that comparisons are possible between the A2L and propane refrigerant tests in the 9007-01 [1] and 9007-02 [2] programs. As with the 9007-01 program, leak rates were almost always higher than the rate corresponding to total loss of charge in four minutes that was generally considered by the IEC/UL 60335-2-40. Generally speaking, this means the scenarios are more severe than they would have been with four minute leaks.

5. Summary

The PTAC testing generated a set of R290 dispersion and ignition data at different release amounts. The results provide useful information to product safety standard IEC/UL 60335-2-40. According to the testing, the following findings are recommended to the IEC/UL 60335-2-40 committee for consideration:

- Raising the current m1 (114g for R290) charge limit per UL 60335-2-40 should be carefully considered especially for floor or near floor mounted products.
- Any potential ignition sources should be avoided underneath installed units and near the projected area at floor level
- Air flow requirements as a mitigation method should be carefully considered in relation to the amount of refrigerant, and perhaps type of refrigerant (A2L's vs A3's).

The testing was more focused on understanding the ignition event severity, rather than the probability of the refrigerant ignition event. The future work should include characterization of refrigerant leak scenarios with actual equipment in "on" and "off" states, and real world ignition sources in terms of ignition energy, quantity, spatial location throughout the room, and activation frequency.

Abstract

The intermittent supply of renewable power and the continuous increase of electric demands pose challenges to the stability of existing electric grids and utilization efficiency of renewable power. The thermal energy storage applied to buildings is capable of utilizing the overproduced renewable power to store thermal energy, which is later discharged to meet thermal demands of buildings when renewable power production decreases. A novel geothermal heat pump system incorporated with underground thermal energy storage was investigated through a case study of applying the proposed system to a residential building in Baltimore, Maryland. A transient one-dimensional heat transfer model of the proposed dual-purpose underground thermal battery (DPUTB) was developed and integrated with simulation models of a dual source heat pump (DSHP) and a typical residential building to form a quasi-steady-state model of the proposed system. Simulation results indicate that the proposed system can shift the building electric demand from peak hours to other times when electricity is cheap. In a cooling season, the electricity consumption during peak hours is reduced by 40% and the associated electricity cost is reduced by 20%.

1. Introduction

In the U.S., the penetration of renewable power generation has increased to reduce greenhouse gas emissions. However, the intermittent outputs of renewable energy pose challenges to the existing electric grid. The grid operators curtail renewable power when the power production is greater than the demand from the consumer. Thus, it reduces the economic and environmental benefits of renewable power [1]. When renewable energy is not available (sunsets, cloudy, etc.), the power demand from the existing grid increases dramatically. It requires the electricity generators ramp up their production rate quickly, resulting in low operating efficiency and high power production cost.

Buildings consume 73% of all U.S. electricity according to Energy Information Administrator [2]. The electricity consumed for space heating and cooling counts 22% and 14% of the total electricity consumption in residential and commercial buildings, respectively, on an annual basis [3]. It means that space heating and cooling for buildings is responsible for 13% of the total electricity consumption each year in the U.S.

Thermal energy storage (TES) is a promising technology that allows storing heat (or cooling energy) generated with overproduced renewable power, or electricity from the grid during off-peak hours, and using them to meet the thermal demands of buildings during peak hours. One promising technology is the integration of TES with heat pump systems [4]. Heat pump technologies utilize electricity to provide space cooling and/or space heating, as well as domestic water heating. The TES integrated heat pump systems provide valuable load

shifting resources to utility companies for reducing its operation cost while meeting the demands for electricity, without increasing power generation capacity [5].

TES can be integrated into a building's thermal system in passive or active ways. The passive applications usually utilize the existing thermal mass of the building. However, it is difficult to control the charging and discharging rate in passive applications, and normally more energy is consumed due to high thermal loss to the ambient. On the other hand, the active applications utilize a dedicated TES and associated heating/cooling system to charge and discharge the TES with more precise control.

Stratified water tanks are widely used for demand side management (DSM) due to its availability and low cost [5-7]. Stratified water tanks integrated with air source heat pump (ASHP) for heating application in residential buildings are investigated before. Renaldi et al. [6] proposed an optimization method to minimize the total operating cost of the system. The simulation result indicated that 6% energy cost reduction can be achieved with the proposed system compared with a conventional gas boiler system when a time-of-use electricity rate is available. Arteconi et al. [5] applied a DSM strategy to shift electric load during 3-hour peak hours to off-peak hours. They concluded that by adding a water tank to the heat pump system, the load shifting effect can be realized without influencing the indoor thermal comfort. However, 4% more electricity was consumed compared to the baseline heat pump system (without TES). Stratified water tanks are also applied for DSM in cooling applications. Yan et al. [7] proposed an active TES using chilled water tank in an office building in Hong Kong. The simulation results showed that the proposed system was able to reduce the capacity of the chiller by 24%. However, 2.6% more electricity was consumed due to additional pumping and thermal loss from the TES tank.

Besides water tanks, phase change material (PCM) tanks [8,9] are also applied to heat pump systems for DSM because of the high energy storage density of PCMs during phase change process. Most previous studies for PCM tank integrated thermal systems are for heating application only. Lizana et al. [8] integrated a stratified PCM tank with an air-water heat pump (AWHP) in a residential building in UK and proposed a DSM strategy to minimize the electric cost by utilizing a time-of-use (TOU) electric rate tariff. The simulation results indicate a 20% electricity cost reduction, while the total electricity consumption increased by 8%. Hirmiz et al. [9] customized a hybrid PCM water tank and integrated it with a ground source heat pump (GSHP) in a residential building in Canada. The system could shift the peak electric demand during 6-hour to off-peak hours. In addition, by applying PCM, the tank volume was reduced by 3 folds compared with using water tanks.

Previous studies concluded that TES integrated heat pump systems could make the electric demand of a building more flexible. With appropriate sizing, the system can shift electric demand from peak period (3 to 6 hours) to off-peak period. If time-of-use electricity rate is available, the load shifting can lead to significant (up to 20%) electricity cost savings. In addition, by applying TES, capacity of the heat pump can be smaller. However, the TES integrated systems always consume more energy (3% - 8% increase) than conventional systems due to the heat loss from the TES tank and the additional pumping power. Moreover, most studies used ASHPs due to their low cost and easy installation. However, the efficiency of an ASHP is usually lower than a GSHP, especially in cold climates. TES tanks in previous studies are installed above the ground, which not only occupy floor area, but also be heavily insulated to reduce heat loss. Besides, neglected by most previous studies, the cost of the TES integrated system is high due to additional component for TES. As a result, its applications is limited despite of its potential benefits to both the building owners and the grid operators.

The current study proposes a novel geothermal heat pump system integrated with an underground thermal energy storage to make the electricity demand of buildings flexible. The proposed system includes a state-of-art design for a dual-purpose underground thermal battery (DPUTB), which combines TES and ground heat exchanger (GHE) into one tank to reduce the initial cost and does not occupy any floor space and roof area for installation. A dual-source heat pump (DSHP) as the second main component of the proposed system can not only achieve higher efficiency than ASHPs, but also reduce the needed size of GHEs. Because the DPUTB is installed underground and any heat loss from the TES can be recovered though the GSHP operation, there is little heat loss to the ambient. This paper presents a preliminary study of the load shifting capability, thermal performance, and associated operating costs of the proposed system.

2. System Description

The proposed system consists of a DSHP and a DPUTB as depicted in Fig. 1. The DSHP is an electricity-driven heat pump using vapor compression refrigeration cycle, which utilizes either the ambient air or the ground as its heat source/sink. A refrigerant-to-air heat exchanger is used in the source side of the DSHP when

the ambient temperature is suitable for achieving a relatively high COP of the heat pump. When the ambient air temperature is too high in summer (or too low in winter) to be used as a heat source/sink, the heat pump switches to utilize the DPUTB as its heat source/sink (through a refrigerant-to-water heat exchanger) for a better COP. The DSHP can reduce the seasonal imbalance of the thermal loads of the GHE and thus reduce the needed size of the GHE.

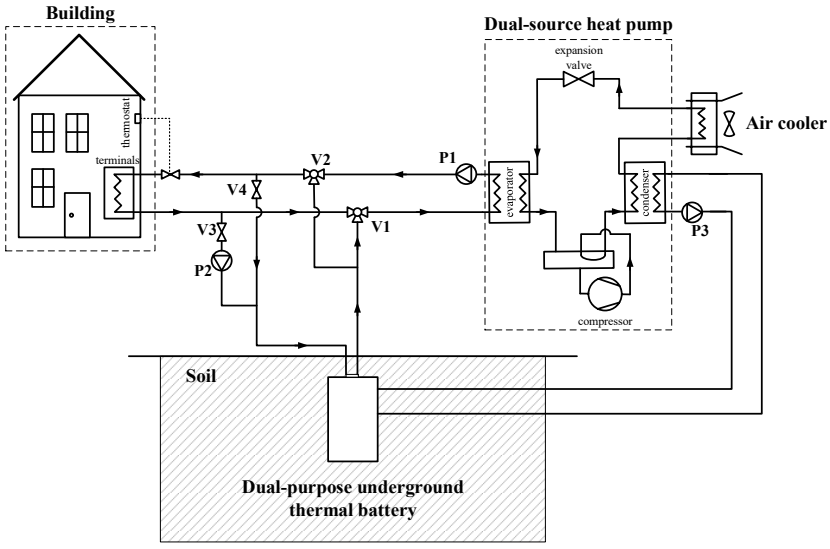

Fig. 1. System configuration diagram (cooling mode, DPUTB charging)

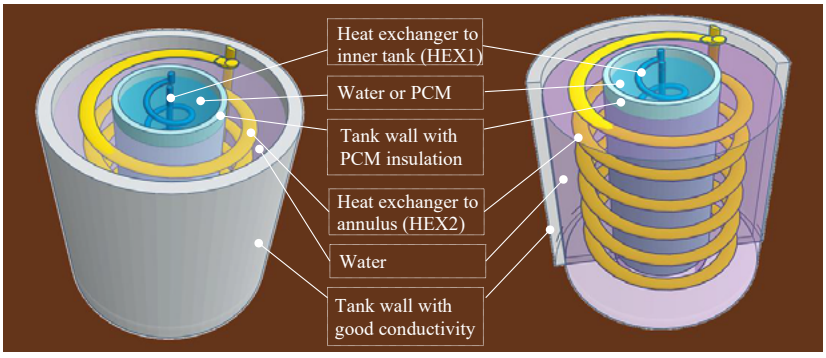

Fig. 2. Schematic of the DPUTB

The schematic of the DPUTB is shown in Fig. 2, it consists of an enclosed inner tank within a larger water tank. The inner tank works as a TES while the outer tank works as a GHE. A low-cost PCM encapsulated in a thin plastic panel is wrapped around the outer surface of the inner tank. Due to the low thermal conductivity and high latent heat of the PCM, it reduces the heat exchange between the inner and outer tanks. Another type of PCM with a different melting temperature is supplied in the inner tank for storing the thermal energy. Two coil heat exchangers are installed in the inner and outer tanks, respectively, to exchange heat with the HVAC system of the building. This design allows for storing thermal energy in the inner tank and later for providing direct heating or cooling to eliminate or reduce the electricity consumption for space heating or space cooling during peak hours of the electric grid. The outer tank of the DPUTB not only exchanges heat with the surrounding soil but also recovers energy losses from the inner tank for more efficient heat pump operation.

3. Component Modeling

3.1. DSHP

The DSHP is modelled as a combination of two conventional heat pumps: an air-water heat pump (AWHP) for air source and a water-water heat pump (WWHP) for ground source. The curve fitting models for the AWHP and the WWHP are developed based on the heat pump models (type 927 and type 941) of TRNSYS [10]. These heat pump models use performance curves of typical AWHP and WWHP units to predict their heating and cooling outputs and associated power consumption based on the inlet conditions from the condenser and evaporator. The rated COPs for AWHP and WWHP are 4.0 and 5.0, respectively.

3.2. DPUTB

A simplified one-dimensional transient model of the DPUTB has been developed in MATLAB [11] based on following assumptions and simplifications:

1. The PCM in the inner tank and the water at the outer tank are both well mixed. They are individual bulks with homogeneous properties within their domains.
2. The DPUTB is cylindrical symmetric and heat transfer occurs only along the radial direction.
3. The convection heat transfer within PCMs is neglected; only the conduction heat transfer is modeled.
4. The PCM's freezing point is identical to its melting point.

The model accounts for the following heat transfer phenomena:

1. Heat transfer between the heat exchanger in the inner tank (HEX1) and the inner tank PCM
2. Heat transfer between the heat exchanger in the outer tank (HEX2) and the outer tank water
3. Heat transfer between the inner tank PCM/water and the outer tank water through the inner tank wall and the PCM wrapped around the inner tank
4. Heat transfer between the DPUTB shell and the surrounding soil
5. Phase change process within the wrapping PCM and the inner tank PCM

3.2.1 Heat Exchanger

HEX1 and HEX2 are heat exchangers that direct contact with the inner and outer tank fluids. The input thermal energy to the tank fluid can be determined using equation (1):

$$q = UA \cdot \Delta T_{lm}, \tag{1}$$

where UA is the product of the overall heat transfer coefficient and the heat transfer area of a heat exchanger; ΔT_{lm} is the logarithm mean temperature difference between the fluid in the heat exchanger and the fluid in the tank at a given time step, which is expressed with equation (2):

$$\Delta T_{lm} = \frac{(T_{HEX,in} - T_{tank}) - (T_{HEX,out} - T_{tank})}{\ln \frac{T_{HEX,in} - T_{tank}}{T_{HEX,out} - T_{tank}}}, \tag{2}$$

where $T_{HEX,in}$ and $T_{HEX,out}$ are the heat transfer fluid temperatures at the inlet and outlet of the heat exchanger, respectively; T_{tank} is the average tank water temperature.

For the current case, the UA value of the heat exchanger is proportional to the mass flow rate of the heat exchange fluid, and it can be determined through experimental data regression.

At steady state, the heat exchange rate is also equal to the enthalpy change of the fluid in the heat exchanger, which can be determined using Eq. (3):

$$q = \dot{m}_{HEX} \cdot c_p \cdot \left(T_{HEX,in} - T_{HEX,out}\right), \tag{3}$$

where $\dot{m}_{HEX}$ is the mass flow rate of the heat transfer fluid; c_p is the specific heat of the heat transfer fluid.

The above equations are solved to determine the heat exchanger outlet temperature at a given time step with known inlet fluid temperature, thus the heat transfer rate can be calculated. The heat transfer rates from HEX1 and HEX2 are used as boundary conditions of the DPUTB model.

3.2.2 Natural convection

The empirical correlations describe the convection heat transfer coefficient between the tank fluid and its surrounding solid surfaces. The Rayleigh number and the Nusselt number can be determined using equation (4) and (5), respectively:

$$\mathrm{Ra} = \frac{g \cdot \beta \cdot |T_s - T_\infty| \cdot L^3}{\nu \cdot \alpha}, \tag{4}$$

where g is the gravitation; β is the thermal expansion coefficient; T_s is the temperature at the surface; T_∞ is the temperature of the fluid at bulk; L is the characteristic length; ν is the kinematic viscosity; and α is the thermal diffusivity.

$$\mathrm{Nu} = \left\{ 0.825 + \frac{0.387 \cdot \mathrm{Ra}^{\frac{1}{6}}}{\left[1 + (0.492/Pr)^{\frac{9}{16}}\right]^{\frac{8}{27}}} \right\}^2, \tag{5}$$

where Pr is the Prandtl number.

Thus the convective heat transfer coefficient can be determined using equation (6):

$$h_{conv} = \mathrm{Nu} \cdot \frac{k}{L}, \tag{6}$$

where k is the thermal conductivity of the fluid in the tank.

The surface temperature of the solid wall in contact with the liquid can be calculated based on the energy balance at the surface:

$$h_{conv} \cdot (T_\infty - T_s) = \frac{k_{wall}}{\Delta x} \cdot (T_s - T_{wall}), \tag{7}$$

where k_{wall} is the thermal conductivity of the solid wall; Δx is the thickness of the wall; T_{wall} is the surface temperature at the other side of the wall.

Equations (4) to (7) are solved to determine the convection heat transfer at the solid surface at a given time step.

3.2.3 Conduction heat transfer

Heat conduction is considered in the tank wall, the surrounding soil, and the wrapping PCM. For 1D heat conduction in the cylindrical coordinate, the conduction heat transfer equation can be expressed as:

$$\frac{1}{r}\frac{\partial}{\partial r}\left(r \cdot k \frac{\partial T}{\partial r}\right) = \rho \cdot c_p \frac{\partial T}{\partial t}, \tag{8}$$

where r is the position in the radial direction; ρ is the density; t is the time step.

Due to the complexity of the whole simulation domain, the explicit method is applied for the numerical calculation. Therefore, the conduction heat transfer equation is discretized into the form expressed in equation (9), subscript i represents the position along the radial direction:

$$\frac{1}{r_i} \cdot \frac{r_{i+\frac{1}{2}} \cdot k_{i+\frac{1}{2}} \frac{T_{i+1} - T_i}{\Delta r} - r_{i-\frac{1}{2}} \cdot k_{i-\frac{1}{2}} \frac{T_i - T_{i-1}}{\Delta r}}{\Delta r} = \rho \cdot c_p \frac{T_i^{new} - T_i}{\Delta t}, \tag{9}$$

The temperatures in the tank wall, the surrounding soil, and the wrapping PCM are determined at each time step with the above numerical method and given boundary conditions at each simulation domain.

3.2.4 Phase change

The latent heat accumulation method [12] is applied to simulate the phase change process within the wrapping PCM and the inner tank PCM. For a certain amount of PCM, the maximum latent heat it can store/release can be determined as:

$$Q_{latent,max} = m \cdot \Delta H, \tag{10}$$

where m is the mass of the PCM; ΔH is the specific latent heat of the PCM.

It is assumed in this model that the temperature of a PCM is kept intact when it is undergoing phase change process. The phase change process is indicated with a 'solid fraction' factor. The 'solid fraction' factor during the melting process of a PCM is quantified using following equation:

$$\theta = 1 - \frac{Q_{latent,acc}}{Q_{latent,max}}, \tag{11}$$

where $Q_{latent,acc}$ is the accumulated latent heat in the PCM during phase change; $Q_{latent,max}$ is the maximum latent heat the PCM can store.

In this model, the PCM wrapping around the inner tank is modeled as a series of coaxial hollow cylinders and each hollow cylinder has uniform temperature and phase status. The temperature and phase status of each hollow cylinder is updated at the end of each time step after calculating the heat transfer within the PCM domain. The inner tank PCM is modeled as one volume with uniform temperature and phase status, which is updated at each time step based on the heat transferred from the heat exchanger and through the wall of the inner tank.

3.3. Control Strategy

The integrated DSHP and DPUTB system can be operated in ten different modes, as listed in table 1. To achieve specific goals (e.g., energy cost reduction, load leveling, etc.), different control strategies can be developed to determine the operation mode at a given time of a day. In this study, a rule-based control strategy is developed to shift the electric demand of the building from peak hours to off-peak hours so that it can take advantage of the time-of-use (TOU) electric tariff to reduce the energy cost of the building. The logic flow chart of this control strategy is shown in Fig. 3.

Table 1. System operation mode description

Mode #	Building Load	Heat Pump Status	TES Status
1	no	off	off
2	yes	off	discharge
3	yes	air-source	off
4	yes	ground-source	off
5	yes	air-source	charge
6	yes	ground-source	charge
7	yes	air-source	discharge
8	yes	ground-source	discharge
9	no	air-source	charge
10	no	ground-source	charge

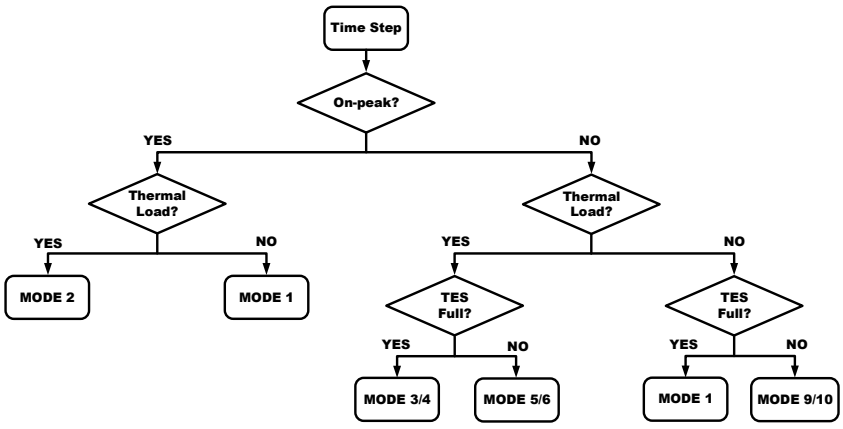

Fig. 3. Control strategy for reducing energy cost

4. Case Study

4.1. Building Information and Equipment Sizing

A typical U.S. residential building [13] in Baltimore, Maryland is chosen for a case study. It is a single-family detached house located with 223 m^2 air-conditioned floor space. The air-conditioning system is a centralized constant volume air system with on/off control to maintain the room temperature within 22.2 to 23.9 °C. The nominal cooling capacity of the air-conditioner used in the building is 2-ton (7 kW) and its nominal COP is 3.97. This air-conditioner is used as a baseline in this study to be compared against the integrated DSHP and DPUTB system.

A pilot TOU electric tariff is used in this study. This TOU electric tariff named 'Schedule RD' was introduced by the Baltimore Gas and Electricity Company for residential customers who have installed smart meters. According to this tariff, during the summer of 2019, the electricity retail price is 0.339 $/kWh between 14:00 and 19:00 on weekdays, which is defined as on-peak hours, and it is 0.064 $/kWh during other time (off-peak hours) [14].

The sizes of the DSHP and the DPUTB are determined based on the thermal load of the building and the control strategy described in Section 3.3. The thermal energy storage capacity of the DPUTB should be no less than the total thermal load during on-peak hours of the design day. It ensures that the stored thermal energy is adequate for providing space cooling during the on-peak period, and thus the heat pump can be turned off to reduce electric demand. The capacity of the heat pump could be smaller than the peak cooling load of the building during a cooling season, but it should be larger than the maximum cooling load during the off-peak period so that it can simultaneously cools the inner tank for storing sufficient cooling energy while providing space cooling during the off-peak hours. To meet the cooling load of the residential building, two identical DPUTBs are needed, and the nominal cooling capacity of the DSHP is 1.75-ton (6.125 kW), which is 12.5% smaller than the baseline air-conditioner. The key parameters of the DPUTB are listed in table 2.

Table 2. Key parameters of the system components

Property	Value	Unit
DPUTB dimensions		
Inner tank diameter	39	cm
Inner PVC shell thickness	0.55	cm
PCM blanket thickness	2.54	cm
Outer tank diameter	101.37	cm
Outer PVC shell thickness	0.82	cm
Height of the inner tank	609.60	cm
Height of the outer tank	609.60	cm
Inner shell thermo-physical properties

UA value	5000	W/°C

4.2. System Simulation

Numerical models of DPUTB and DSHP, as well as the control strategy, are implemented in MATLAB and integrated together to simulate the performance of the integrated DPUTB and DSHP system at each time step (60 seconds).

The hourly cooling load and electricity consumption of the building resulting from using the baseline air-conditioner during the entire cooling season is obtained from computer simulation of the residential building using typical meteorological year (TMY3) weather data [15]. The simulation-predicted hourly cooling load is used as the inputs to the simulation model of the integrated DPUTB and DSHP system.

4.3. Design-Day Simulation Results

Some featured results for a design-day (July 21) simulation of the integrated DPUTB and DSHP system with the rule-based control strategy are shown in Fig. 4. The first sub-figure clearly shows that a considerable amount of electricity demand has been shifted from on-peak (14:00 – 19:00) to off-peak hours.

From 0:00 to 8:00, due to the relatively low ambient temperature, the DSHP operates as an ASHP to supply space cooling to the building as well as to charge the DPUTB. The operating COP of the ASHP is stabilized at around 5 (4th subplot). The solid fraction of the inner tank PCM keeps increasing until it is fully charged (i.e., when the average temperature of the PCM is 3ºC lower than its melting temperature) at around 6:00 (3rd subplot). As long as the inner tank is fully charged, the heat pump solely operates to satisfy the cooling demand of the building. Otherwise, the heat pump works to charge the inner tank and to meet the thermal load of the building simultaneously. During this period, there is no heat rejection to the outer tank of the DPUTB. Thus, the temperature of the outer tank water is slightly cooled down by the inner tank and the surrounding soil, as can be observed from the 2nd subplot.

From 8:00 to 14:00, while it is still in the off-peak period, the ambient temperature is higher than 26.7 ºC, which is the threshold for switching from ASHP to GSHP. Therefore, instead of rejecting condensing heat to the ambient air via the refrigerant-to-air heat exchanger, the DSHP rejects condensing heat to the soil via the heat exchanger in the outer tank of the DPUTB. It can be observed from the 2nd subplot that the outer tank water temperature increases and the heat transfer rate from the tank to the soil also increases (5th subplot). The average operating COP of the GSHP is around 5.5 (4th subplot), and it decreases with the increase of the outer tank temperature.

The on-peak period begins at 14:00 and ends at 19:00. During this period, the heat pump is completely turned off (5th subplot), and the cooling energy stored in the inner tank of the DPUTB is used to meet the thermal load of the building. A significant reduction of the stored cooling energy can be observed from the decreasing trend of the solid factor of the PCM as shown in the 3rd subplot. Since the heat pump is turned off, there is no heat rejected to the outer tank of the DPUTB, and its temperature is cooled down by the surrounding soil, as depicted in the 2nd subplots. After 19:00 (the end of the peak hours), the heat pump is turned on to simultaneously cool the building and the inner tank of the DPUTB. It can be observed that right after 19:00, the electric demand of the integrated DPUTB and DSHP system is higher than the baseline, this is because that

the DSHP operates at its full capacity to meet the building thermal load and to charge the DPUTB at the same time, while for the baseline case, the air conditioner only works partially to meet the building thermal demand.

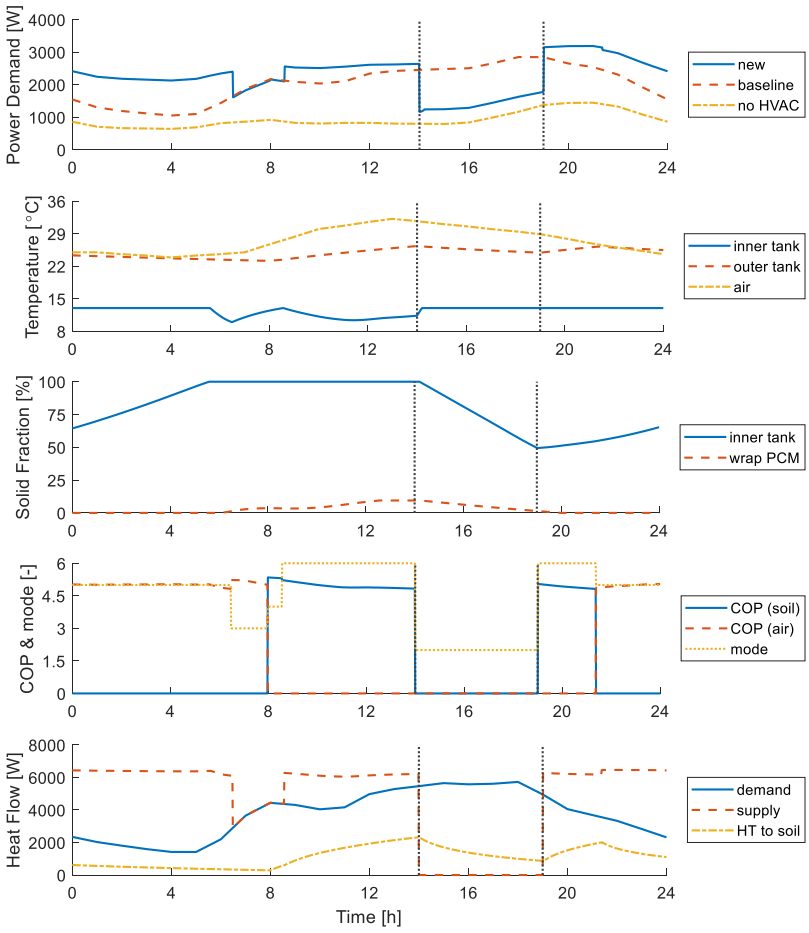

Fig. 4. Featured simulation results of the integrated DPUTB and DSHP system on the design-day (July 21)

The power consumption and the electricity cost of the design day are summarized in Table 3. The result shows that by applying the novel system with the rule-based control strategy, the daily electricity consumption is increased by 11%. However, the on-peak electricity consumption contribution (on-peak electricity consumption divided by total daily electricity consumption) is reduced from 26.9% to 13.1%. The electricity cost is reduced by 19.5%. It indicates that the novel system with the proposed control strategy can effectively shift the electric load from on-peak to off-peak period, but more electricity is consumed during the whole day.

Table 3. Energy consumption and cost for design-day simulation with rule-based control

System	Control	Total electricity consumption [kWh]	On-peak electricity consumption [kWh]	Cost [$]
Baseline	conventional on/off	49.06	13.21	6.77
Novel	rule-based control	54.43	7.14	5.45

4.4. Simulation Results of a Cooling Season

A seasonal simulation (June 1 to September 30) is conducted to investigate the long-term performance of the integrated DPUTB and DSHP system. Fig. 5 shows some of the simulation results. The 1st subplot of Fig. 5 indicates that, with the cost-reduction oriented control strategy, the hourly electric demand of the integrated DPUTB and DSHP system fluctuates within 640 – 3500W in each day. Overall, this control strategy cannot flatten the electric demand profile of the building. To achieve load leveling with the integrated system, a different control strategy needs to be used. During the entire cooling season simulation, the outer tank water temperature ranges from 15 ºC to 30 ºC (2nd subplot), which ensures the DSHP operate at a relatively high COP when it switches to ground source. The air source operation of the DSHP (when the ambient temperature is relatively low) gives more time to the outer tank for dissipating heat to the surrounding soil and thus cools down the outer tank water temperature. As shown in the 2nd subplot, the outer tank water temperature recovers to its original level after the entire cooling season operation. The 3rd subplot shows the solid fraction profile of the inner tank PCM and wrapping PCM. The stored latent cooling energy of the inner tank PCM never exhausted, which indicates that the sizing of the DPUTB is reasonable. The wrapping PCM is solid at the beginning of the cooling season because its melting temperature (15 °C) is higher than the surrounding soil temperature (14.4 °C). The wrapping PCM is melted gradually after cooling season starts, as indicated by the decrease of its solid fraction. The wrapping PCM cycles between melting and solidification on a daily basis (i.e., melting when heat from the GSHP is rejected into the outer tank, and re-solidifying when releasing heat to the surrounding soil and the inner tank). The simulation result indicates that the DPUTB maintains a significant temperature difference between the inner and outer tank every day.

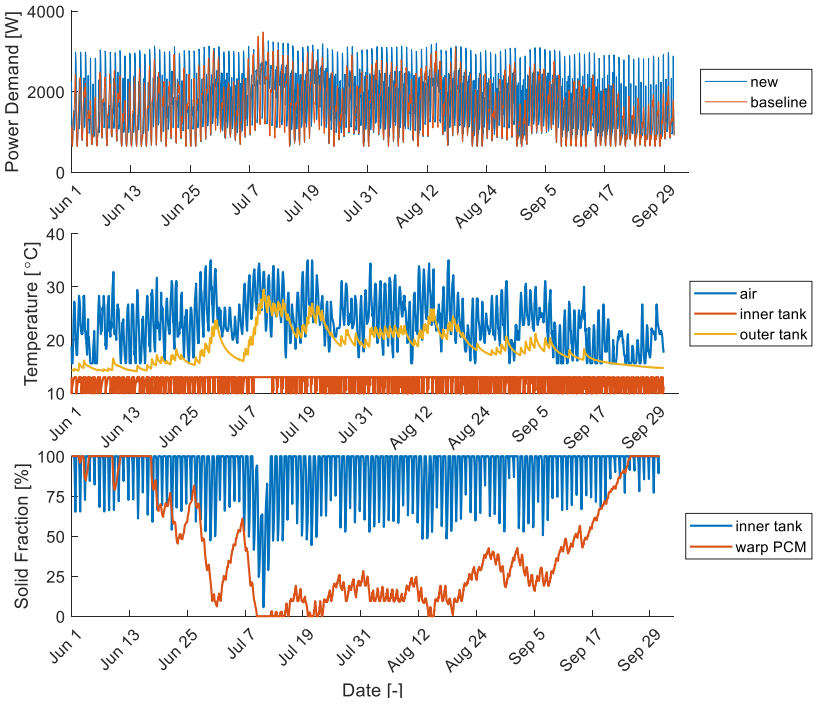

Fig. 5. Featured simulation results of the integrated DPUTB and DSHP system during a cooling season

The electricity consumption and the associated cost during the entire cooling season are listed in Table 4. These data show that although the electricity consumption of the entire building (including both HVAC and non-HVAC electric consumption) is increased by 4.5%, the on-peak electricity consumption of the building is

reduced by 40% compared with that resulting from using the baseline air-conditioner, and the electricity cost is reduced by 19.5% over the entire cooling season.

Table 4. Energy consumption and cost for seasonal simulation with rule-based control

System	Control	Total electricity consumption [kWh]	On-peak electricity consumption [kWh]	Cost [$]
Baseline	conventional on/off	4764	1333	671
Novel	rule-based control	4978	805	540

5. Conclusions

This study conducts a preliminary evaluation of a novel dual-source heat pump (DSHP) integrated with an underground thermal energy storage system (DPUTB) for shifting the electric demand of a residential building in the United States during a cooling season. A simplified numerical model has been developed for the DPUTB. A computer simulation of the integrated DPUTB and DSHP system is conduced to evaluate its load shifting performance and resulting energy cost. Following conclusions can be drawn from the simulation results:

- The system shifts 5-hour on-peak electricity consumption for space cooling to off-peak period, which results in a 40% reduction in the peak electricity consumption of the building over the entire cooling season
- The associated electricity cost reduction is around 20%, which is higher than other active TES systems reported in existing literature
- The heat pump capacity is reduced by 12.5% compared with the baseline air-conditioner, which does not have any TES
- The COP of the DSHP remains high (around 5) during the cooling season
- Total electricity consumption increases by 4.5% over the cooling season due to additional pumping

Further work includes optimizing the charging control of the inner tank and applying better thermal insulation to reduce heat transfer between the inner tank and the outer tank. It is also planned to investigate the heating season performance of the integrated system. More advanced controls, such as model-based control or artificial intelligence, will also be investigated for improving the capability of the integrated system for effectively reshape the electric demand profile in response to the demand side management signal of the electric grid while satisfying all the thermal demands of the building.

Field Performance of Domestic Heat Pumps for Heating and Hot Water in Switzerland

Ralph Kuster*, Manuel Prinzing, Matthias Berthold, Cordin Arpagaus, Mick Eschmann, Stefan S. Bertsch
NTB University of Applied Sciences of Technology, Institute for Energy Systems, Werdenbergstrasse 4, CH-9471 Buchs, Switzerland

Abstract

This study presents the development, the methods, and the state of the art of heat pump field tests as they are currently carried out by the Heat Pump Test Center (WPZ) in Buchs. Since 2016, heat pumps for hydronic heating systems in single-family houses in Switzerland have been investigated. So far, nearly 20 air-source and geothermal heat pumps, primarily located in the lowlands have been added to this governmental quality assurance program. For each heat pump system, calibrated sensors record approximately 50 data points at 10 seconds intervals, which ensures very low measurement uncertainty.
The aim of this field study is to record the efficiency of the real systems in operation and to draw comparisons with characteristic parameters from laboratory measurements and manufacturer data. Further goals are the identification and optimization of possible deficiencies in planning and installation as well as in the controls of the heat pump devices. The results of field measurements show the importance of careful design and installation of these systems. The optimal integration in retrofit systems (building renovations) is also a major challenge.
Heat pumps installed in new and refurbished buildings have been investigated with different system boundaries. The results show significant differences between the systems as well as typical installation faults. After a year of baseline performance evaluation, the systems are optimized to determine the potential of such measures and better define guidelines for planners and installers. An overview of such measures is also presented.

1. Introduction

The use of domestic heat pumps (DHP) in Swiss households for heating and domestic hot water production is advancing. The number of heat pumps sold in Switzerland in 2018 increased by almost 10 % compared to 2017 and almost 19 % compared to 2016 [1]. 70 % of the heat pumps are air/water heat pumps (AWHP), 28 % brine/water heat pumps (BWHP) and 2 % are groundwater heat pumps (GWHP).

Along with increasing DHP sales, the estimation of the field performance of such heat pump systems is gaining importance since the efficiency of heat pumps reacts sensitively to their integration into the heating system and the settings of the heat pump controller. Such performance gaps cannot be determined by measuring the system in the laboratory, but only by taking measurements at the actual place of use. Therefore, 25 years ago, a comprehensive field study of DHP in Switzerland, called FAWA (field analysis of heat pump installations) was launched [2], which was commissioned by the Swiss Federal Office of Energy (SFOE) and carried out with the support of industrial and academic partners.

Between 1996 and 2003, a total of 221 heat pumps with a maximum heating capacity of 20 kWth were measured, mainly in new single-family houses. According to the defined system boundary (Seasonal performance factor SPF (JAZ)) [2] an average coefficient of performance (COP) of 2.7 for AWHP-systems

* Corresponding author. Tel.: +41 81 755 31 82
E-mail address: ralph.kuster@ntb.ch

and 3.5 for BWHP-systems were recorded. At that time, data was still recorded manually, at best once a week.

Outside of Switzerland, DHP-field studies were performed in several other countries starting in 2005 with the Frauenhofer (ISE) studies [3] [4]. The first ISE study showed average seasonal performance factors (SPFH3) of 2.7/3.5 (AWHP/BWHP) whereas the second study in 2009 revealed slightly increased factors for both AWHP (2.9) and BWHP (3.9) systems.

In contrast to the SPF definitions used in Switzerland, many European studies are based on the harmonized systems boundary definitions (SPFH1 to SPFH4) introduced during the SEPEMO project (SEasonal PErformance factor and MOnitoring for heat pump systems in the building sector) in 2011 [5] [6].

Gleeson et al. [7] investigated eight different European studies and the respective system boundaries or key figures used (Table 1).

Table 1. Overview of key figures in European field studies [7]

Field study	No. of units	*SPF1 (JAZ1)*	*SPF2 (JAZ2)*	SPF_{hps}	SPF_{H1}	SPF_{H2}	SPF_{H3}	SPF_{H4}	DHW share
FAWA [2]	221	-	221	-	-	-	-	-	50%
Frauenhofer 2009 [3] [4]	74	-	-	-	74	74	74	74	100%
Frauenhofer 2005 [3] [4]	70	-	-	-	-	-	70	-	100%
DTI	150	-	-	-	-	-	-	150	100%
LAHR [8]	25	25	25	-	-	-	-	-	unknown
SPTRI 2007	5	-	-	5	-	-	-	5	100%
SPTRI 2010	6	-	-	-	6	-	6	-	86%
EST	71	-	-	-	-	-	-	-	77%
Total	622	25	246	5	80	74	150	229	

Apart from the FAWA study, only the Lahr field trials (2006 to 2014) [8] performed in Germany used the SPF definitions, which makes direct comparison difficult. In fact, performance figures of field test studies are only meaningful in combination with their respective boundary conditions. All further results presented in this work will use the performance figures and the system boundaries defined by the Swiss Federal Office of Energy (SFOE).

The heat pump test center WPZ at the University of Applied Sciences of Technology in Buchs, CH is an EN 17025 and EN14511 certified inspection authority [9]. It offers comprehensive testing service in the field of heat pump and refrigeration technology. Field measurements from the extended monitoring period between 2015 and 2019, which were commissioned by the SFOE, are currently being evaluated.

The main objective of the monitoring study was to identify suitable indicators based on the data measured and evaluated over the period of two years. Subsequently, comparisons should show optimization potentials of the systems, which can then be implemented. Each year, approximately five new heat pumps are included in the series of measurements.

The current heat pump field study at the Heat Pump Test Center (WPZ) in Buchs is carried out in cooperation with the Swiss Federal Office of Energy (SFOE) and pursues the following strategy:

- Investigation of the real-life performance of heat pump systems.
- Identification of optimization potential.
- Annual addition of five heat pumps to the campaign.
- Reliable measuring data through pre-calibration of the field measuring system.
- Meaningful measuring data thanks to high sampling rate and accurate measuring devices.
- Implementation of suggested optimizations after two years of recording and evaluation.

The ongoing study currently comprises nearly 20 heat-pump systems mainly located in the German speaking lowlands of Switzerland.

2. Technology, boundaries and methods of the field tests

Compared to the earlier studies in the 1990s, the measurement methodology and data acquisition technology have changed considerably. Nowadays, thanks to digitalization, much more data is available. Short recording intervals (10 s) can be used to describe temporal processes in heat pump systems in detail, enabling an easier detection of defects such as heat losses and unwanted circulation. Based on the collected data series, it is also possible to investigate the following processes deeper, which was not feasible with manual readings [9]:

- starting behavior,
- defrosting,
- on/off cycling,
- detailed breakdown by different levels of utilization,
- measurement at the different system boundaries,
- value of the building/structural condition, and
- effect of auxiliary devices on efficiency (circulating pump, heating elements, etc.).

Due to the short sampling time and the high-resolution data, processes can be viewed not only energetically but also in terms of performance over time. Thus, the measured values can be assigned to a clear chronological sequence. For example, the efficiency of domestic hot water generation and heating water charging can be considered separately.

It is also possible to categorize processes in which the compressor is switched off and only the auxiliary heater is active (standby power consumption analysis) [9]. Such temporal differentiation is becoming increasingly important for the calculation of meaningful key figures. Another advantage of having high-resolution data is the ability to distinguish between the heating and cooling modes of a heat pump. This is particularly interesting for BWHP systems, as no reversible compressor and cycle is required and the excess heat can be fed into the ground. Due to global warming and the resulting hot summers, the demand for heat pump systems with cooling function has significantly increased already in Switzerland.

As mentioned, the SFOE sets its own guidelines for key figures and system boundaries. In terms of energy figures, they are defined as follows [9]:

$$SPF = \frac{Q_{SH}+Q_{DHW}}{E_{tot}-E_{CP,Sink}-E_{ext,HE}} \quad (1) \qquad HUR = \frac{Q_{SH}+Q_{DHW}}{E} \quad (2)$$

$$SUR_{DHW} = \frac{Q_{DHWU}}{E_{DHW}} \quad (3) \qquad Q_{HD} = \frac{Q_{SH}}{E_{RA}} \quad (4)$$

$$THR = \frac{Q_{SH}+Q_{DHW}}{E_{RA}} \quad (5) \qquad HR_{DHW} = \frac{Q_{DHW}}{E_{RA}} \quad (6)$$

$$\eta_{DHW} = \frac{Q_{DHWU}}{Q_{DHW}} \quad (7)$$

The annual performance factor *SPF* mainly determines the efficiency of the heat pump. Only the electrical energy of the compressor, fan (AWHP), source pump (BWHP) and the control electronics of the heat pump are considered in this indicator. The heat utilization ratio *HUR* also includes the electrical energies of the heat sink circulating pump and all auxiliary heating elements. This way the efficiency of the complete heating integration is illustrated and made comparable to other heating systems. The third parameter, the SUR_{DHW} (system efficiency of domestic hot water use), shows the hot water efficiency with respect to usage, including all storage and distribution losses. In addition, this key figure can also be used to assess domestic hot water heat pumps (DHWHP).

Fig. 1 shows the corresponding system boundaries [9]. It can be seen, that the SEPEMO boundaries SPF_{H1} and SPF_{H2} match with *COP, SPF* according to the SFOE [7] [9]. However, the SPF_{H3} does not include the circulation pump and the auxiliary heating of the DHW tank like *HUR* does. In contrast to the outermost boundary SUR_{DHW} the SPF_{H4} does include the entire HP-System with both DHW and space heating buffer tank and is therefore not included in the schematic below.

In order to assess the influence of the building itself or the user behavior and its location, the characteristic values Q_{HD} and *THR* are determined and displayed. However, since the interior temperature is not recorded for any of the 13 measurement the determination of user influences is limited. The heating degree days $HGT_{20,12}$ are determined by a heating limit temperature of 12 °C and a target internal temperature of 20 °C. The $HGT_{20,12}$ is then calculated from the difference between the average daytime temperature and 20 °C. The $HGT_{20,12}$ are only counted if the average daytime temperature is lower than the heating limit (here 12 °C) [9].

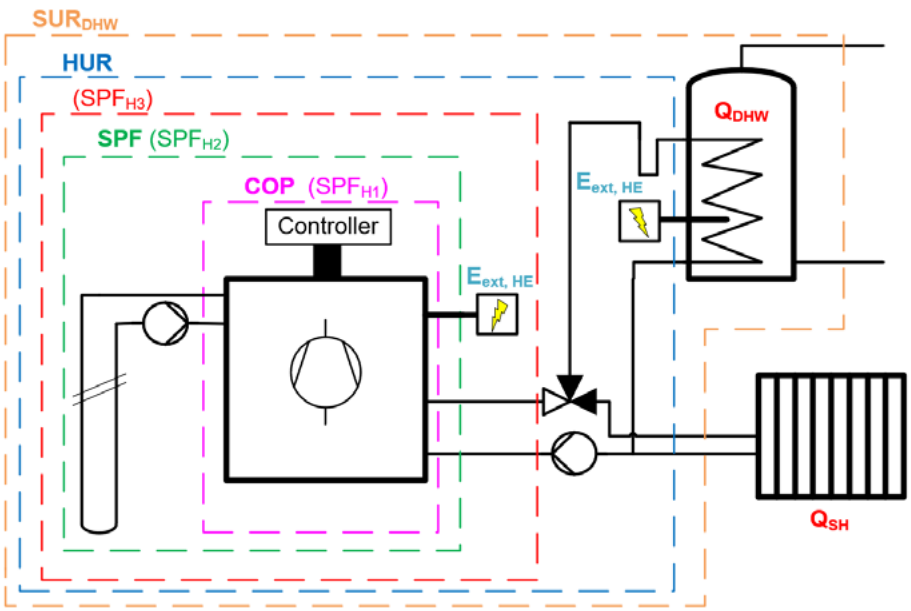

Fig. 1. System boundaries and key figures (*SUR*, *HUR*, *SPF*, *COP*) based on the SFOE [9] and SEPEMO definition [7]

Thermal and electrical energy numbers are measured as numerical integration of several power sensors with a sampling interval of 100 ms. With this approach low sensor costs were combined with high accuracy and the ability to gather rapid changes in the system. The values are then recorded every 10 s, leading to an averaging of 100 datapoints and a small statistical error.

Of course, a discretization error cannot be avoided. This can cause problems if the measured variable changes abruptly. However, it has been shown that for the majority of measurement series a recording interval of 30 s would already be sufficient, since thermodynamic systems tend to change at a slow pace.

The performance values themselves are formed from the effective measured variables according to the established methodology.

By using a volume flow sensor and temperature measurements, the mass flow is determined via the density, where $\rho_w = f(T)$. The heat output for example is then calculated as follows:

$$\dot{Q}_{heat,i} = \dot{m}_w \cdot c_{p,w} \cdot \Delta T = \dot{V}_w \cdot \rho_w(T_{supply}) \cdot c_{p,w}(T_{supply}) \cdot (T_{supply} - T_{return}) \quad (8)$$

The volume flow is measured in the supply pipe. The temperature difference between supply and return flow is determined from two temperature measurements. The formula (9) shows that the temperature measurements are included several times in the calculation. This means that the measurement error of the temperatures has a strong effect on the overall measurement uncertainty of the heat output. For this reason, great importance is attached to temperature measurement that is as accurate as possible. The aim is an overall uncertainty of the target values of <10 %. To reliably achieve this goal, a measurement uncertainty of the temperature measurement (absolute) of ± 0.02 K has to be met. Calibrated PT-100 sensors with four-wire technology are immersed in the flow and thermally decoupled. For redundancy reasons, important temperatures points are measured twice and the sensors are calibrated and immersed in the flow. The basic placement of the sensors in the system can be seen in Fig. 2. However, the real positioning can be slightly different for each case depending on the type of HP-system or building.

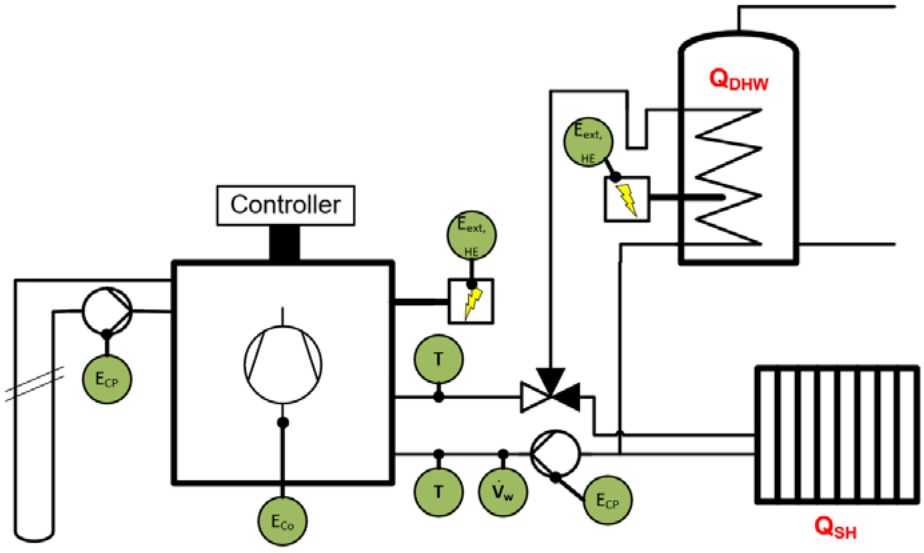

Fig. 2. Basic placement of sensors in a typical heat pump system according to the WPZ [10]

After measurement, the data is automatically read and stored daily on a server in Switzerland for further processing. The storage structure includes 5 different databases and is relational. That means each piece of information is only stored once in one of the five databases. This makes it very easy to keep the data up-to-date and consistent [10].

For data protection reasons, the link to the personal data is made via specially generated ID's, whereby the personal data are stored in the other databases and not apparent in plain language. Furthermore, the database system is also designed to evaluate external measurement data.

As mentioned, every year approximately five new installed heat pump systems are added to the ongoing field study. Arpagaus et al. [10] explained the sequence of a complete measurement and evaluation cycle for a new installation of a system:

1. Application of a customer (who wants to install a heat pump system privately).
2. Calibration of the heat pump with field measuring equipment at the WPZ in Buchs under laboratory conditions.
3. Comparison of laboratory measurements with manufacturer's specifications.
4. Installation of the heat pump system on site, whereby the intended field measuring equipment is also installed.
5. Commissioning of the heat pump system in the presence of an employee of the WPZ.
6. Ongoing measurement of the heat pump system.
7. Comparison and analysis of measured data with laboratory and field test data.
8. Recommendations for optimization and improvements after one year of data collection.
9. Implementation of the proposed optimization in coordination with the customer.
10. Control measurement to record improvements of the heat pump system.
11. Field measuring equipment remains on site with the customer, and data recording is continued.

Inadmissible defects and weaknesses of the heat pump itself are usually detected during laboratory measurements. On the construction site of the building, it should be noted that the installation of the heat pump system as well as its commissioning and handover to the customer is the responsibility of the planning office and the heating installer. The WPZ staff only coordinate the installation of the necessary sensors and data acquisition. Possible errors or defects of the HP systems caused by the installation or commissioning are detected with the help of the data during the measurement phase. Suitable improvement measures or optimizations are suggested to the customer, which then can be carried out under the responsibility of the HP installer.

3. Results, analysis and optimization of current field studies

The results presented in this section include measurements taken in the heating period of 2017/18 and 2018/19 (two years) respectively. In total 13 heat pump devices have been analyzed and compared within the current study, out of which 7 are Air/Water heat pumps (AWHP) and 6 are Brine/Water heat pumps (BWHP) with vertical boreholes. Overall 9 out of 13 devices are operated as variable speed compressors. The data was evaluated from standard heat pump devices that have not yet been optimized based on these field studies.

Fig. 3 shows the connection between the annual coefficient of performance (SPF) and different design temperatures [9].

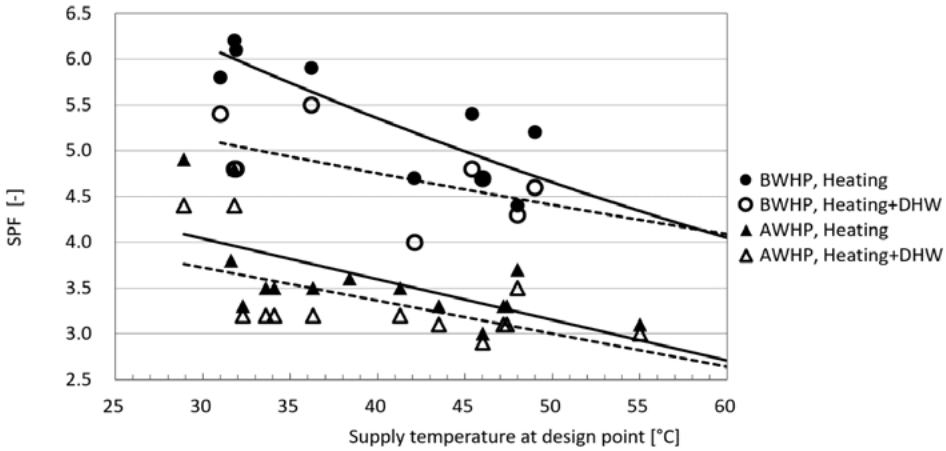

Fig. 3. Efficiency (*SPF*) of Air/Water heat pumps (AWHP) and Brine/Water heat pumps (BWHP) depending on predefined heating and heating+DHW curves.

The data is displayed as a function of the heating curve pre-set on the heat pump. It can be seen that Brine/Water heat pumps in new buildings (supply temperature of approx. 30 °C at the design point) achieve an annual efficiency (*SPF)* of more than 6 in pure heating operation. In combination with domestic hot water (DHW) production, the *SPF* drops to approx. 5.2. In contrast, Air/Water heat pumps achieve an efficiency of about 4.0 for heating, and 3.7 for heating+DHW production.

As expected, the efficiency decreases with higher supply temperatures. Especially refurbished buildings need higher supply temperatures due to their radiator heating system. However, with a *SPF* of over 4.0, BWHP systems are still very suitable for such renovated buildings. Even compared to new variable-speed AWHP, BWHP still show a significant efficiency advantage of approximately 30 %.

Table 2 provides a more detailed overview of the evaluated performance of AWHP and BWHP by heating and heating+DHW application.

Table 2. Annual Coefficient of Performance (SPF) for different AWHP and BWHP applications [9]

Supply temperature at design point	35 to 30°C (New building)	45 to 40°C (Renovation)	55 to 55°C (Old building)
Heating AWHP	3.7	3.3	2.9
Heating BWHP	5.7	5.0	4.4
Heating + DHW AWHP	3.5	3.1	2.8
Heating + DHW BWHP	4.9	4.6	4.3

As already mentioned, it is essential to use comparable system boundaries in practice when matching systems. Significant differences can be identified between the efficiency of heat production and the heat actually used especially when it comes to DHW production. This is partly caused by the use of electric heating elements (e.g. Legionella circuit), but mainly due to storage losses. Fig. 4 shows a comparison of the average annual coefficient of performance *(SPF)*, heat utilisation ratio *(HUR)* and system utilization ratio *(SUR_{DHW})* for AWHP and BWHP systems [9].

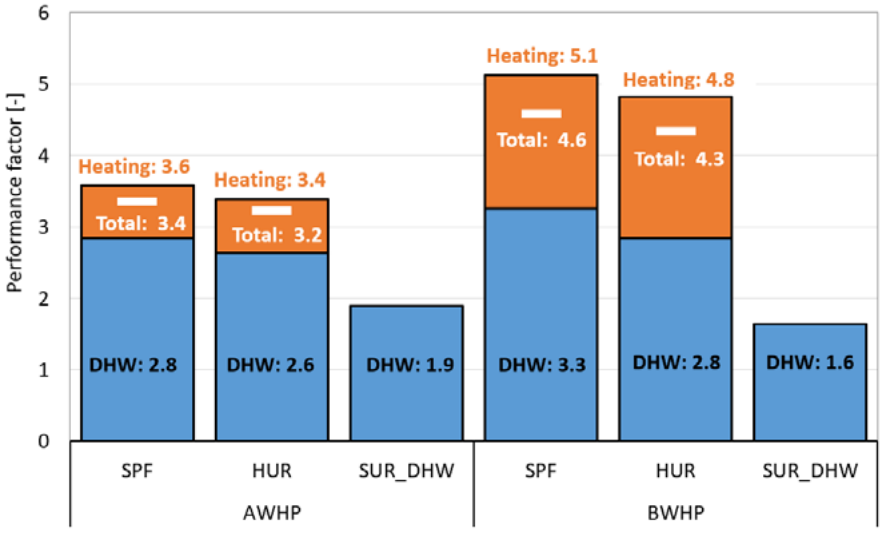

Fig. 4. Comparison of averaged *SPF*, *HUR* and SUR_{DHW}

As expected, the efficiency of DHW production is 17.5 % to 19 % lower than the overall efficiency for heating+DHW production due to the higher sink temperatures.

For BWHP this difference is much bigger (28 % to 35 %) because of lower source temperatures compared with AWHP in summertime. It is also remarkable that the *HUR* is 0.1 or 0.3 points lower than the *SPF*. This is mainly due to the electric heating elements for Legionella control and the circulation pumps. No electric heating element had to be used to support the heating system of any heat pump investigated during the period under consideration. This also applies to the cold periods at the end of February, beginning of March 2018 which showed outside average temperatures between -6 to -9 °C and up to 2 K below the design temperature.

For conceptional reasons, the system utilization ratio *(SUR_{DHW})* can only be determined for DHW production and it is considerably lower than the *HUR*. This is primarily caused by storage losses, especially for buildings with a low DHW demand. When it comes to single-family houses the overall system efficiency suffers particularly when a DHW circulation is used to keep the distribution lines warm. Therefore, hot water circulation is clearly not recommended for such applications from an energetical point of view.

The detailed data recording of several measured variables during more than one heating period offer the determination of various optimization possibilities and the comparison of different objects with regard to the heating settings.

An important optimization scope of heat pump systems is the proper adjustment of the heating curve and the heating limit respectively. Considerable differences were found between properties within the same building standard. New buildings in particular, were found to have a heating curve that is too high with respect to the outside temperature. Nevertheless, only three heating curves out of 13 monitored objects were adjusted downwards whereas two were increased. This is because many residents were satisfied with the current setting and no adjustment was desired. By integrating an intelligent heating curve with averaged outside temperatures, the annual heating energy demand can be reduced distinctly. One of the monitored new buildings shows theoretical potential savings of 6 % of the annual energy demand by solely adapting the upper heating limit without affecting comfort [9]. The upper heating limit is defined as the ooutside temperature at which heating is automatically turned off.

In a concrete example of an implemented heating curve adjustment, a rather low *SPF* of 2.6 at a daily mean temperature of 7 °C in the period from 10/01/2017-12/17/2017 was successfully increased to *SPF*=3.7 (42 %) in the second recording period until 10/31/2018.

A considerable optimization potential can also be found in DHW production. AWHPs benefit greatly from a larger charging timeframe at midday with a previous charging delay that leads to a reduced set temperature. Since temperatures at noon can be over 10 K higher than in the morning, charging efficiency can be increased by 10 to 20 % [9]. Although this optimization measure seems obvious, only in one HP-system controller out of 13 this measure was implemented to make use of a smaller temperature-lift at noon.

Around 50 % of the investigated heat pump systems use only electric auxiliary heating (heating rod) to perform their weekly Legionella program by heating up the water tank to over 60 °C. Three systems first make use of the compressor to support charging, which would be an obvious method to reduce the electric energy demand. In a typical example, 180 kWh electric energy can be saved annually by implementing this simple software modification to always preheat the domestic hot water using the compressor before switching to auxiliary heating, with no further costs.

4. Conclusions

Between 1996 and 2017 more than 600 heat pump systems, mainly in single-family houses, were investigated in the field in Europe. On average, slightly more (approx. 60 %) brine/water heat pump (BWHP) systems were recorded than air/water heat pump (AWHP) systems. Although the amount of data collected over these years is important, it can only be used in part for comparison, due to different definitions of key figures and system boundaries or long sampling intervals.

Detailed analyses of temporal processes are possible by recording power values instead of energy values. This requires short sampling intervals (<30 s) in order to adequately map dynamic processes.

Great importance is attached to the measurement of temperature because of its major influence on the overall uncertainty. Therefore, the supply and return temperatures are measured with an uncertainty of ± 0.02 K (absolute) using PT-100 sensors and four-wire technology. Together with the prior calibration of the whole field measuring equipment in the laboratory, an overall uncertainty of the target values (*COP, SPF*) of <10 % was achieved. Of course, these measurement accuracies require relatively complex and expensive measurement equipment.

However, such precision is not always required or necessary. In the field of building performance estimation, cheaper and simpler solutions can be found recently.

Frei et al. [11] described a concept that combines a variety of different sensors for temperatures, humidity, heat flux, CO_2 etc. embedded as a wireless sensor network (WSN) with open source software platform for communication and data analysis. Although the field of application showed is different, there is common ground and some ideas may be useful for future solutions. Such an installation would help to identify major errors in the applications.

The current study, which now includes almost 20 heat pump systems in the field, clearly shows strong dependence of the annual performance factor *(SPF)* on the supply temperature and the selected heat source. Therefore, AWHPs in new buildings reach an average *SPF* of 3.7 for floor heating (35 °C) whereas BWHPs attain a *SPF* of 5.7. With higher supply temperatures of around 50°C found in old buildings average SPF values of around 2.9 for AWHP and 4.4 for BWHP were measured, respectively.

Combined systems for heating and domestic hot water (DHW) production show 3 to 9 % lower coefficients of performance (e.g. SPF) values due to the increased supply temperatures.

After investigation of the monitored heat pump systems for more than one heating period, various optimization potentials were identified, such as intelligent heating curves or Legionella routines. By implementing these simple software updates, the charging efficiency of DHW could be increased by 10 to 20 %. Typical optimization measures are:

- Adjustment of the heating curve and heating limit.
- Increased charging timeframe at midday.
- Preheating of DHW with the compressor.

In the field of refurbished buildings BWHPs are recommended. For drawing the correct conclusions when comparing heat pump systems, it is crucial to use the correct system limits and boundaries. The current field study shows, that the investigated heat pumps work well overall, but there is still potential of improvement, especially when it comes to DHW production.

Theoretical investigation of high-temperature heat pump cycles for steam generation

Frédéric Bless*, Cordin Arpagaus, Stefan Bertsch

NTB University of Applied Sciences of Technology Buchs, Werdenbergstrasse 4, 9471 Buchs, Switzerland

Abstract

This paper presents a thermodynamic analysis of different heat pump cycles that are capable of delivering 150 °C (4.8 bar) saturated steam from 80 °C recovered waste heat. A detailed comparison of the advantages and disadvantages of the following cycles is presented:

1. Transcritical cycle using butane (R600),
2. Classical closed-cycle using low GWP hydrofluoroolefin (HFO) refrigerant (e.g. R1233zd),
3. Reversed Brayton cycle using carbon dioxide (R744) or argon (R740),
4. Closed-cycle using R600 or R1234ze(Z) with flash tank and additional steam compressors for mechanical vapor recompression, and
5. Open-cycle using water (R718) as working fluid and multiple steam compression stages.

Performance parameters such as COP, compressor efficiency, pressure ratio, steam generation rate, cycle controllability, safety, running and investment costs, and component availability are evaluated and discussed. Under the assumed operating conditions (e.g. temperature lift of approx. 70 K), the theoretically calculated COPs of these cycles range between 1.3 and 3.1. In the transcritical R600 cycle, only a small part of the heat can be used to generate steam, limiting the COP to about 1.3. However, the efficiency can be increased by parallel hot water generation in a second gas cooler. Decisive for a system with a classical closed-cycle heat pump (COP of 1.8) are the use of an environmentally friendly refrigerant (e.g. HFO) and a temperature-resistant compressor with cooling function and stable lubrication. The Reversed Brayton cycle (COP of 2.3) requires a compressor with very high isentropic efficiency (> 0.9) in order to achieve reasonable efficiencies. Depending on the application, a temperature glide on the heat source can be advantageous to transfer more heat. The availability of oil-free compressors is crucial for open steam compression cycles (COP of 3.1). Their achievable pressure ratio determines the number of compression stages. Overall, the study contributes to a better understanding of steam generating heat pump cycles for industrial heating processes and it highlights the current research and technological gaps.

1. Introduction

1.1. Steam generation heat pumps (SGHP)

Electrification of heat generation in the industrial sector is a trend, which is continuously growing. Heating with fossil fuel has a higher environmental impact. Furthermore, due to the decreasing cost of renewable electricity and the introduction of a carbon tax in some countries, heating by fossil fuel is not always the cheapest solution anymore [1]. Heat pump technology using energy from waste heat, ground heat or air, offers

E-mail address: frederic.bless@ntb.ch

an efficiency that is much higher than a heating system based on combustion [2]. However, heat pump systems are limited in the maximal achievable supply temperature. Thus, high-pressure steam (e.g. 15 bar and higher) cannot easily be generated efficiently by heat pump systems, but low-pressure steam (e.g. < 6 bar) can be produced by heat pump processes, especially if a heat source with a high temperature (e.g. waste heat of 60 °C to 80 °C) is available. The advantages of steam compared to hot water are especially the much better heat transfer due to the latent heat release during condensation and the easier temperature control [3].

Mechanically driven vapor compression heat pump systems for steam generation is an evolving technology that is becoming more widespread in the coming years to reduce primary energy consumption and greenhouse effect gas emission [4]. A characteristic constructive difference to a conventional heat pump is the condensing part. The generated steam is either used directly or further recompressed by mechanical vapor recompression (MVR) [5]. A flash tank is normally used as a reservoir for the two-phase water.

The advantages of a steam generation heat pump (SGHP) are in particular the recovery of industrial waste heat in the range of approx. 60 °C to 100 °C and the conversion into low-pressure steam (e.g. < 6 bar) for many potential application fields, e.g. distillation of alcohol, condensation, disinfection, sterilization of food and beverages, concentration of liquids and juices, humidification, or drying processes [4, 6, 7, 8]. Steam generation takes place at a relatively low temperature when using waste heat, thus avoiding exergy losses compared to the combustion of fossil fuels at high temperatures [6, 7]. Moreover, a SGHP can generate more heat from the same primary energy source than a fossil-fueled boiler [9].

1.2. Literature review on SGHP

Several authors investigated the suitability of SGHP by thermodynamic simulations [2, 10, 11, 12]. Experimental investigations are rather rare. Table 1 summarizes a selection of experimental research studies on SGHP categorised by organization, heating capacity, heat source and steam temperature, heat pump cycle, compressor, refrigerant, and COP.

Table 1. Selection of experimental research studies of steam generation heat pumps (SGHP)

The Korea Institute of Energy Research (KIER) has researched on SGHP since about 2013. Lee et al. [15] investigated a 25 kW HTHP for the production of low-pressure steam in a suitable cycle configuration. An internal heat exchanger (IHX) was implemented in the HTHP cycle to ensure superheating of the refrigerant R245fa. The generated heat from the HTHP was transferred in the condenser to a circulating pressurized water circuit. By reducing the pressure, part of the water was converted into steam (flashing method). A steam reservoir separated the steam and the water. In an open circuit configuration, additional water is supplied to the flash tank. With this configuration, steam temperatures of 104 to 123 °C (1.2 to 2.2 bar) were reached. At 60 °C heat source and 105 °C steam temperature a COP of about 3.5 was achieved.

Wang et al. [14] developed a larger SGHP that recovered waste process heat and generated steam at 120 °C. A flash tank served as phase separator. By optimizing the experimental setup, a heating capacity of 101.4 kW and a COP of 3.05 was achieved at 70 °C heat source temperature.

Chang et al. [13] studied the design of a high-temperature condenser for a SGHP with R245fa and 300 kW capacity. For saturated steam of 128 °C (2.3 bar) a steam production rate of 0.422 t/h was evaluated.

Yoo et al. [3] from the Seoul National University designed a laboratory-scale SGHP system and observed a 25% and 80% increase in COP and heating capacity, respectively, with increasing heat source temperature from 60 to 80 °C. The SGHP showed a much better performance compared to a steam boiler.

From the same research group, Kang et al. [6] reviewed recent research studies on SGHP systems. More recently, Kang et al. [9] conducted an experimental study on the performance of a laboratory-scale SGHP with IHX for performance increase. The system consists of an HTHP with a second stage using a flash tank and MVR. The COP was 2.95 at 125 °C, 3.24 at 120 °C and 3.59 at 115 °C steam temperature. Up to 10.8 kg/h steam was generated. The integration of an IHX could increase the amount of steam by 22%.

In Japan, already in 1985, the researchers Yamazaki and Kubo [16] presented a 400 kW heat pump operated with pentane (R601) providing condensation temperatures of up to 135 °C. The heat pump generated low-pressure steam of 130 °C using waste heat of 90 °C as heat source. A variable-capacity screw compressor was used with a motor power of 75 kW. A COP of 4.5 was reached at 80 °C evaporation and 135 °C condensation.

In 2011, Kobe Steel Ltd., CRIEPI (Central Research Institute of Electric Power Industry), and Japanese electric companies have jointly developed and commercialized the KOBELCO Steam Glow Heat Pump (SGH) SGH120 and SGH165, which enable steam temperatures of 120 °C and 165 °C (6 bar). The rated performance of SGH120 is 520 kg/h of steam with a COP of 3.5 at 65 °C heat source [8]. The SGH165 uses an additional water flash tank and MVR to achieve a higher temperature and steam pressure. About 890 kg/h of steam at 165 °C is generated with a COP of 2.5 when using waste heat of 70 °C. Kaida et al. [4] from CRIEPI investigated experimentally the steam generation rate, energy efficiency and controlled performance of the SGH165 under various operating conditions. More recently, Kaida et al. [27] also presented first experimental results of R1224yd(Z) as an environmentally friendly alternative to R245fa, which is to be phased out in the foreseeable future due to high Global Warming Potential (GWP) of 858. At operating point W50/W95, R1224yd(Z) exhibited a 3% higher heating capacity and 12% higher COP compared to R245fa.

Latest developments in heat pump technology in Japan include a transcritical butane (R600) heat pump with a target maximum temperature of 200 °C and a calculated COP above 3.5 at 80 °C heat source (i.e. waste heat). In a joint project with Mayekawa and Waseda University, Kimura et al. [17] developed such a prototype for heating thermal oil from 100 ˚C to 180 ˚C. The experimental setup consists of two oil-free centrifugal compressors with active magnetic bearings. The gas cooler has a capacity of 300 kW. Due to the flammability of the refrigerant, the test apparatus is explosion-proof and enclosed in a housing with active ventilation. Experimental performance evaluation of the system is ongoing.

For condensation temperatures beyond 140 °C to 150 °C, water (R718) is becoming increasingly efficient and very attractive compared to other refrigerants. There are a few studies on HTHPs using water as refrigerant, as summarized by Bertsch et al. [28]. Bless et al. [2] theoretically analyzed different steam generation methods with open cycles. Results showed that water vapor compression methods using water injection require about three times less energy than direct heating systems (i.e. gas-fired boilers or electrical heating).

Shibata et al. [7] from Hitachi proposed an SGHP with water as refrigerant and a four-stage centrifugal compressor with water spray intercooling. The proposed system generates 5'000 kg/h of steam at 130 °C by recovering the waste heat from 60 °C hot water. A test apparatus was developed to validate the first stage of the steam compressor at sub-atmospheric pressure, i.e. compression from 0.2 bar (65 °C) to 0.4 bar (148 °C).

In China, Wu et al. [18] from Shanghai Jiao Tong University investigated the performance of a very high temperature heat pump (VHTHP) prototype using water as refrigerant. An oil-free twin-screw water vapor compressor with water injection was developed. With condensing temperature rising from 117 °C to 150 °C and constant evaporating temperature of 85 °C, the COP decreased from 6.10 to 1.96. The heating capacity decreased from 285 kW to 162 kW, respectively.

In France, Bobelin et al. [22] from EDF (Électricité de France) were among the first to build a 200 kW VHTHP pilot plant in 2012, which can supply hot water of up to 140°C, or low-pressure steam. The heat pump operates with IHX, subcooler, and two parallel scroll compressors. ECO3, a refrigerant mixture containing R245fa, was used. COPs of 2 to 3 were achieved at 125 °C condensation and 50 °C to 60 °C evaporation temperature. Chamoun et al. [23, 24] presented experimental investigations of a water (R718) vapor HTHP pilot plant in 2012 for industrial heat recovery. After condensation, the water was collected in an accumulator and was expanded to low pressure in a flash tank. The main technical feasibility was demonstrated attaining a condensation temperautre of up to 145 °C. Waste heat of 85 °C to 95 °C was used as source providing a heat output of more than 380 kW. At 94 °C source and 121 °C sink temperature, a COP of about 5.5 was measured.

In the Netherlands, Wemmers et al. [19] designed a pilot R600 heat pump able to deliver low-pressure steam of up to 2.4 bar (125 °C) from 60 °C waste heat at a COP of 1.9. The HTHP was developed from commercially available components to ensure quick market introduction. The heat pump configuration also includes a subcooler in order to heat process water at 70 °C.

In Norway, in a cooperation project between NTNU and SINTEF, Bamigbetan et al. [21] reported on the experimental performance of a 20 kW cascade HTHP with propane (R290) in the low-stage and butane (R600) in the high-stage for high temperature heating up to 115 °C. The heat pump was found to have an average COP of 2.1 for a temperature lift of 98 to 101 K and 3.1 for 58 to 72 K, which makes it a better alternative to gas boilers at current carbon emissions and electricity cost rates.

Tveit [20] from Olvondo Technology AS presented an industrial HTHP capable of producing steam up to 10 bar (184 °C) using 80 °C to 90 °C from district heating as the heat source. The so-called SPP HighLift heat pump is based on a reversed Stirling cycle with helium (R704) as working medium, which is continuously in the gas phase. A closed hot water circuit heats the feed water to the saturated steam temperature. In a case study in a dairy plant, the heat pump generates steam for sterilizing UHT milk (for long-life products) at 135 °C to 150 °C for a few seconds. Simulated data showed a heat capacity of 449 kW and a COP of 2.1 at 183 °C heat sink and 85 °C heat source temperature.

Finally, it is worth mentioning the works of Linton [25, 26] from the National Research Council Canada from 1990, who presented a 45 kW steam generating HTHP test facility running with R113 (ozone depletion potential ODP of 0.85) and R123 (ODP of 0.03). This was before the Montreal Protocol entered into force, which banned ozone-depleting substances. The heat pump contained an IHX and a piston compressor with a water-cooled oil cooler. The test stand operated with 55 °C to 80 °C hot water as heat source and produced saturated steam from 103.5 °C to 135.5 °C. The COP with R113 was 2.7 at 75 °C/135 °C and 3.2 with R123 at 65 °C/135 °C.

In summary, the above literature review shows that experimental research on SGHP has intensified worldwide in recent years. Most studies are based on laboratory and prototype tests with heating capacities in the range of a few 100 kW. The majority of pilot plants generate steam temperatures of 130 ± 20 °C. Often a multi-stage configuration with one HTHP and one condenser with pressurized water circuit, flash tank and MVR is used. The average COP is around 3.2 at a temperature lift of 60 K using 70 °C waste heat.

As can be seen, R245fa is predominantly used in SGHP as refrigerant as it offers a suitable temperature range. For subcritical processes, a high critical point for two-phase heat exchange at the steam generation temperature is crucial. However, because of its high GWP of 858 researchers turned to the use of natural refrigerants like hydrocarbons (R600) or water (R718). New synthetic hydrofluoroolefins (HFO) and hydrochlorofluoroolefins (HCFO) with very low GWP such as R1233zd(E), R1224yd(Z) and R1336mzz(Z) are also preferred and investigated. More details on HTHP can be found in Arpagaus et al. [29, 30].

Beside mechanically driven vapor compression heat pumps, thermally driven absorption cycles are also an option for waste recovery and steam generation. As these cycles are not the focus of this study, reference is made to relevant review literature for further details [31, 32].

1.3. Goals of this study

The goal of this study is to analyze different heat pump cycles in order to produce saturated steam at 150 °C (4.76 bar). The influence of various refrigerants, heat source temperatures, and isentropic efficiency of the compressor(s) on their efficiency, cost, and complexity are investigated theoretically. This study compares the following five different heat pump cycles:

(1) ***Transcritical cycle:*** A transcritical cycle is when the heat sink temperature is above the critical temperature of the refrigerant. The heat is suppled via a gas cooler (not a condenser) with a temperature glide. The glide can be an asset in terms of efficiency for certain applications. However, when it comes

to evaporating a fluid, a temperature glide is a disadvantage. In this study, the natural refrigerant butane (R600) is used to generate heat above 155 °C, making the cycle transcritical.

(2) ***Classical closed-cycle HTHP:*** A HTHP is simulated using the common subcritical closed-loop cycle. The condensation temperature was fixed at 155 °C. At this temperature there are only a few refrigerants available, which can be used below their critical temperature. R1233zd(E) was used in this simulation as is it one of the few low GWP HCFO refrigerants with a critical temperature higher than 150 °C.

(3) ***Reversed Brayton cycle:*** A reversed Brayton cycle, also known as gas refrigeration cycle or Bell Coleman cycle, was simulated as well. In a reversed Brayton cycle, the refrigerant stays in gaseous state. In order to use refrigerants that are in the gas state at the low temperature of the heat source, the refrigerants used in the simulation were R744 (CO_2) and R740 (argon).

(4) ***Closed-cycle heat pump with mechanical vapor recompression:*** As only a few refrigerants are subcritical up to 155 °C a combined cycle was simulated, consisting of a low-stage HTHP creating steam at temperatures between 90 °C to 130 °C and a second-stage steam recompression system. This temperature was then fixed to 110 °C in order to optimize the COP while keeping the number of compression stages to two. Depending on the pressure ratio of the steam compressor, multiple compression steps are necessary to reach the desired high pressure. The refrigerants used in the HTHP simulations were R600, R1234ze(Z), and R1233zd(E). The cycle is called high temperature heat pump with mechanical vapor recompression (HTHP with MVR).

(5) ***Open-loop water heat pump:*** This cycle first expands the water to the necessary low pressure in order to evaporate it directly by the heat source. The steam is then re-compressed to reach the desired temperature at the saturation state. Depending on the evaporating pressure and the pressure ratio of the steam compressor, multiple compression stages and inter-cooling sections are needed.

1.4. Refrigerants

The refrigerants studied need to be compatible with the future standards otherwise this study will contain information which will be quickly irrelevant. The European directive on mobile air conditioning systems (MACs) (Directive 2006/40/EC) will prohibit the use of F-gases with a global warming potential (GWP) more than 150 times greater than carbon dioxide [33]. The refrigerants used in the simulations are R1233zd(E), R1234ze(Z), R600 (butane), R718 (water), and R744 (CO_2) with a GWP of less than 10. Some refrigerants like R600a (isobutane) were not simulated because they have very similar properties to the ones mentioned above. Table 2 shows some properties of these refrigerants.

Table 2. Properties of the refrigerants used in this simulation study. ODP = Ozone Depletion Potential (R11 is the ODP reference of 1), GWP = Global Warming Potential (CO_2 is the GWP reference of 1), ASHRAE Standard 34 ranks the toxicity (A, B) and the flammability (1, 2L, 2, 3) of a refrigerant.

Refrigerant	ODP	GWP	Safety group
R1233zd(E)	0.00034	1	A1
R1234ze(Z)	0	6	A2L (slightly flammable)
R600 (butane)	0	4	A3 (flammable)
R718 (water)	0	0.2	A1
R744 (CO_2)	0	1	A1

2. Methodology

To compare the cycles, saturated steam is generated at 150 °C (4.762 bar), and the initial water state is assumed to be 10 °C at 1 bar. The generation of steam is split into two heat exchangers. First, the water is compressed to its evaporating pressure, then the first heat exchanger preheats the water to the evaporating temperature, and finally the second heat exchanger evaporates the water.
Some cycles use steam compression, which compresses the steam to the final state. For example, the open-loop water cycle is different, it first expands the water to a lower pressure, evaporates it, and then compresses it. An IHX is used in some cycles to recover some energy from the subcooling to superheat the refrigerant. The superheating at the compressor inlet is fixed at 10 K for the HTHP and the HTHP with MVR cycles and to 14 K for the transcritical cycle using R600, to avoid wet compression.

The COP of a cycle corresponds to the ratio of the enthalpy difference between the final water state (saturated steam at 150 °C, 4.76 bar) and the initial water state (10 °C, 1 bar) and the work needed by the compressor(s). Each compressor work is calculated by the enthalpy difference between the enthalpy h_1 at the outlet of the compressor and the enthalpy h_0 at the inlet (compressor work = $(h_1 - h_0)$). The outlet enthalpy depends on the isentropic efficiency of the compressor (η_{is}).

EES (Engineering Equation Solver, from F-Chart) is used to simulate the different cycles. However, code for the Reversed Brayton could not converge, thus a self-made Python code using the Coolprop library for the refrigerant data was used instead. The following assumptions are made:

- Pinch point of 5 K in every heat exchanger
- Isentropic efficiency of 0.75 (if not otherwise specified)
- No heat losses in the system (e.g. pipes, heat exchanger, etc.) and no pressure losses
- No energy consumption of water pump(s) (negligible compared to the compressor power)
- Constant temperature glide of 20 K on the heat source
- In the case where heat is delivered at higher and lower temperature than 155 °C, only heat to create the steam is considered (5 K pinch point) and the rest of the energy is used to warm the water from the initial temperature to the final temperature before the evaporation.
- The fresh water is first pumped to its final pressure for all cycles except for the HTHP with MVR cycles and for the open loop R718 cycle (see Figure 1 for more details on the cycles).
- Fixed pressure ratios for steam compressors with a maximum of 2.5. In case of steam compression, the number of compressor stages is thus depending on the pressure ratio of each compressor.
- Between each compression stage, intercooling is added by injecting liquid water at the same pressure to cool the overheated steam to its saturated state.
- Controllability: The heat pump cycles are assumed to be regulated to keep the generated steam constant while the heat source varies.
- Safety and emissions depend on the refrigerant used. The safety concerns may origin from the high pressure needed in the heat pump cycle or from the toxicity or flammability of the refrigerant. The environmental impacts only occur if there is a leakage of the refrigerant. Each refrigerant has a certain GWP summarized in Table 2.

Operating costs are directly dependent on the COP and capital costs vary by cycle. A cost estimation of each component is made to compare the investments costs of the cycles. Using the COP of the cycle, the total cost of the systems is estimated over a period of 15 years. For the reversed Brayton cycle, the expander price is estimated to be the same as a compressor. Equation (1) is used to estimate the price (see Chapter 2 in [34]):

$$C_e = C_b \left({}^{Q}/_{Q_b} \right)^M \cdot f_m \cdot f_p \cdot f_t \tag{1}$$

where C_e is the equipment cost, C_b the known base cost for a capacity of Q_b, M the constant depending of the equipment, and the f's are correction factors for the material of construction, pressure, and temperature. The correction factors where fixed for all components at 1, 1, and 1.6 respectively. C_b, Q_b, and M are given in Table 2.1 of reference [34]. The capacity Q is calculated as function of the cycle for a particular condition.

For the cost analysis, the heating capacity of the heat pump is fixed at 200 kW, which corresponds to about 266 kg/h of saturated steam at 150 °C (4.762 bar). General investment costs are hard to determine and the results have to be taken with care. The yearly electricity consumption cost is calculated using the following equation:

$$Yearly\ electricity\ cost = 7'000\ [\mathrm{h}] \cdot cost_{elec}\ \left[{}^{\$}/_{\mathrm{kWh}} \right] \cdot \frac{200}{COP}\ [\mathrm{kW}] \tag{2}$$

The cost of electricity ($cost_{elec}$) is 0.13 $/kWh with taxes, which is approximatively the EU-28 weighted average retail electricity price for industry for the last couple of years (Figure 4 in reference [35]). The yearly maintenance cost was fixed to 6% of the capital cost according to Table 5 from Wang and Zhang [36]. The capital cost of the cycle is an estimation of all the component costs according to equation (3), and the two formulae for the cost of the expansion valve and the piping and instrumentation coming from Table 3 of reference [36].

$$C_{\text{expansion valve}} = 114.5 \cdot \dot{m} \tag{3}$$

where $\dot{m}$ is the mass flow of the refrigerant. The piping and instrumentation costs are assumed to be 28% of the sum of all the components cost (except the steam compressors), as described in [36].

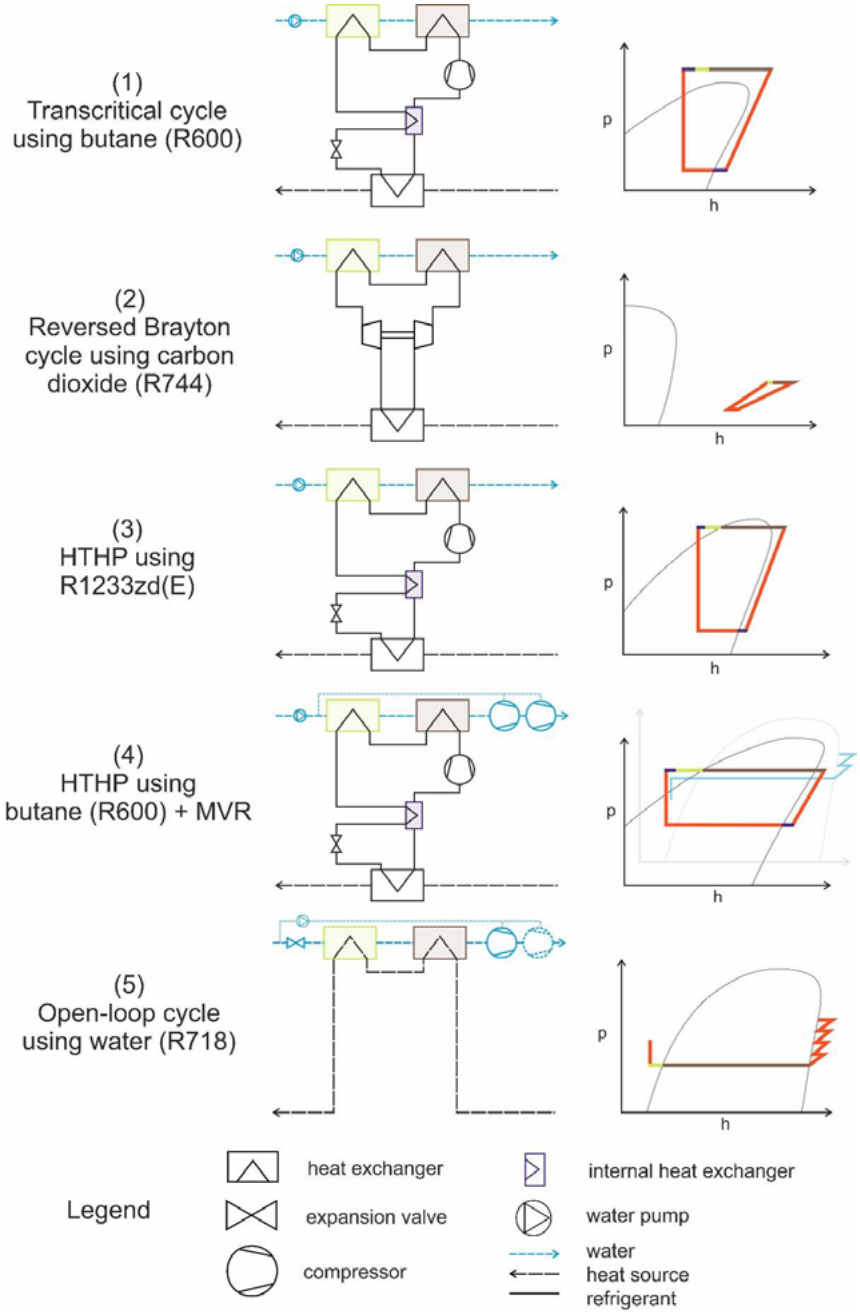

Fig. 1. Schematics and p-h diagrams of the five investigated heat pump cycles. (1) Transcritical R600 cycle, (2) Reversed Brayton cycle with R744 (CO_2) or R740 (Argon). (3) Classical closed-cycle HTHP using R1233zd(E), (4) Closed-cycle HTHP with mechanical vapor recompression (MVR), and (5) Open-loop cycle with R718 (water).

3. Results

3.1. COP simulations

The COP is simulated with different heat source temperatures and different isentropic efficiencies of the compressor(s). Figure 2 shows the COP for the different heat pump cycles generating steam of 150 °C (4.76 bar) as a function of the heat source outlet temperature (with constant temperature glide of 20 K on heat source) with an isentropic efficiency of 75%. As expected, the COP of each cycle increases with higher heat source temperature. The reversed Brayton cycle is the cycle least affected by the increase in source temperature. For the open-loop R718 heat pump cycle, the number of compressions stages varies as follows: six stages for temperatures below 40 °C, five for temperatures between 40 and 50 °C, four for temperatures between 50 and 70 °C, and three for temperatures above 70 °C. Since the steam compressor is not perfect, each compression step leads to a loss in process performance. This explains the lower COP of the open-loop cycle with water at lower source temperature compared to the HTHP with MVR cycles. For heat source temperatures of 75 °C and above the cycle's efficiencies are comparable. The transcritical cycle and the reversed Brayton cycle are not as efficient due to their temperature glides in their heat sink whereas the other cycles have a constant temperature.

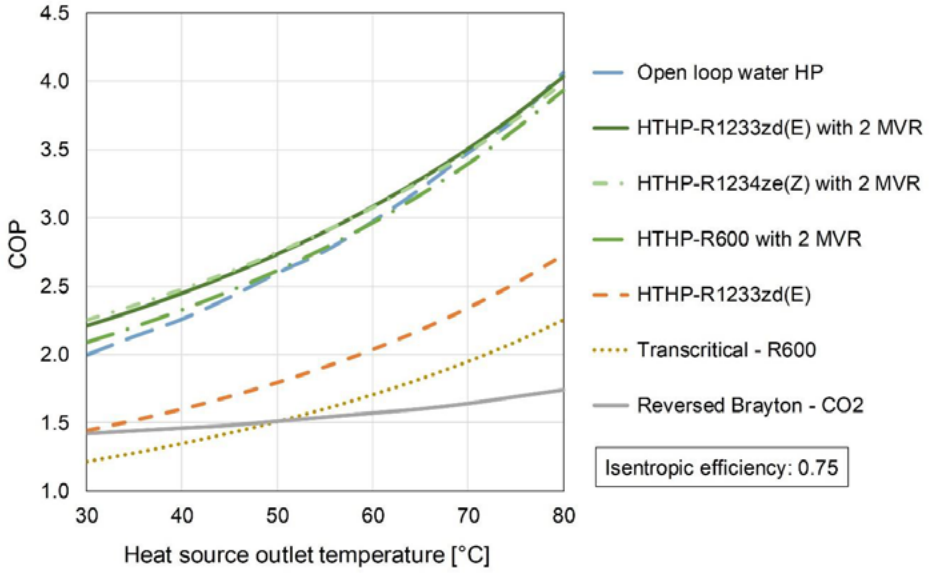

Fig. 2. COP for the different heat pump cycles generating steam of 150 °C (4.76 bar) as a function of the heat source outlet temperature (heat source temperature glide: 20 K, heat sink water inlet: 10 °C, isentropic compressor efficiency: 0.75)

Figure 3 shows the COPs as a function of the isentropic efficiency of the compressor(s) using a heat source inlet/outlet temperature of 80/60 °C. The increase of the COPs is linear except for the reversed Brayton cycle where the relation is much stronger than linear. The reversed Brayton cycle becomes most efficient for steam generation if it is operated with a compressor with a very high efficiency. The HTHP+MVR cycles and the open-loop water HP are still more efficient up to η_{is} of 95%, only with 98.5% and above the reversed Brayton cycle is above all the other cycles.

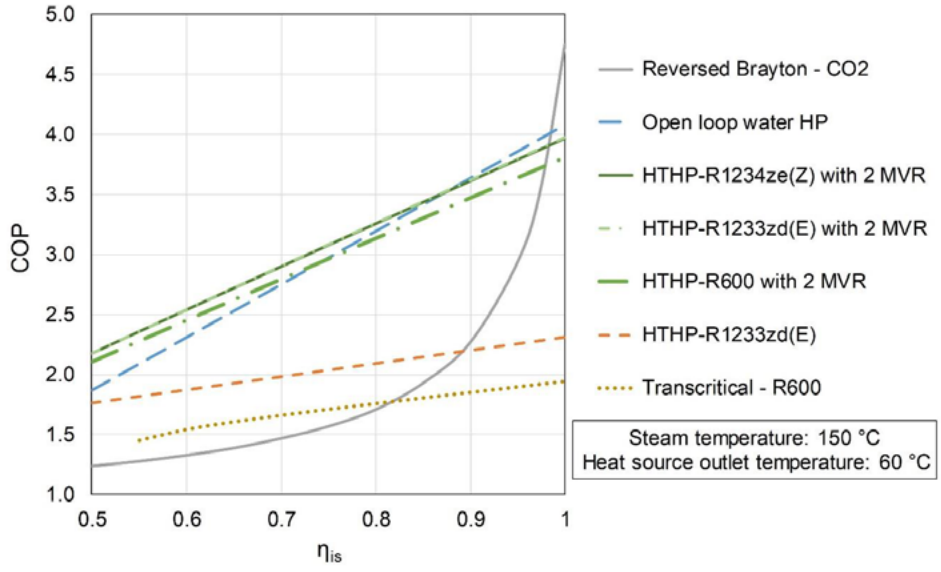

Fig. 3. COP for different heat pump cycles generating steam of 150 °C (4.76 bar) at 60 °C heat source outlet temperature (20 K temperature glide) as a function of the isentropic efficiency of their compressor(s) (η_{is}).

3.2. Cost analysis

Table 3 shows some estimated cost for the representative cycles at 60 °C heat source outlet temperature and η_{is} 75 %. The HTHP-R600 with 2MVR is simulated with a HTHP having a condensation temperature of 110 °C. The HTHP and the transcritical cycles have roughly the same capital cost due to their similarity. The open loop cycle with R718, as seen in Table 3, has a price similar to the previous cycles even though it needs 4 compressors; the reason is this cycle needs less heat exchangers. The reversed Brayton cycle shows the highest cost of all cycles. The main reason is that its compressor needs around twice the power compared to the other cycles. This can be schematically seen in the p-h diagram of the cycle in Figure 1 (2), where the ratio of the enthalpy difference of the compressing step over the heating step is small. Furthermore, the expander also costs much more than the expansion valve used in the other cycles.

Table 3. Estimation of the capital costs, the maintenance, and the electricity costs for a particular condition (60 °C heat source outlet temperature, η_{is} = 75 %) for each cycle. The HTHP-R600 with 2MVR cycle is simulated with a condensation temperature of 110 °C.

Cycle	Capital cost (CC) [$]	Yearly maintenance cost (6% of CC) [$]	Yearly electricity consumption cost [$]
(1) Transcritical R600 cycle	174'054	10'443	106'433
(2) Reversed Brayton with R744	516'697	31'002	115'924
(2) Reversed Brayton with R744 with η_{is} = 95%	640'451	38'427	59'477
(3) HTHP with R1233zd(E)	182'258	10'935	89'216
(4) HTHP with R600 with 2 MVR	217'388	13'043	61'279
(5) Open loop cycle with R718 (4 MVR)	181'868	10'912	61'279

Figure 4 shows an estimation of the total costs (i.e. investment and operating costs) as a function of the year according to the costs displayed in Table 3. The graph shows, which cycles are the most interesting in terms of cost depending on its usage. The transcritical R600 has the lowest capital cost, however, after only one year of operation (by the conditions assumed), the standard HTHP-R1233zd(E) and the open loop R718 HP are cheaper. One year later, the HTHP-R600 with 2 MVR also becomes a cheaper option.

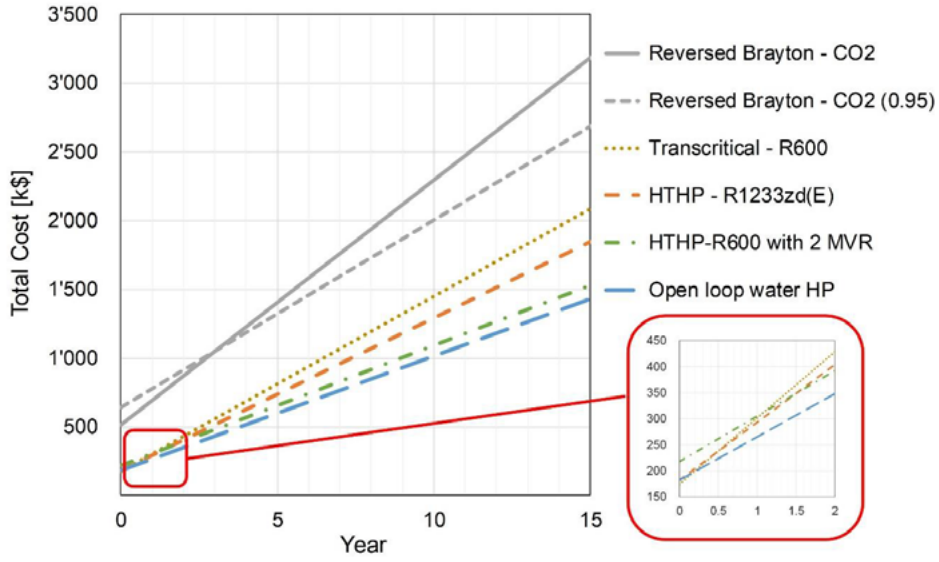

Fig. 4. Total cost (capital cost, maintenance cost, and operating cost) for the different heat pump cycles for 15 years with the following conditions: heat source inlet temperature: 80 °C, isentropic efficiency: 0.75 (except for the second reversed Brayton where it is 0.95), k$ corresponds to 1'000 $.

The maintenance costs were estimated simply by estimating a percentage of the capital cost, but do not consider the simplicity of the maintenance. To get an overview of the complexity of the different cycles, Table 4 summaries the number of components included in each cycle.

Table 4. Components of the five heat pump cycles.

Cycle	Heat exchanger (evaporator, condenser, gas HEX, or IHX)	Compressor	Steam compressor	Expander
(1) Transcritical	4	1		
(2) Reversed Brayton	4	1		1
(3) HTHP	4	1		
(4) HTHP with MVR	4	1	2	
(5) Open loop	2		4	

Table 4 shows that the first three cycles are very similar in terms of components. The reversed Brayton cycle has an additional expander, which is linked to the compressor. Such a system can be achieved with a turbo compressor and an expander on the same shaft [37]. The cycle with the additional steam compressor(s) has to deal with more compressors and more control. The open loop R718 cycle has only half the number of heat exchangers, which reduces the need for cleaning depending on the fluid used, but the high number of steam compressors makes this cycle particularly difficult to control and the complexity makes it more difficult to optimize and operate at its best efficiency.

4. Discussions

No combination of cycles was analyzed in this study, which could increase the COP by using different refrigerants with lower temperature lifts, instead of having one refrigerant with a high temperature lift. The cycle combining the transcritical heat pump as low stage with the reversed Brayton cycle as high temperature stage was nevertheless analyzed, as it seemed like a good combination due to the temperature glide in the heat sink of the former cycle and in the heat source of the latter. Although this system shows a 28% higher COP compared to the transcritical R600 cycle and has similar costs (the system has more components but with lower

unit prices), this combination is much more complex to control and offers no increased performance over the HTHP cycle in terms of efficiency.

The reversed Brayton cycle is interesting when the isentropic efficiency of the compressor is very high. When η_{is} of the compressor(s) are above 90%, the cycle is a good alternative for HTHP especially when the temperature lift is higher than 100 °C. However, the only heat pump compressor with isentropic efficiency higher than 90% found nowadays is the Rotational Heat Pump from ECOP [38]. This near market-ready machine is using an original idea: a rotational heat pump where the entire system (i.e. heat exchangers, expansion) is located inside a rotating cylinder that acts as a compressor [38].

The availability of heat pump components for temperatures higher than 120 °C is limited. Although components exist, they are far more expensive than standard low-temperature components for conventional heat pumps. This issue should dissipate in the future as soon as HTHP become more common. For the two cycles, which recompress the steam, an oil-free compressor is mandatory depending on the usage of the steam in order to avoid contamination. Oil-free steam compressors are not common in the market for low- to mid-range power (e.g. tens of kW to hundreds of kW). Steam compressors are more often used in the high-power range for MVR in order to recover the steam, which hasn't condensed [39].

The number of case studies of HTHPs in industry producing steam is very scarce [12, 15, 20, 40]. There are some articles that propose closed-cycle R718 heat pumps [23, 24, 41], and many articles on HTHPs [30, 42, 43]. As described in the literature review at the beginning of this paper, there are also some publications on experimental studies producing steam by heat pumps from Korea [3, 9, 13, 14, 15], Japan [4, 8, 16, 17, 27], China [18], Europe [19, 20, 21, 22, 23, 24], and Canada [25, 26], as well as theoretical works [2, 10, 11, 12].

Validation of this theoretical work is important to gain the trust of industries in order to build pilot projects.

In terms of technical readiness level, the five cycles analyzed can be put into three categories. The transcritical HP and HTHP are at the production level, the reversed Brayton cycle with high isentropic efficiency is according to [38] at the validation level, and the low- to mid-range HTHP with MVR and the open-loop R718 HP are considered to be at the development level.

5. Conclusions

Different heat pump cycles were simulated in order to generate saturated steam at 150 °C (4.76 bar) using only low GWP refrigerants that are future-proof according to the F-gas regulations. They show different COP trends depending on the heat source temperature and the isentropic compressor efficiency. A transcritical heat pump or a reversed Brayton cycle can be very efficient to generate heat at different temperatures thanks to the temperature glide in their heat sink. However, these cycles are not as efficient when used to generate steam at constant heat sink temperature. The heat pump cycles using steam recompression offer higher efficiency and are cheaper after a few years, taking into account maintenance and operating costs.

The authors hope that this study will promote further research into heat pump cycles for steam generation and, above all, motivate the realization of prototypes and pilot projects. The validation of such a study is crucial to rapidly increase the technical readiness level of heat pump cycle for low-pressure steam generation.

Control optimization of a double stage heat pump with desuperheater in multi-family NZEBs

Fabian Ochs[a*], William Monteleone[a], Nicola Franzoi[a], Georgios Dermentzis[a]

[a]University of Innsbruck, Innsbruck, 6020, Austria

Abstract

Two multi-family buildings (MFB) with together 26 flats were designed to achieve a net Zero Energy (NZE) balance for heating, domestic hot water (DHW) preparation and all auxiliary energies. The roof of one of the MFB is covered by PV, the other is partly used for PV and partly for solar thermal (ST). A double-stage ground water heat pump (HP) with hot gas desuperheating (DSH) provides the remaining energy for heating and DHW. The system was designed with a low temperature distribution system (floor heating) and separate decentral fresh water preparation (DHW plate heat exchanger) for low thermal losses and optimal efficiency.
Detailed performance maps of the double-stage HP pump with DSH were generated analyzing the monitoring data and by means of refrigerant cycle simulation. Simulation based optimization was performed with the aim to operate the HVAC system with improved performance. Different system configurations (i.e. with or without ST, with different buffer storage sizes, with different control strategies and set points) can be compared and evaluated also considering (seasonal) variations of the share of renewables in the electricity mix.

Keywords: NZEB; Multi-family buildings; double stage heat pump; desuperheater; building and HVAC simulation

1. Introduction

In order to reach the ambitious targets of a sustainable energy system, strong efforts in improving energy efficiency in the building sector are required, see [1]. Only with a combination of passive (i.e. building envelope) and active (i.e. HVAC system) measures as well as integrating renewable energies (RE) these targets can be reached. System solutions, i.e. well designed and matching components with a robust control scheme and the possibility of easy quality control, are required.

While there is a discussion among experts about the most economic building energy standard (e.g. whether it is Passive House standard or less ambitious), it is undiscussed that heat pumps (HP) will play a major role in heating (and cooling) of buildings. HPs exist in a large variety with respect to the source (air, water, ground, waste heat) and the sink (air, water; low temperature heating, DHW etc.) and in almost any size (from some 100 W to several 100 kW). Even though there is experience with HPs since several decades and a strong development of HPs within at least the last 20 years, there is still a lack of knowledge of HP operation and optimal system design for nZEB [2,3]and in particular nZE multi-family buildings [4, 5]. In [6, 7, 8, 9] increasing performance of installed HP systems within the recent years is reported. However, the market and its players lack experience and guidelines for HP system for nZEB are still missing (see also e.g. IEA HPT Annex 49).

In this paper, a case study of two NZE multi-family buildings in Passive House standard is presented with an innovative HVAC system. In this work, it is presented, how by means of simulation with models that were parameterized using detailed monitoring data (refrigerant cycle as well as building and HVAC simulations), failures could be detected and how the performance could be improved. The results can be used to derive guidelines for HP system design and failure detection and quality control.

2. Case Study

In Innsbruck Vögelebichl, two multi-family buildings (MFB) were designed to achieve a net Zero Energy (NZE) balance for heating, domestic hot water (DHW) preparation and auxiliary energies. The roof of one of the MFB is covered by PV, the roof of the other MFB is partly used for PV and partly for solar thermal (ST). A double-stage ground water (GW) heat pump with hot gas de-superheating provides the remaining energy for heating and DHW.

2.1. Buildings

The two buildings with together 26 flats and together 2149 m² of treated area (see Fig. 1) were already described in detail in [10, 11, 12, 13]. The buildings were designed to reach Passive House Standard (Heating Demand HD ≤ 15 kWh/(m² a)). One roof of the MFB is covered by PV (99.8 m²), the other is partly used for PV (52.5 m²) and partly for ST (73.6 m²).

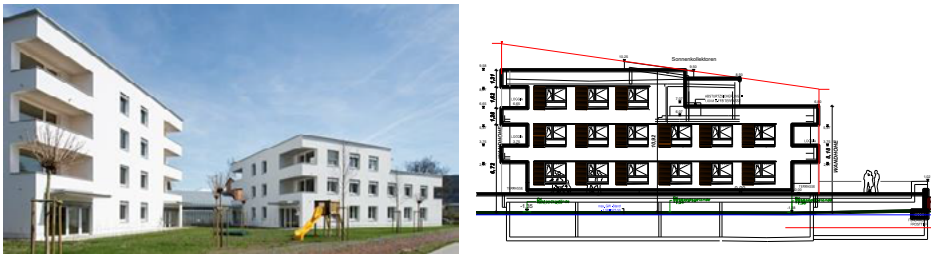

Fig. 1. (left) two multi-family buildings in Passive House standard (NHT, Innsbruck Vögelebichl), (right) west view on south building with 10 flats

2.2. Heat Pump System and Hydraulic Scheme

A ground water (GW) heat pump (HP) (with two stages, i.e. two parallel compressors) and solar thermal collector (SC) field charge the buffer store which provides heat with a low temperature heat distribution and the separate decentral fresh water preparation (DHW plate HX) to the buildings, see Fig. 2. The double-stage HP is equipped with hot gas (HG) de-superheating. Depending on the operation mode (heating or DHW preparation), the flow of the HP enters the buffer store (BS) at the top or at 1/3 of the height from the top. The combined return of the heating and DHW loop enters the large 6 m³ buffer store depending on the temperature level either at the bottom or at about 1/3 of the height of the tank in order to enhance stratification. The electric backup heater (BH) is currently not in use.

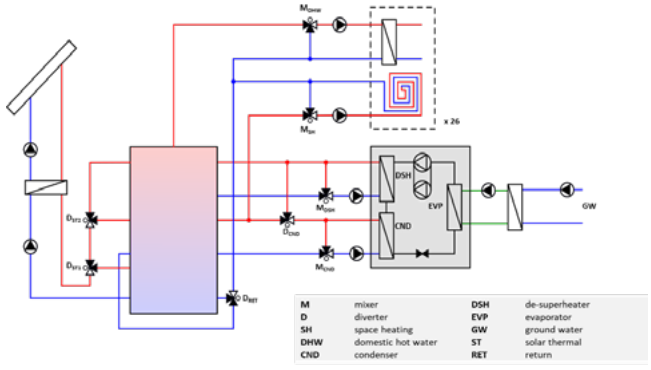

Fig. 2. Simplified hydraulic scheme with Solar Collectors (SC), Buffer Store (BS), 2-stage ground water heat pump (HP) with hot gas HG) desuperheating (DSH) in heating mode with floor heating (FH) and decentral heat exchanger (HX) for domestic hot water (DHW) preparation

2.3. Heat Pump

The heat pump has a nominal capacity of 52 kW (at W55, see Table 1). The performance map (PM) data of the HP according to the manufacturer is available only for double-stage operation and without DSH loop. PM data is available for other source temperatures, but no data is available for single-stage operation and for operation with desuperheating loop. Hence, the required performance maps have to be generated using dynamic monitoring data, which will be described shortly in the next section.

According to the EN 14511 measurements (compare table 1) there is not DSH or the DSH is in series to the condenser.

Table 1. Performance map (PM) of the double-stage HP with R410A according to data sheet (EN 14511)

(data sheet) EN 14511	W35	W45	W55
Heating Power at W10 / [kW]	58	55	52
COP at W10 / [-]	6	4.6	3.7
El. Power at W10 / [kW]	9.7	11.8	13.9
Cooling Power at W10 / [kW]	49	43	38

2.4. Double stage heat pump

Double-stage HPs are on the market already for several years. Double-stage HPs feature higher investment costs but have potentially lower operation costs. A double-stage compressor has a low capacity, which is 50% or about 70% in most models, and high capacity (100%). Variable-speed or modulating compressors vary capacity from about 40% to 100% in increments of less than 1% and are the most efficient. They have the highest advantage if either the source (e.g. air) and or the sink have variable temperature or power level (e.g. for heating).

With a single-stage HP, the compressor runs only at full load capacity, i.e. once the required temperature level is satisfied, the compressor turns off. A double-stage compressor can operate at part load or full load

capacity. The two-stage HP compressors turn on and run until stage two of the thermostat is satisfied, then one compressor continues to run at a lower level, stage one. If the HP is connected directly to the heating system, this would allow to avoid swings, i.e. for a more even room temperature.

Potentially, the double-stage HP consumes less energy and does not have to work as hard to adjust to swings in room temperature. This could result in a lower operating cost while keeping occupants at the same comfort level. In [14] it was found that such a coupling process improved energy efficiency ratio by 20 % compared to a purely air source HP.

2.5. Heat Pump with Desuperheater

One possibility to improve the performance of a HP in residential applications is a desuperheater (DSH). The additional heat exchanger between the compressor and the condenser of the HP transfers the heat of the superheated refrigerant to a secondary circuit. It is suited for DHW preparation (directly or indirectly via a storage tank) because of the relative high temperature level that can be reached (e.g. 55 °C to 60 °C). The condensation of the de-superheated refrigerant takes place in the condenser of the HP at lower temperature level, e.g. at 35 °C in case of floor heating system and the heat is transferred to the heating system directly or via a separate buffer storage tank.

An energetic advantage is obtained as a part of the heat for DHW preparation that has to be provided at high temperature with usually relative low performance in “DHW preparation mode” is provided at higher efficiency at low condensing temperature in “heating mode”. During this simultaneous operation (heating and DHW preparation), the HP operates at a lower condensing pressure compared to DHW preparation only. The amount of high temperature heat that can be provided and that reduces operation hours at low efficiency depends on the heating load and heating demand of the building (load duration curve). An extensive investigation for a single family home can be found in [15] and in [16]. In [13] the theoretical upper limit of performance increase by use of a DSH was shown as a function of the ratio of heating and DHW demand.

2.6. Buffer Tank

A scheme of the buffer tank is shown in Fig. 3 with inlets and outlets for (left) the heat generation part and (right) for the load. The dots indicate the position of the temperature sensors. The tank was modelled with the storage model of the Carnot Blockset in Matlab/Simulink.

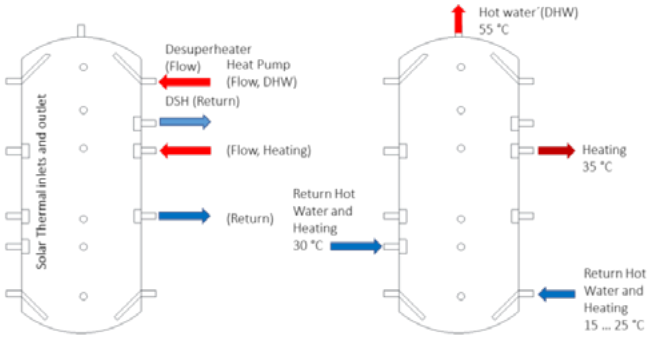

Fig. 3. Hot water tank (6 m³) with (left) heat generation (ST, HP DHW, HP Heating and desuperheating and (right) outlets for hot water preparation and heating and common return inlets

2.7. Hydraulic integration of desuperheater

The sizing and integration of the desuperheater is a nontrivial problem. Generally, the desuperheater can be connected in a parallel loop, as currently implemented in this system (Fig. 4), or it can be connected with a controlled diverter valve and can be operated in mixed parallel/series operation (Fig. 5). In parallel operation, either speed controlled circulation pumps or flow temperature control mixing loops are required to achieve the appropriate flow temperature. The latter is implemented in this system.

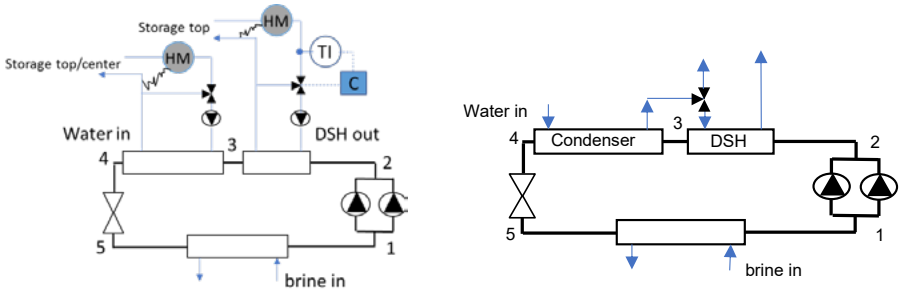

Fig. 4. (a) Parallel operation of condenser and desuperheater with flow temperature control of condenser and DSH with heat meter (HM), temperature indicator (TI) and controller (C) (TI and C of the condenser loop are not shown for better visibility); (b) Flow temperature control of condenser and DSH (mixed parallel / series operation)

2.8. Control

Theoretically, only for the heat pump eight different operation modes exist as shown in the following figure. The current implementation of the system does not allow operating the desuperheater in series, a slight change of the hydraulic scheme would be necessary. Currently, the HP is operated either in DHW mode (if the top third of the storage tank is below 48 °C, set point temperature of storage top temperature = 52 °C) in stage II or in heating mode in stage I or II depending on the outdoor temperature. An improved system concept is shown in the discussion section.

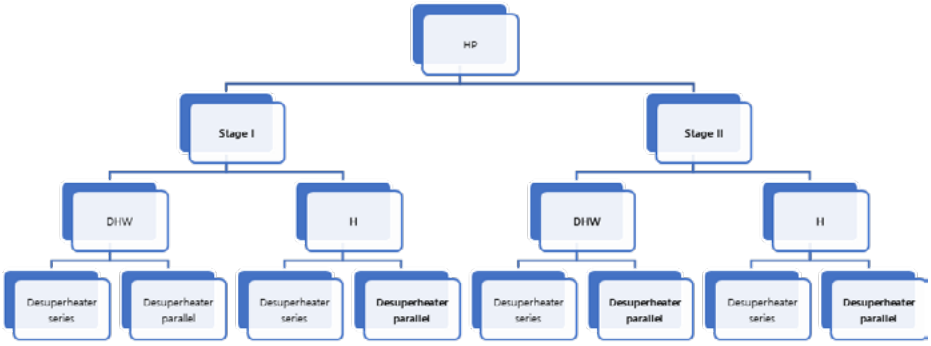

Fig. 5. Theoretical control options of a double stage heat pump with desuperheater and current control implementation in bold (stage I, and stage II heating mode, stage II DHW mode; DSH always in parallel operation)

2.9. Monitoring System

Detailed monitoring of the buildings (all flats in one of the two MFB), the HVAC system including thermal losses and the performance of PV and ST allowed to study the behavior of NZEBs in practice. The simulation-assisted analysis of the monitoring data allowed to identify problems and faults of the installation and of the operation. By means of simulation, influences of climate and of the user behavior (set points, etc.) could be considered and the monitoring results could be normalized to standard conditions.

The measurement system consists of Pt100 (1/3 DIN), heat meters and electricity meters. The measurement system is connected to the BMS and readings are stored with a 1 min. time step. Data is post-processed and average or integrated values are reported.

Detailed monitoring results were collected for a period of three years, analyzed by means of dynamic simulation and the performance of the buildings was evaluated with respect to the aim of achieving the NZE balance. The dynamic building and HVAC simulation was performed with Matlab/Simulink.

3. Research Questions

The following research questions can be defined:

- Does a double-stage outperform a single-stage HP?
- Is there a cost benefit and is there a benefit with respect to service life (i.e. can excessive on/off cycles be avoided)?
- What is the optimum control strategy for a double stage HP?
    - for heating and for DHW preparation
    - in combination with a buffer storage
- What is the theoretical and real benefit of the DSH?
- Does a 2 + 2-pipe system outperform the 3 pipe system (with common return of heating and DHW loop)?
- By how much can the storage stratification and the system performance be improved by variable input heights of the return flow to the tank?

The particular question in this project is whether the performance of a HP can be improved in these MFBs with very high energy standard (PH Standard) with relative low heating demand (15 kWh/(m² a) and relative high DHW demand (ca. 25 kWh/(m² a)) and by how much? And can the goal of NZEB be achieved?

4. Method

Firstly, based on the analysis of monitoring results, conclusions on the actual performance are derived and typical operation conditions of the heat pump are identified. Secondly, refrigerant cycle simulations are performed in order to identify the performance map for the different operation modes. Finally, dynamic simulations are performed in order to detect faults in the current system and to identify possible improvements with respect to the control strategy and set points but also regarding improved system design.

5. Monitoring Results

5.1. Heating Load and DHW demand

The heating load is 24 kW for both buildings according to the design (PHPP, max. daily average). DHW load adds approx. further 12 kW with a buffer tank acc. to the standard recommendations. For the south building detailed data of each flat is available. The maximum daily heating load is 7 W/m² (see Fig. 6). There is a clear trend of heating load vs. ambient temperature, which is not typical for passive houses. The heating capacity of the heat pump in stage I is always sufficient to cover the heating load of the building. However, in stage II higher share of desuperheater can be expected.

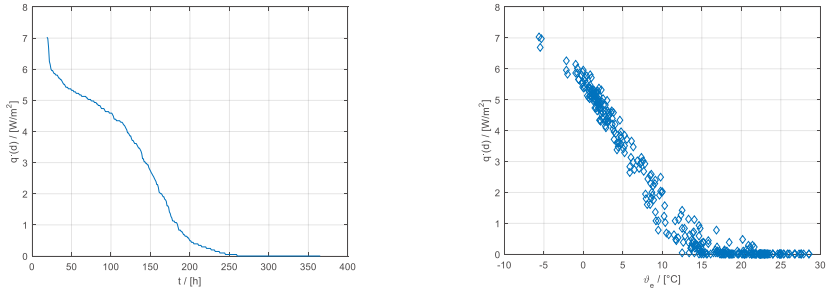

Fig. 6. (a) Load duration curve of the south building and (b) daily heating load vs. ambient temperature

Domestic hot water demand is not monitored in detail. The total delivered DHW from the storage is measured and includes distribution losses. In 2018 it was 26 kWh/(m² a) and in the range of the predictions. The flow temperature to the decentral fresh water heat exchangers is in the range of 52 °C and always sufficient to provide hot water with sufficient comfort.

5.2. Electricity Energy Demand and Net Zero Energy Balance

In 2018, the electricity consumption of the HP was 21 MWh and auxiliary energies were responsible for 14 MWh. The PV field produced in average around 27 MWh. Fig. 7 reports the electric energy balance for the years 2016 to 2018. In spite of the reduced total energy demand in 2018 (mainly because of the decreased heating demand), the NZE balance was not achieved. (Remark: Actually, the PV production was 24.5 MWh in 2018 because of a technical failure of the inverter of the north building PV field. A yield between 26.6 MWh and 27.2 MWh can be predicted based on data of 2016 and 2017 for the case without the failure).

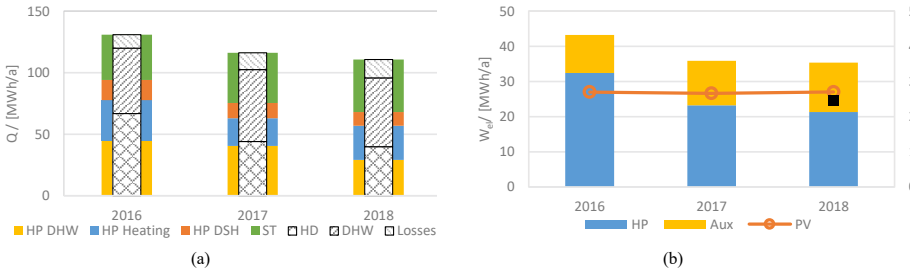

Fig. 7. Thermal (a) and electric (b) balance with HP, auxiliary energies (aux) and photovoltaic (PV)

5.3. HP Operation

A series of typical HP operation modes is shown in Fig. 8. The HP operates with full capacity (stage II) in DHW mode. Also the DSH delivers around 11 kW. The condenser power is 28 kW. With the electric power of the compressor of 14 kW, the COP is 2.8. In heating mode (with single compressor operation) the heating power is 25 kW. No useful desuperheating can be measured. The COP under these conditions is 6.25 (4 kW of electric power). There is one short period with heating mode at stage II with a small contribution by the DSH. It has to be mentioned here, that the heat meters measure the heat that is delivered to the storage tank. In order to deliver the energy at the required temperature level, flow temperature control is implemented, as shown in Fig. 4, above. Furthermore, it is important to remark that the presented operation of the HP does not represent the optimum configuration but is the one implemented and is used to identify the HP operation and generate the PMs.

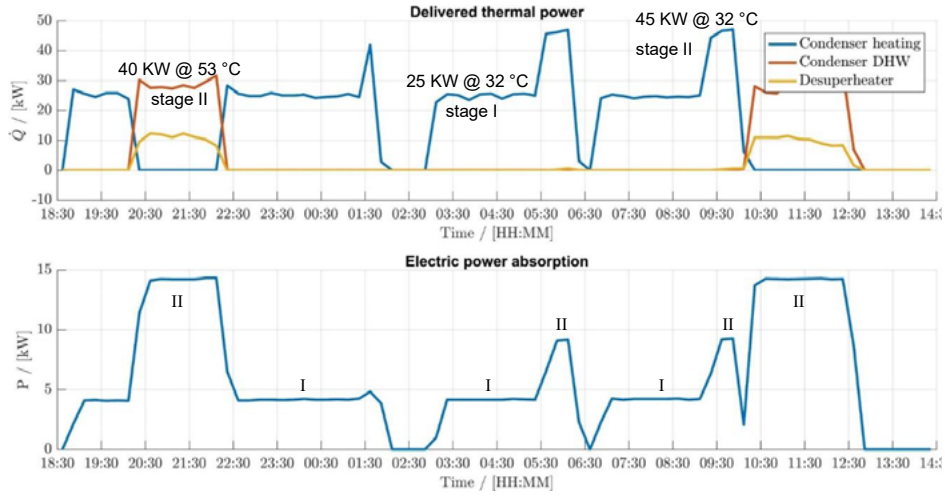

Fig. 8. Heat Pump operation with different operation modes (stage I and stage II, DHW and Heating with and without DSH)

6. Component and System Modelling

6.1. Refrigerant Cycle

A simplified scheme of the refrigerant cycle of a double-stage HP with DSH is shown in Fig. 5. In order to predict the performance of the HP under various conditions, a simplified physical vapour cycle model was developed in Matlab using the CoolProp database for refrigerants [17]. Pressure losses in and between the components are disregarded with the exception of the pressure loss in the condenser, which can be considered by a given pressure difference Δp_{cond}. Subcooling and superheating are considered in a simplified way with given temperature differences ΔT_{sub} and ΔT_{super}, respectively.

The evaporator is divided in three sections (film evaporation, evaporation and superheating). The heat transfer coefficients are assumed to be constant in each section. The following equations are applied.

$$\dot{Q}_{evap} = \dot{m}_b \cdot \Delta h_b = \dot{m}_{ref} \cdot (h_1 - h_5) \quad (6)$$

$$\dot{Q}_{evap} = \sum UA_{evap,i} \cdot \Delta\vartheta_{log,evap,i} \quad (7)$$

Correspondingly, the condenser is divided in desuperheating, condensation and sub-cooling sections with constant (i.e. given) heat transfer coefficients.

$$\dot{Q}_{cond} = \dot{m}_w \cdot c_w \cdot \Delta T_w = \dot{m}_{ref} \cdot (h_3 - h_4) \quad (8)$$

$$\dot{Q}_{cond} = \sum UA_{cond,i} \cdot \Delta\vartheta_{log,cond,i} \quad (9)$$

Then for the DSH it applies that

$$\dot{Q}_{DSH} = \dot{m}_{w,DSH} \cdot c_{p,w} \cdot \Delta T_{w,DSH} = \dot{m}_{ref} \cdot (h_2 - h_3) \quad (10)$$

$$\dot{Q}_{DSH} = UA_{DSH} \cdot \Delta\vartheta_{log,DSH} \quad (11)$$

The mass flow of the refrigerant

$$\dot{m}_{ref} = D \frac{N_{min}}{60\ \mathrm{s/min}} \cdot \rho_{suc} \cdot \eta_{vol} \quad (12)$$

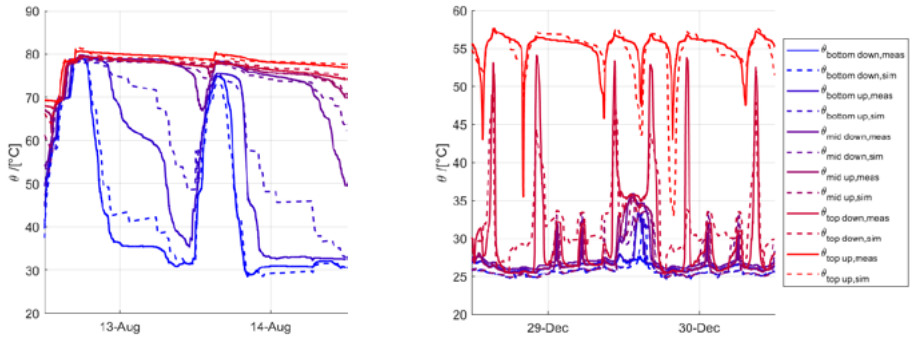
is a function of the displacement and of the volumetric efficiency. The compressor power in the refrigerant cycle is calculated based on the isentropic efficiency η_{is}.

$$P_{comp} = \dot{m}_{ref} \cdot \frac{h_{2s} - h_1}{\eta_{is}} \quad (13)$$

where $h_{2s} = h(p_{dis}, s_1)$ is the enthalpy of superheated gas at isentropic compression. The isentropic efficiency η_{is} depends on the compression ratio, which is a function of the compressor discharge p_{dis} and suction p_{suc} pressure.

$$\tau = \frac{p_{dis}}{p_{suc}} \quad (14)$$

Both, the volumetric and the isentropic efficiency can be approximated based on literature data by a polynomial or a 2D-lookup table.



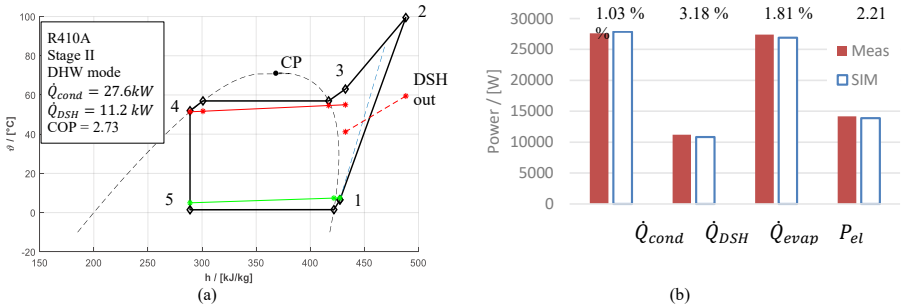
The electrical efficiency of the compressor η_{el} is approximated with a linear function depending on the compressor temperature. Then the performance of the HP can be calculated as follows

$$COP_{HP} = \frac{\dot{Q}_{cond} + \dot{Q}_{DSH}}{P_{\mathrm{el,comp}}} \quad (15)$$

7. Results

7.1. Buffer Storage

The measured and simulated storage temperatures for a period in winter and in summer (with ST operation) are shown in Fig. 9. Overall, the agreement is acceptable. In detail, there are some deviations in the dynamic behavior during some days for some sensors, but with respect to the research question discussed in this paper, the deviations are acceptable.



(a) (b)

Fig. 9. Measured (meas) and simulated (sim) storage temperatures for a period in summer (a) and in winter 2018 (b)

The measured thermal losses are within an average factor of about 10 times higher than the predicted ones (for a tank of that size and with that insulation level, corresponding to a ErP class C tank, EU efficiency classes for storage losses). One main reason is that losses from pipes, valves and pumps between the tank and the heat meters are included in the energy balance. Unwanted buoyancy flows could be excluded by analyzing the monitoring data for all hydraulic loops except for the cooling loop (in summer the ground water can be used with a heat exchanger to do some cooling with the floor heating system.) This is still under investigation.

7.2. HP Model Parameterization

The simplified physical HP model, described above, was parameterized using measured data from monitoring. The source temperature showed little variation between around 8 °C and 12 °C over the course of the year. Two typical operation modes were identified: DHW operation with desuperheating at double-stage and heating mode at single-stage without significant desuperheating. The resulting refrigerant cycle is shown on the following Fig. The corresponding heating power (condenser, DSH and evaporator) and electric power (compressor) are shown in Fig. 10. The deviations are highest for the DSH with 3.2 %.

(a) (b)

Fig. 10. (a) Refrigerant Cycle at DHW operation mode with DSH, stage II; (b) Comparison of measured and simulated heating powers and electric powers and relative deviations (remark: the presented operation of the HP does not represent the optimum configuration)

7.3. PM of Heat Pump Model DSH

With the parameterized HP model, performance maps for the different operation modes were generated. These include

- Stage I or stage II
- DSH in series (i.e. without separate DSH loop) or separate DSH loop
- DSH inlet temperature

$$\dot{Q}_{cond}, \dot{Q}_{DSH}, P_{el} = \mathrm{f}(\vartheta_{src}, \vartheta_{snk,} \vartheta_{DSH}, stage, DSH) \qquad (16)$$

Fig. 11 (left) reports the heating power of the HP. The uncertainty of the model is indicated by the error bars and is in the range of 6 kW. Fig. 11 (right) shows the corresponding COP. It is significantly lower than the COP according to the data sheet. One reason for lower performance is the lower volume flows on the source and sink side compared to the measurement acc. to the standards. Furthermore, a slight degradation of the heating capacity of the HP could be identified within the first three years of operation, which could be explained by some refrigerant leakage. Further detailed investigations will be carried out to identify the reason for the deviation of the measured data and the data sheet.

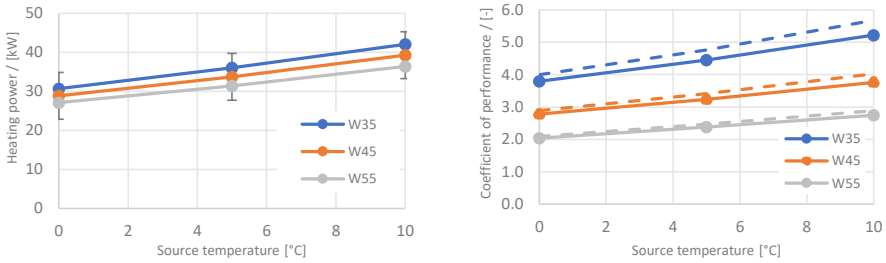


Fig. 11. Heating power for stage 2 (left) and COP for stage I and stage II (right) for the configuration with DSH in series to the condenser as in Fig. 5 (series configuration)

7.4. Dynamic Heat Pump Model DSH

The comparison of measured and simulated thermal power in condenser and desuperheater as well as electric power of the compressor(s) (bottom) is shown in Fig. 12 for a typical day in winter. The agreement is overall acceptable for all the three operation modes (heating stage I and II, DHW preparation stage II).

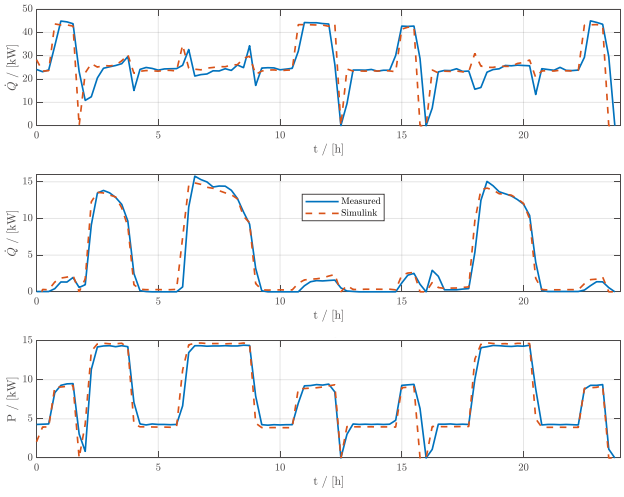

Fig. 12. Comparison of measured and simulated thermal power in condenser (top) and desuperheater (center) as well as electric power of the compressor(s) (bottom) for a typical day in winter

8. Discussion

The simulation assisted analysis of the monitoring results of the two buildings and of the HVAC system (including distribution losses, heat pump performance factors, auxiliary electricity demand, solar thermal and PV yield) allows to identify and solve problems that frequently occur during commissioning of the system. With the help of the simulation study, the control of the system can be optimized in order to reach the anticipated performance.

The net zero energy balance (for heating and DHW and auxiliary energies) could not be achieved during the first three years of monitoring. The implementation of first optimization measures shows a reduction of the demand. The performance of the HP is significantly lower than expected based on data sheet PM. There is a potential improvement of the performance by using the DSH loop, however, due to the high COP in heating mode in stage I that mode should be preferred. the following control scheme is recommended see Fig. 13. Optimal switching between single and double stage operation in heating mode is subject of current investigations.

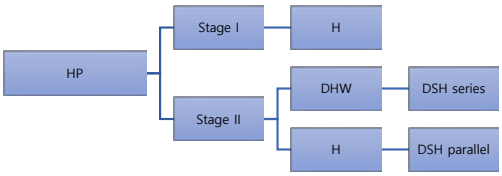

Fig. 13. Recommended operation modes: stage II in winter, stage I in intermediate season; (DSH in series in heating mode stage I)

Predictions based on results after introduction of improvements show that Net Zero could be achieved, see Fig. 14. In future projects more care should be taken in the appropriate dimensioning of the components (in particular heat pump capacity and storage volume) Passive House (PH) standard is key for achieving NZEB level for heating, DHW and aux. energies. If appliances was included in the energy balance, additional PV on the south façade would be required.

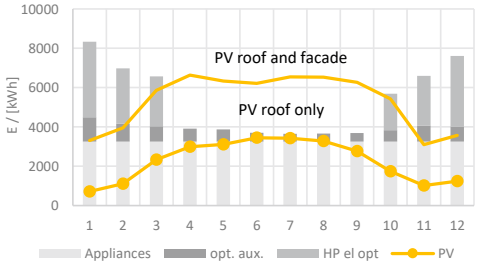

Fig. 14. Predicted monthly electric energy balance after improvements with appliances and with additional PV on the façade

A Simulink model of the HP was developed. The multi-dimensional PM model allows to simulate different HP operation strategies with and without DSH as well as single and double-stage operation. The optimization of both, the control strategy and of the components, is performed with the aim to operate the HVAC system with improved performance. Predictions show that the NZE can be achieved with improved control strategy and when the auxiliary energies are reduced.

9. Conclusions

Two multi-family buildings (MFB) with together 26 flats were designed to achieve a net Zero Energy (NZE) balance for heating, domestic hot water (DHW) preparation and all auxiliary energies. The roof of one of the MFB is covered by PV, the other is partly used for PV and partly for solar thermal (ST). A double-stage ground water heat pump (HP) with hot gas desuperheating (DSH) provides the remaining energy for heating and DHW. The system was designed with a low temperature distribution system (floor heating) and separate decentral fresh water preparation (DHW plate heat exchanger) for low thermal losses and optimal efficiency.
Detailed monitoring of the buildings, the HVAC system including thermal losses and the performance of the

HP, PV and ST allowed to study the behavior of NZEBs in practice. The simulation-assisted analysis of the monitoring data allowed to identify problems and faults of the installation and of the operation (i.e. control). Detailed performance maps of the double-stage HP pump with DSH were generated analyzing the monitoring data and by means of refrigerant cycle simulation. Simulation based optimization was performed with the aim to operate the HVAC system with improved performance. Different system configurations (i.e. with or without ST, with different buffer storage sizes, with different control strategies and set points) can be compared and evaluated also considering (seasonal) variations of the share of renewables (RE) in the electricity mix. Recommendations for the design and for the operation of the HP system (including control optimization) for MFB and blocks of buildings can be derived from the simulation results. It is evident that basic monitoring of the performance of the HVAC system is required to detect faults and to be able to guarantee efficient operation (quality control).

Numerical analysis of the vortex tube characteristics used within a high temperature heat pump

[a]Austrian Institute of Technology, Giefinggasse 2, 1210 Vienna, Austria

Abstract

The application of heat pumps in high temperature processes bears a high potential with respect to energy savings and reductions of greenhouse gas emissions. As heat pumps operating at high temperatures typically involve high refrigerant pressure levels, followed by high expansion work in the refrigerant cycle, an increase in energy efficiency can be achieved by recovering a part of that expansion energy. This paper investigates the applicability of vortex tubes as expansion devices in heat pumps. A vortex tube separates an incoming high-pressure stream into a cold and hot low-pressure stream, respectively. The flow field characteristics inside a vortex tube are investigated using state-of-the-art CFD tools. Two possible heat pump cycles utilizing a vortex tube are presented and evaluated using a one-dimensional model of a heat pump. It is shown that the applicability of a vortex tube as expansion device in a heat pump is limited due to several restricting factors. One promising configuration and application is identified and presented in detail, where the use of a vortex tube improves the COP by 19% over a standard heat pump.

Keywords: Ranque-Hilsch effect; Expansion work; Energy efficiency; CFD; 1D system simulation.

1. Introduction

In standard heat pumps, the expansion process takes place in an isenthalpic throttle valve. Replacing the throttle valve by a so-called Ranque-Hilsch vortex tube has been previously proposed e.g. by Nellis and Klein [1] and Sarkar [2]. A vortex tube, originally invented by Ranque in 1933 [3] and further refined by Hilsch [4], is a simple device with no moving parts, consisting of a tube, where a high-pressure fluid is injected tangentially through nozzles. The fluid develops a swirling flow pattern of high angular velocity, separating the fluid into a stream of high temperature fluid exiting on one axial end near the outer radius of the tube, and a stream of low temperature fluid exiting on the other axial end near the center of the tube. By controlling a valve at the hot end, the fraction of mass flow exiting at the cold side, $\gamma = \dot{m}_c/\dot{m}_i$, called the cold fraction, can be adjusted. In general, if γ increases, T_h increases, and T_c decreases for decreasing γ. At $\gamma = 0.5$, both the hot and cold temperature separation are equal.

Until today, this unique temperature separation effect, called the Ranque-Hilsch effect, is not entirely physically explained, although numerous investigations have been conducted. Hilsch [4] suggested that kinetic energy is transferred from the center to the outer part of the tube through internal friction, with shear work being the underlying mechanism of the temperature separation. Reynolds [5] identified heat and energy fluxes due to turbulent mixing as result of radial pressure and temperature gradients, buoyancy forces and Reynolds shear stresses as underlying physical processes. Ahlborn and Gordon [6] analyzed the vortex tube as a classical refrigeration cycle, identifying a primary loop at the outer radius of the tube as the coolant loop and a secondary

loop close to the center of the tube as refrigerant loop which performs heat rejection at the outer radius and energy absorption at the center.

Throughout the many investigations that have been conducted both experimentally and numerically on the vortex tube, the working fluid was mostly air. Very little research has been conducted on working fluids other than air. Balmer [7] experimentally analyzed the expansion of liquid water inside a vortex tube, concluding that for inlet pressures of 20 to 50 MPa, a temperature separation of 10 to 20 K is obtainable, notably with both outlet temperatures being higher than the inlet temperature. Although the necessary pressure lies two orders of magnitude above the pressures usually employed in a vortex tube operated with air, Balmer [7] concluded that the working fluid does not necessarily need to be compressible for a temperature separation to occur. Collins and Lovelace [8] performed experiments with two-phase propane inside a vortex tube. This study is especially interesting for the use of vortex tubes in refrigeration cycles, as propane is a common refrigerant and the expansion process in a standard heat pump occurs within the two-phase region. It was concluded in [8] that for inlet vapor qualities above 80%, a significant temperature separation can be obtained, but when the inlet vapor quality is further lowered, the Ranque-Hilsch effect vanishes rapidly.

Based on the research that has been done on the Ranque-Hilsch effect, it does not seem reasonable to replace the throttle valve of a heat pump cycle with a vortex tube, although this has been proposed earlier. The refrigerant entering the throttle valve is usually fully condensed liquid, and pressure levels in heat pumps are by far not sufficient for the Ranque-Hilsch effect to occur with a liquid as working fluid. Also, when two-phase refrigerant enters the vortex tube, e.g. by not fully condensing the fluid, the vapor quality would need to be very high. Therefore, it is concluded that when using a vortex tube inside a heat pump cycle, it must be assured that it is always operated with a fluid in fully gaseous (i.e. superheated) state. This has similarly been concluded previously by Mohiuddin and Elbel [9].

In order to assess different heat pump cycles and analyze possible COP-improvements, a CFD model of the vortex tube has been developed. In this way, the characteristics of the vortex tube under different refrigerants, geometries and operating conditions could be obtained and used for 1D-simulations of different heat pump configurations.

2. CFD Model

The flow inside the vortex tube is modeled as steady, three-dimensional, turbulent and compressible. Therefore, the three-dimensional Favre-averaged Navier-Stokes equations and continuity equation, together with an equation for the conservation of energy are used. The Reynolds stress tensor that comes up when time- (or Favre-) averaging the equations is modeled through the Boussinesq Assumption employing the Standard k-ε turbulence model, which was shown to predict the flow inside a vortex tube with sufficient accuracy, e.g. by Dutta et al. [10]. The model was used with scalable wall functions, making the solver always set $y^* \geq 11.225$ to ensure the first grid point is placed within the fully turbulent sub-layer even if the near-wall mesh is too fine. Viscous heating, i.e. the thermal energy created by viscous shear was included as previous research suggests this mechanism is important in vortex tube flows. Also, a compressibility correction in terms of a dilatation dissipation was included in the k-equation. The density of the fluid was modeled with the ideal gas law, with all material properties being constant except for the specific heat when performing simulations with refrigerants, where c_p was given linear temperature-dependency. To solve this set of equations, a pressure-based coupled solver was used, employing second-order upwind schemes for density, momentum and energy equations, first order upwind schemes for k- and ε-equations, and a second order scheme for pressure. Simulations have also been performed using the third-order MUSCL scheme, but did not show significant changes in the solution, and were therefore omitted for enhancing convergence.

A mesh consisting of tetrahedral cells, with refinements near walls, was used. A purely hexahedral mesh was also created but did not show changes in the solution. Mesh independence was ensured by running numerous simulations with meshes of different cell numbers, using the value of $\Delta T_{h,c} = T_{h,c} - T_i$ for judging mesh independence.

The inlets and outlets were defined as pressure-inlets and pressure-outlets. All walls were treated with a no-slip condition. To judge convergence, besides monitoring the scaled residuals, mass-averaged values of total temperature at both outlets of the vortex tube, T_h and T_c, and the cold fraction, γ, were monitored.

3. Flow pattern

3.1. Air

At first, the geometry used in the study of Skye et al. [11] was used, which is given in Table 1. The exact geometry could not be reproduced, as the dimensions of the hot outlet are unknown, as is the exact geometry of the inlet. The CFD model of [11] was two-dimensional, with a radial exit and a continuous annular inlet, and exhibited discrepancies between experimental and numerical pressure values. Hence also the experimental and CFD results of [11] differ.

Table 1. Vortex tube geometry:

symbol	description	value
L	working length	106 mm
D	tube diameter	11.4 mm
r_c	cold outlet radius	3.1 mm
A_i	total inlet area (6 nozzles)	8.2 mm^2

The working fluid was air, the inlet total pressure was kept at 483 kPa and the inlet total temperature was kept at 294 K. The cold outlet static pressure was kept at ambient pressure and the hot outlet pressure was varied to adjust γ. The results of these simulations are given in Figure 1, where the separation of the hot and cold exit temperatures from the inlet temperature, ΔT_h and ΔT_c, are plotted for varying cold fractions γ. Also, the results of [11] are plotted in Figure 1 for comparison. The obtained results match the CFD results of [11] quite well. It is noted that both the CFD model of this study and that of [11] underpredict the experimental values of ΔT_c. Nevertheless, the qualitative results are identical, exhibiting the same steepness of T-γ-dependency, with $\Delta T_h = \Delta T_c$ at $\gamma \approx 0.5$ and a larger overall temperature separation towards very high values of γ.

Figure 2 shows the profiles of tangential and axial velocity over the radius of the vortex tube at different axial locations. Figure 3 shows the radial profiles of total and static temperature at different axial locations. Both Figures match the velocity- and temperature-profiles produced by Behera et al. [12], suggesting that the physical processes inside the vortex tube are accurately modeled in the underlying CFD-model. In Figure 4, a contour plot of total temperature distribution over the vortex tube is given. Figure 5 shows a contour plot of density.

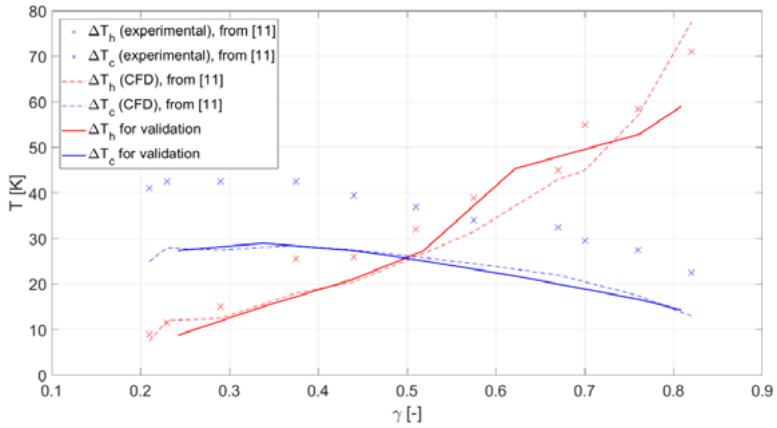

Fig. 1. Total temperature separation at hot and cold outlet as function of γ plotted against CFD and experimental results of [11]

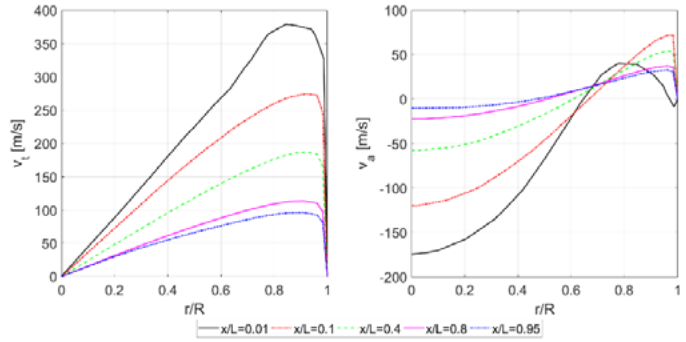

Fig. 2. Tangential (left) and axial (right) velocity profiles at different x/L-locations (air, $\gamma = 0.6$)

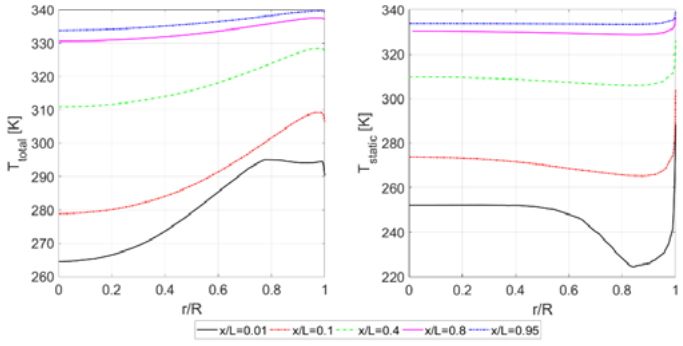

Fig. 3. Total (left) and static (right) temperature profiles at different x/L-locations (air, $\gamma = 0.6$)

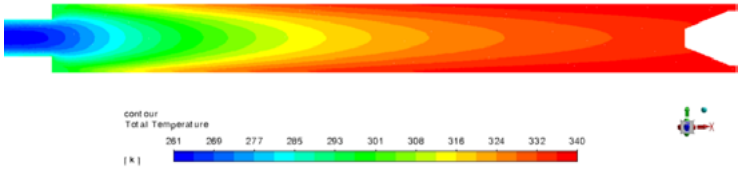

Fig. 4. Contour plot of total temperature throughout the vortex tube (air, $\gamma = 0.6$)

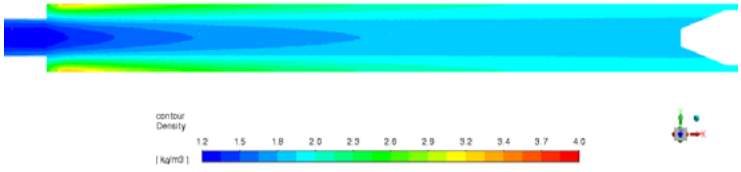

Fig. 5. Contour plot of density throughout the vortex tube (air, $\gamma = 0.6$)

3.2. Water

In order to investigate the flow of an incompressible fluid inside a vortex tube, simulations using liquid water as working fluid have been conducted. The same geometry was used as in the above simulation with air. The geometry is in its overall size comparable to that used by Balmer [7] for experiments with water, although the exact geometric specifications of [7] were not provided. The overall temperature separation obtained for an inlet pressure of 50 MPa was, depending on the cold fraction, around 10 K, with both T_h and T_c being above inlet temperature, which is congruent with the results of [7]. A contour plot of total temperature distribution throughout the vortex tube is provided in Figure 6. It is notable that with water as working fluid, the radial temperature gradient seems to be significantly lower than with air (compared to Figure 5), the temperature variation seems to be almost purely axial. Figure 7 shows tangential and axial velocity profiles and Figure 8 shows total and static temperature profiles at the same axial locations as in the above simulation with air. While the tangential velocity profiles exhibit a similar behavior, the maximum axial velocity at the center is, in contrast to the case with air, not found at $x/L = 0.01$, but at $x/L = 0.1$. Also, the axial velocities at the outer radius exhibit a sharper peak. For the temperature profiles shown in Figure 7 it is notable that while the static temperature profiles seem to be resembling that of the case with air, the total temperature profiles show much less change over the radius compared to Figure 3.

Generally, the flow patterns in terms of velocity and temperature distribution differ from the usual ones observed in vortex tubes operated with gaseous fluids. Another interesting observation is, that when viscous heating is excluded from the CFD model, a lower, yet still significant temperature separation occurs with air. Excluding the viscous heating term from the CFD model for calculations with water, however causes the temperature dissipation to fully vanish, i.e. no temperature gradient over the entire domain of the vortex tube can be observed. This shows that at least in the numerical model, thermal energy created by viscous shear is the only underlying physical process causing the temperature separation. As the results of the numerical analysis deliver similar results to the experimental study of Balmer [7], it is questionable if the Ranque-Hilsch effect is the reason for the temperature separation observed in [7]. The fact that with water both outlet temperatures are higher than the inlet temperature supports the theory that viscous shear is the main reason for this temperature separation.

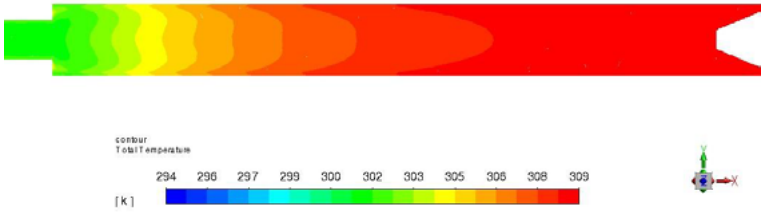

Fig. 6. Contour plot of total temperature throughout the vortex tube (water, $\gamma = 0.54$)

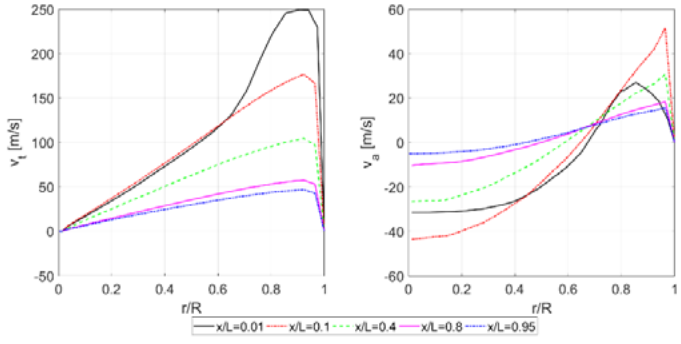

Fig. 7. Tangential (left) and axial (right) velocity profiles at different x/L-locations (water, $\gamma = 0.54$)

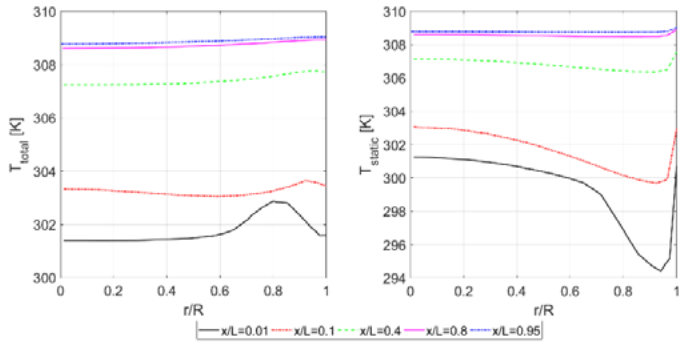

Fig. 8. Total (left) and static (right) temperature profiles at different x/L-locations (water, $\gamma = 0.54$)

3.3. Other Fluids

Simulations with other fluids, mainly natural and synthetic refrigerants, and helium have been conducted. It was noted that in general, the Ranque-Hilsch effect decreases with an increasing molar mass of the fluid. Therefore, helium, being the second lightest element, showed the largest temperature separation. For refrigerants, which generally have a higher molar mass than air, a smaller temperature separation was observed. Using helium as working fluid in a vapor compression cycle is however not feasible as even isentropic compression of helium involves very high temperature rises.

Apart from the molar mass, also thermal conductivity, viscosity and heat capacity ratio of a fluid have been reported to have a significant influence on the Ranque-Hilsch effect [13,14].

As the geometric specifications of the used vortex tube were derived from vortex tubes usually used with air, it is unclear whether a fundamentally different design could substantially improve the Ranque-Hilsch effect when employing a refrigerant. Also, as detailed studies of vortex tubes with refrigerants as working fluids where all geometric specifications and boundary conditions are given were unavailable, a validation of the CFD model for the use of other fluids than air was not possible. Hence, CFD results have to be treated with caution and should merely be used as initial probing to identify possible applications where further experimental investigations seem reasonable.

Figure 9 shows simulation results in terms of hot and cold exit total temperature separation from inlet total temperature for two different vortex tube geometries (different length-to-diameter ratio). The working fluid is R1336MZZ(Z), with an inlet pressure of 10 bar and a cold outlet pressure of 1.978 bar. It can be seen that a change in length-to-diameter ratio has a negligible effect on the temperature separation, and while the pressure ratio between inlet and cold outlet is comparable to that of the case with air (Figure 1), the magnitude of the temperature separation is significantly lower with R1336MZZ(Z) as working fluid.

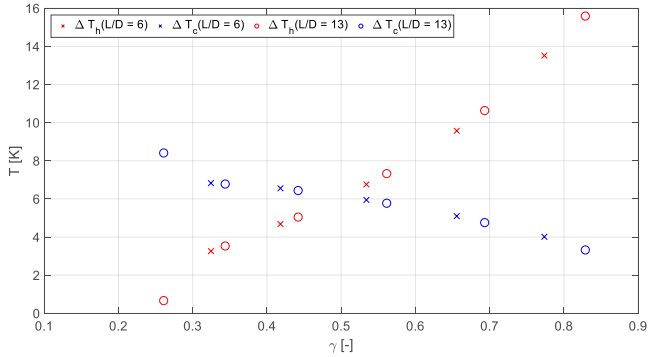

Fig. 9. Total temperature separation at hot and cold outlet as function of γ for two different geometries (R1336MZZ(Z))

4. Applications

Although vortex tubes have been investigated for almost one century by now, and find some specialized applications, there are still no heat pump or refrigeration cycles that make use of the Ranque-Hilsch effect. The focus of this investigation is set on high temperature applications as they are found in industrial steam generation. In Austria, steam generation accounts for 29 % of usable energy in industrial applications, with the majority of that energy being sourced from natural gas, bearing a large potential for the reduction of CO2 emissions [15]. However, to initiate a shift towards the use of (regeneratively sourced) electrical energy for steam generation calls for efficient means of heating. Two possible heat pump cycles for such applications making use of the Ranque-Hilsch effect are presented and discussed here.

4.1. Intermediate Expansion Heat Pump Cycle

When using a vortex tube for expansion in a heat pump cycle, the most promising cycle layout seems to be one introduced similarly by Mohiuddin and Elbel [9]. The schematic layout and log(p)-H-diagram is given in Figure 10. From state 1 to 3, the cycle is identical to that of a conventional heat pump. From state 3 to 4 the refrigerant is expanded to an intermediate pressure level, between that of condenser and evaporator, inside a throttle valve. Then, liquid (5a) and vapor (5b) are separated, with the vapor being fully expanded to evaporator pressure inside a vortex tube (6b/6c). The hot stream (6c) can then be used for further heating purposes, depending on the absolute temperature. The cold stream (6b) is internally recuperated and then mixed with the fully expanded (7a) and evaporated (8) remaining refrigerant.

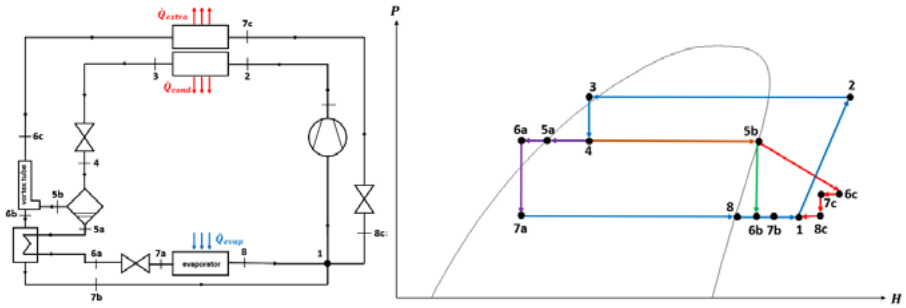

Fig. 10. Schematic cycle layout and theoretical log(p)-H-diagram (based on [9]) of a heat pump with vortex tube expansion

The COP-improvement of such a configuration when compared to a traditional heat pump is estimated by Mohiuddin and Elbel [9] to be around 5 to 10% over a conventional heat pump cycle. Choosing an adequate intermediate pressure level, p_{int}, is crucial for such a configuration, as with p_{int} decreasing, a greater amount of vapor can be utilized inside the vortex tube, but at the same time, the temperature separation effect inside the vortex tube decreases with decreasing inlet pressure. It seems intuitive that there must be an optimum. To estimate the location of this optimum for a given refrigerant, the analytical formulae for calculating the temperature separation inside a vortex tube that were developed by Ahlborn and Gordon [6] were used. These read:

$$\Pi_T = \frac{T_h}{T_c} \approx 1 + \frac{(\kappa-1)\zeta(\gamma+1)}{\kappa} \tag{1}$$

$$\zeta = \frac{p_i - p_c}{p_i + 2p_c} \tag{2}$$

where κ is the heat capacity ratio and p_i and p_c are inlet and cold outlet pressure, respectively. The temperature separation estimated by Eq. (1) is only a very rough estimate, derived using many assumptions, and not taking into account any geometric considerations. Nevertheless, even if the absolute value of Π_T is

far off the reality, its relative change with respect to pressure ratio is believed to show a qualitatively similar behavior to that of a real vortex tube, therefore not influencing the location of that optimum. Using the fact that at $\gamma = 0.5$ the hot and cold temperature separation are equal, absolute temperature values can be obtained:

$$T_h|_{\gamma=0.5} - T_i|_{\gamma=0.5} = T_i|_{\gamma=0.5} - T_c|_{\gamma=0.5} \quad (3)$$

$$T_h|_{\gamma=0.5} = \frac{2T_i|_{\gamma=0.5}}{1+1/\Pi_T} \quad (4)$$

Now, the quantity to be maximized is the difference of enthalpy flow rate between hot and cold outlet, as this quantity includes both the temperature separation, ΔT, that increases with increasing intermediate pressure level and the mass flow rate inside the vortex tube, $\dot{m}$, which decreases with increasing intermediate pressure:

$$\Delta\dot{H} = c_p \dot{m} \Delta T \rightarrow max \quad (5)$$

In Figure 11, $\Delta\dot{H}$ is plotted for a heat pump cycle with R600 as refrigerant, with a condenser pressure $p_{cond} = 26.63$ bar and evaporator pressure $p_{evap} = 6.864$ bar. It can be seen, that there is a clear optimum, below which the inlet pressure of the vortex tube is not high enough, and above which the vapor fraction entering the vortex tube is too low. In this case, the optimum intermediate pressure level is found at $p_{int} = 20$ bar. Any classical heat pump configuration can theoretically be modified in this way. The important question is in each case, if T_h is high enough to be usable with γ being low enough to for the hot end mass flow to be of significant amount.

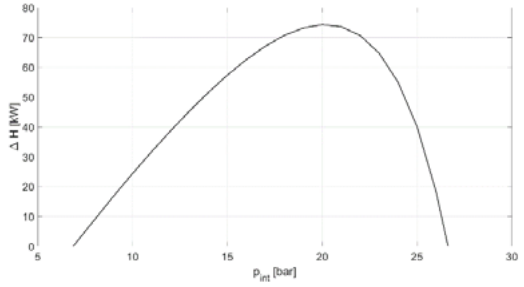

Fig. 11. $\Delta\dot{H}$ as function of p_{int} for R600 in a high temperature heat pump, calculated according to Eqs. (1)-(5)

Apart from maximizing the output of usable energy of the vortex tube itself via Eq. (5), it is at least equally important to tune T_h to a value at which the additional heat provided at the vortex tube's hot exit can be used.

4.2. Heat Boost Cycle

Another way to operate a vortex tube while ensuring the fluid entering the vortex tube remains purely gaseous is a heat boost cycle, which has also previously been suggested by Mohiuddin and Elbel [9]. A schematic layout of such a cycle is given in Figure 12. From state 1 to 2 liquid refrigerant is pumped to a high pressure, where it is then fully evaporated (state 3). From state 3 to 4a/4b, the gaseous refrigerant is expanded inside a vortex tube, using the superheated vapor at state 4a for steam generation.

The advantage of the combined vortex tube heat boost cycle is that the temperature level can be lifted without an increase in pressure. Also, for a given heat source at an already high temperature level, where

otherwise exergetically expensive resistive heating is employed for heat boosting, this configuration seems to be a reasonable alternative. On the other hand, only a small fraction of the overall refrigerant mass flow can be used for steam generation, as high hot end temperatures inside a vortex tube occur at high cold fractions.

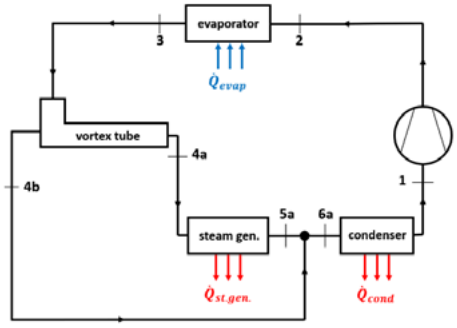

Fig. 12. Schematic cycle layout of a standard vortex tube heat boost cycle with vortex tube

5. Results

A one-dimensional system simulation model for the intermediate expansion cycle (based on the schematic layout presented in Figure 10) was developed as shown in Figure 13. By using the results generated from the CFD model of the vortex tube for different operating conditions and refrigerants to model the vortex tube within these 1D-system simulations, different applications in terms of temperature- and pressure levels, refrigerants and mass flow rates were evaluated. The CFD results of the vortex tube were incorporated in the 1D-model as a lookup-table containing data for several operating conditions. The aim of these system simulations was to identify applications and refrigerants for which the use of vortex tube expansion is promising in terms of COP-improvement.

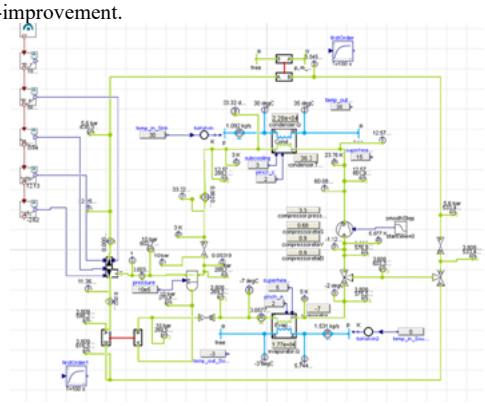

Fig. 13. System simulation model of an intermediate expansion heat pump cycle

As presumed from the findings in Section 4, the intermediate expansion cycle was found to outperform a conventional heat pump cycle in the presence of the following two circumstances:

- A high difference in condenser and evaporator pressure is present, allowing for a relatively low level of intermediate expansion pressure while still maintaining a high enough inlet pressure at the vortex tube.

- The refrigerant exhibits a relatively flat saturation line, yielding a high vapor quality at intermediate expansion pressure level.

Of the conducted simulations, the most promising in terms of COP – improvement was a heat pump cycle aimed at industrial applications where a waste heat source at 70 °C was used to provide heat for steam generation at 160 °C with R1336MZZ(Z) as refrigerant. As a high temperature lift is needed, the difference in condenser and evaporator pressure is high, which in combination with the properties of the refrigerant leads to a significant vapor quality after intermediate expansion. In Figure 14, the log(p)-H-diagrams of both the conventional heat pump cycle and the corresponding intermediate expansion cycle are given, with the hot exit stream of the vortex tube marked in red and the cold exit stream of the vortex tube marked in orange. As can be seen, the separation at intermediate pressure level, combined with the non-isenthalpic expansion in a vortex tube leads to an increased condenser and evaporator heat flow. The COP of the intermediate expansion heat pump cycle was shown to be 19 % higher than that of a conventional heat pump for the same application. The additional heat provided by the hot exhaust of the vortex tube was not used for COP calculations as it is highly case-dependent whether a heat sink exists where this heat can be utilized. Therefore, if demand for additional heat at the temperature level of the vortex tube's hot exit is needed, the COP might increase further.

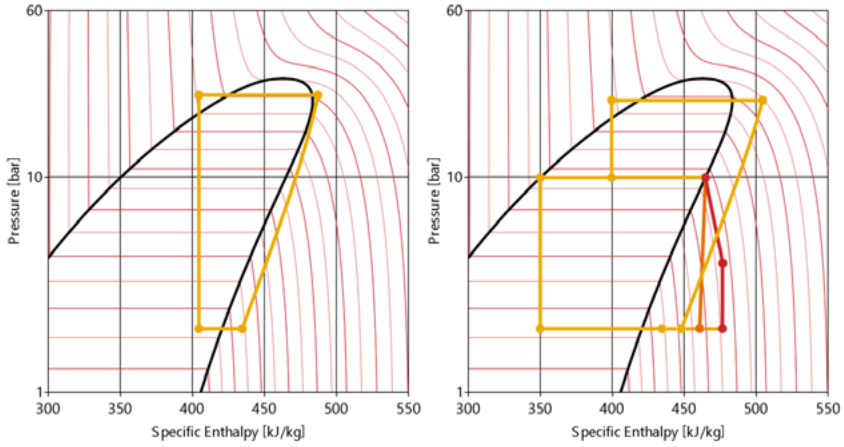

Fig. 14. Log(p)-H-diagrams of conventional (left) and intermediate expansion (right) heat pump cycle for steam generation with R1336MZZ(Z) (result of one-dimensional simulation using results of CFD simulations of a vortex tube)

6. Conclusions

- Although vortex tubes can be operated with liquid working fluids at sufficient inlet pressure, it is not obvious that the underlying physical processes are the same as within vortex tubes operated with gas. The numerical analysis presented here strongly suggests that it is not the same effect that causes energy separation within a vortex tube when operated with liquid as with gas.
- When designing heat pump configurations that involve expansion inside a vortex tube, it is concluded crucial that the fluid remains in gaseous state inside the vortex tube. Two such cycle layouts are presented.
- From the results of CFD simulations it is observed that the Ranque-Hilsch effect decreases when using refrigerants as working fluids. This is believed to partly stem from the higher molecular weight of refrigerants compared to air.
- One of the two presented heat pump configurations, the intermediate expansion heat pump cycle, was simulated and compared to a conventional heat pump cycle. It was found that while for many applications the COP-improvement is negligible, there are cases where vortex tube expansion from an intermediate pressure level can significantly improve the COP. One such cycle aimed at

industrial steam generation using R1336MZZ(Z) as refrigerant is presented and shows a COP improvement of 19 % over a conventional heat pump.
- By identifying promising cases for further investigation using the tools presented in this study - namely a detailed three-dimensional CFD simulation of the vortex tube, combined with a one-dimensional analysis of the heat pump cycle - a foundation for further experimental investigations can be established.

Abstract

Heat pumps are a key technology in Germany's energy system transformation process for achieving the federal government's environmental goals. A crucial factor, increasing heat pump's comfort, is its acoustics. Air-to-water-heat pumps need a compressor and a fan to operate efficiently. Both components have sound emissions that can be disturbing regarding humans' psychoacoustics. Thus, it is necessary to develop energy efficient and quiet heat pumps.

Within this work, we show that it is possible to estimate energetic and acoustic performance of heat pumps in dynamic simulation models simultaneously. Therefore, we link the Sound Source Extension Library to a dynamic heat pump simulation model, designed using the AixLib. The acoustic signatures of compressor and fan are coupled to their corresponding rotational speeds. Furthermore, we apply an Extremum Seeking Controller to operate the heat pump in an energy-acoustic optimum mode, which is specified by a predefined target function. By consequently optimizing the evaporator fan speed, we are able to reduce overall acoustic emission of the simulated heat pump by about 8 dB(A) while increasing its energy efficiency by about 4 %.

1. Introduction

Within Germany's energy transition process, air-to-water heat pumps are a promising technology in order to replace conventional heating systems in the building stock. To accelerate the replacement process, there is an urgent need to improve their energy efficiency and user comfort. The coefficient of performance (*COP*) is a common measure to estimate heat pump's energy efficiency. Many studies investigate the influence of used refrigerant and building's temperature levels on the *COP*. Almost all of these studies aim for a *COP* maximization by optimizing either design or operation. Simultaneously, an increasing issue related to user comfort is heat pump's noise emissions. With regard to the A-weighted acoustic emissions, the fan and compressor of an air-to-water heat pump are the main sources of noise. According to Graf [1], the evaporator fan causes 90% of the noise perceived in the neighborhood. Reducing fan's noise emission by optimal design and operation implies a great potential to increase heat pump's user comfort. Apparently, both measures depend on component design and operation. However, energy efficient design and noise emission reduced design are contrary. The same applies for energy efficient and noise emission reduced operation. Since many design studies already exist, we focus on operation optimization within this work.

On the one hand, energy efficient operation studies discuss different heat pump control approaches. These commonly differ between rule-based-control (RBC), extremum seeking control (ESC) and model predictive control (MPC). Compared to conventional control approaches, MPC shows greatest potentials in order to

* Corresponding author. Tel.: +49 241 80 49 786; fax: +49 241 80 49 769.

increase energy efficiency. Nonetheless, expert system understanding is necessary to set up a MPC. ESC, in contrary, is easy to implement, as it is a model-free method.

On the other hand, there are two approaches reducing noise emissions. The primary measures include the acoustic optimization of the components or the acoustic optimization of the operating point. Secondary measures decrease sound radiation indirectly through silencers and sound insulation capsules. This work focuses on the acoustic optimization of the operating point. Manufacturers have implemented measures, to reduce the sound emission of the heat pump during night, by changing speeds of fan and/or compressor. This procedure is normally done solely based on time of day, which is set by the installer or user. The mode is called differently ranging from "silent" to "quiet" mode of operation.

However, a simultaneous operation optimization of energy efficiency and noise emission reduction was not identified in the literature, yet. Therefore, we introduce an approach that concurrently takes energetic and acoustic optimal operation (EAO) into account. According to Burns and Laughman [2], it is possible to provide a constant cooling capacity at different compressor and fan speeds. These combinations imply different energy efficiencies as well as noise emissions. Using multi-objective optimization, we can determine the trade-off between energetic and acoustic optimal operation.

Therefore, this work contributes to the EAO operation of heat pumps:

- Chapter 2 gives an overview on the literature regarding energy efficient operation as well as acoustic signatures of heat pumps. Furthermore, we introduce the basics of ESC.
- In Chapter 3 we describe the energetic simulation model. In addition, we show the acoustic data and how it was measured. Lastly, we describe the coupling approach of both models and apply it to ESC.
- We apply ESC to our model in order to simultaneously optimize acoustic emission and energetic efficiency in Chapter 4.
- Chapter 5 discusses results conducted before.
- We summarize our findings and give an outlook in Chapter 6.

2. State of the Art

In order to replace conventional heating technologies such as gas- or oil-fired boilers heat pumps need to be improved economically, ecologically and user-friendly. Therefore, increasing their energy efficiency and decreasing their noise emissions have an integrated potential to accelerate the replacement process.

2.1. Energetic assessment of heat pump systems

A common instantaneous thermodynamic measure for heat pump's energy efficiency is its *COP*. The *COP* is described as the quotient of heat extracted from the condenser $\dot{Q}_{\mathrm{Cond}}$ divided by the power to drive the compressor P_{Comp}:

$$COP = \frac{\dot{Q}_{\mathrm{Cond}}}{P_{\mathrm{Comp}}}. \tag{1}$$

Different studies use the *COP* as target function to determine the heat pump with highest efficiency according to different refrigerants or operating points. Using this target function an optimization program maximizes the condenser heat $\dot{Q}_{\mathrm{Cond}}$ and minimizes the compressor power P_{Comp}.

In order to introduce a simultaneous approach to optimize energetics and acoustics, the fan power has to be taken into account as well. Therefore, we introduce the system's coefficient of performance:

$$COP_{Sys} = \frac{\dot{Q}_{\mathrm{Cond}}}{P_{\mathrm{Comp}}+P_{\mathrm{Fan}}}, \tag{2}$$

which sums up the power consumption of the fan P_{Fan} in the denominator. This consideration allows an energetic assessment of both noise sources.

Considering the heat pump as a heat supply system, however, implies that the building's heat demand is fixed. As consequence, a heat pump system has to deliver a fixed amount of heat at a minimized sum of compressor power and fan power. Since we have no heat pump prototype yet, we assess the potential of EAO in a realistic simulation study. Conducting simulation studies requires an energetic heat pump model.

In the literature, many modelling approaches of heat pumps are widely discussed. Typically, approaches distinguish between black box, grey box and white box modelling. On the one hand, black box approaches allow a fast calculation of heat pump's behavior within a certain validated scope. Results from physical extrapolations, however, are restricted applicable.

On the other hand, white box models emulate real physical system with its geometrics. Therefore, complete understanding of the system is necessary. This modelling approach reveals the advantage of perfect system behavior estimation. In contrary, calculation speed is often very low.

A trade-off between both black box and white box approach is called grey box approach. It bases on physical equations to estimate its behavior and simplifies equations at some points by mathematical descriptions. Hence, we apply a grey box approach to estimate the physical behavior of the heat pump at reasonable simulation speed. In addition, we need information about the component's acoustic signature itself in order to determine their acoustic behavior.

2.2. Acoustic signature of heat pumps

Acoustic emissions of heat pumps can be retrieved using a variety of methods. For certification purposes – depending on the acoustic characteristics of the climate chamber - sound intensity measurements using scanning techniques or sound power measurements with a number of microphones distributed in the climate chamber are performed. According to the standards – in the end – one value for the sound power level will be given on the label for the standard operating point. This also means, that the transient behavior of the sound emission, the directivity of the sound emission and the effect of operating the heat pump at different conditions is not covered. For the measurements, which are the base for the simulations presented here, an acoustic dome with 61 microphones was used to record the acoustic sound pressure level at positions surrounding the heat pump as a function of time (see Figure 1). The data can then be used to calculate the transient A-weighted sound power level.

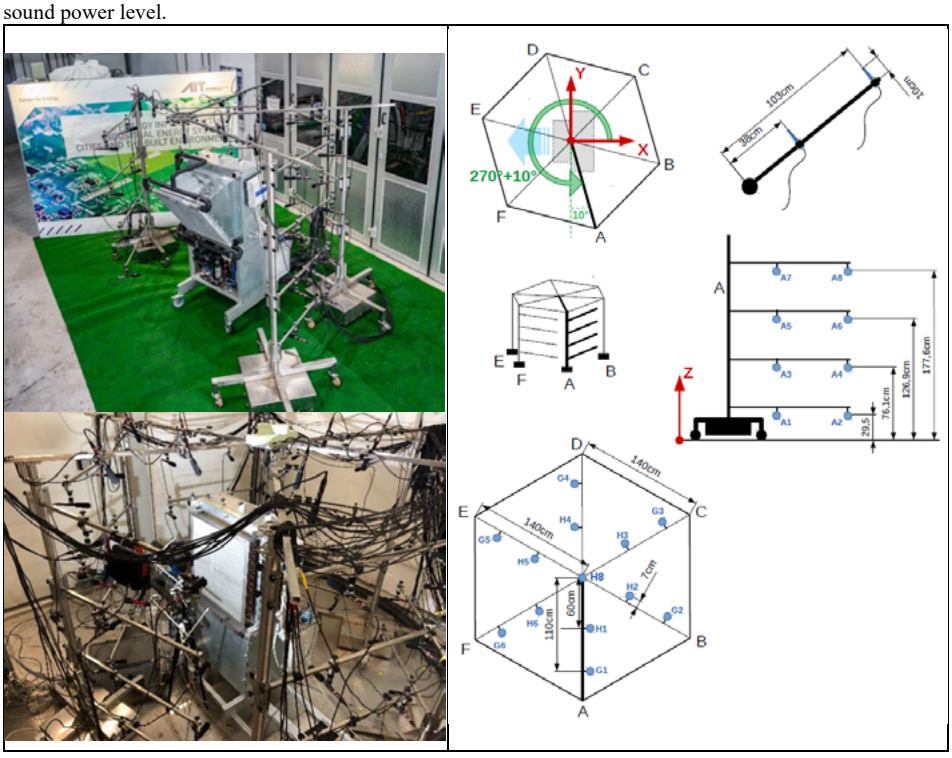

Fig. 1: Presentation image of a part of the acoustic dome around the SilentAirHP (top, left), which has been used to generate the data and SilentAirHP (bottom) in the climate chamber at AIT surrounded by the acoustic dome during frosting experiments; Geometrical setup of the acoustic dome. 48 microphones are placed on the sides, 13 microphones above the heat pump (right).

In order to simultaneously optimize heat pump's energetics and its acoustics, an optimization procedure is necessary. In this work, we therefore apply a model-free, adaptive Extremum Seeking Controller.

2.3. Extremum Seeking Control (ESC) applied to heat pumps

Common adaptive control methods, the two linear and non-linear, aim to control the output of a process to a known set point or a reference trajectory. The aim of ESC, however, is to find a manipulated variable, so that the variable to be controlled is kept at a minimum or maximum [3]. The manipulated variable is therefore disturbed periodically by a perturbation signal. This results in an oscillation of the system output. By determining the gradient between the manipulated variable and the system output, the manipulated variable can be modified so that the system output is optimized. Applying ESC, in addition to a target function t an amplification factor K and the parameters of the gradient estimator, must be determined.

In contrast to MPC, this is a model-free procedure. For the application of ESC in real processes, no model of the controlled system must exist. The method was already used in the 1950s [4] and has gained in importance due to the stability proofs of Krstic and Wang [5] in 2000. In the last 10 years, ESC has established itself as a promising control strategy for energy optimization of HVAC devices [6, 7]. In the Literature, simulation studies exist in which ESCs are tested on simulation models as well as studies in which it was implemented on test benches.

Burns and Laughman [2] applied ESC with conventional gradient estimation for the first time to a chiller in 2012. They investigated the fan's influence on the electrical power consumption of the entire plant. The temperature was kept constant by controlling the compressor speed. They were able to determine that at a constant cooling capacity different, equivalent combinations of compressor speed and fan speed exist. The electrical power consumption of the system was reduced from 700 W to 450 W by ESC. This corresponds to an improvement in the COP from 2.9 to 4.4. In their experiment, the nominal fan speed was almost doubled, and the compressor speed was reduced to the minimum frequency of 35 Hz. After activation, the algorithm took about two hours to reach the optimum.

Koeln and Alleyne [8] implemented ESC with classical gradient estimation in 2014. They investigated the influence of the expansion valve opening on subcooling. For cost reasons, the installation of a pressure sensor at the compressor outlet often is renounced. Subcooling is therefore unknown and cannot be controlled. The authors used ESC to find an optimal expansion valve opening for COP-optimal subcooling. They improved the COP by 9 %. The algorithm took three hours to reach the optimum.

The work of Xiao et al [9] deals with a multivariable ESC. By simultaneously optimizing the speeds of the evaporator's and condenser's fan of an air-to-air heat pump, the power consumption was reduced from 625 W to 325 W.

Burns et al. [10] developed a gradient estimator based on a recursive-least-square estimator. Thereby they were able to reduce convergence time by a time scale. They investigated the influence of the temperature at the compressor outlet on the electrical power consumption. By using ESC to determine the optimum target value for the outlet temperature, they were able to reduce the power consumption from 535 W to 450 W. This corresponds to a 14% improvement in COP. In subsequent work by Burns et al. [11] in 2018, the performance of ESC was further improved and the convergence time was reduced to 50 minutes in an experiment.

The literature review shows that a great potential exists to optimize HVAC systems using ESC. A contribution that simultaneously optimizes energetics and acoustics of heat pumps was not identified, yet. Therefore, we show in Chapter 3 the methodology to apply ESC in order to optimize heat pump's energy efficiency and its acoustics during operation.

3. Dynamic modeling of a vapor compression system

Since we have no prototype of a heat pump at our institute, yet, we firstly set up two heat pump models: one for its energetic and one for its acoustic behavior. In a second step, we connect both models. Therefore, we link the compressor's and fan's noise emissions according to their rotational speeds. Lastly, we define the target function and apply ESC to our simulative prototype.

3.1. Energetic Modeling of Vapor Compression System

Regarding the trade-off between accuracy and simulation speed, we choose a grey box approach to model our system's components. The used components are taken from the Aixlib [12], an open-source Modelica library. Therefore, we use following approaches to model all components.

Based on efficiency correlations, the compressor model is validated against measurement data. We use energy and mass balances according to state changes based on these efficiency correlations. We apply the same approach to model the expansion valve. The heat exchangers are modeled using the Epsilon-NTU method. At

the evaporator air-side, we implemented an additional Nusselt correlation to model the behavior of heat transfer as a function of air velocity. Applying energy conversion and mass continuity, air velocity is cubic proportional to the fan power.
A simple PI-controller controls heat pump's supply temperature by adjusting compressor's speed. Another one keeps a constant level of superheated vapor at the evaporator outlet by controlling expansion valve's opening.

3.2. Coupling acoustic measurement data to dynamic energetic simulation model

Using a highly symmetric hexagonal setup, 61 microphones are surrounding the heat pump (see Figure 1, right). The microphones are calibrated with a 94 dB calibrator operating at 1000 Hz. Sound pressure levels are continuously recorded and later analyzed using Fast Fourier Transformation FFT techniques to be able to access the A-weighted sound power levels as a function of time.

The SilentAirHP is an experimental air-to-water heat pump which was designed to provide a heating power of 5 kW at a heating water temperature of 35 °C at an ambient air temperature of 2 °C. The refrigerant R410A was used and the entire heat pump was located inside the AIT climatic chambers during the measurements. Inside the chamber, the temperature and the humidity could be defined and kept constant. The heating water was cooled with the in-house chilled water reservoir guaranteeing a sufficient heat transfer from the condenser, whereby the back flow of the heating water was regulated to 30 °C. The compressor was operated with a controllable rotational speed (a speed of 98Hz corresponds to a 5 kW heating power at 2 °C outdoor temperature and 35 °C warm-water temperature). An internal controller, which uses the superheating of the refrigerant as reference variable controlled the degree of opening of the expansion valve. The superheating was always set to 7 °C during the experiments.

Typical experiments at a given operating point yield the transient sound power level together with the transient thermodynamic parameters of the climate chamber and the heat pump (see Figure 2).

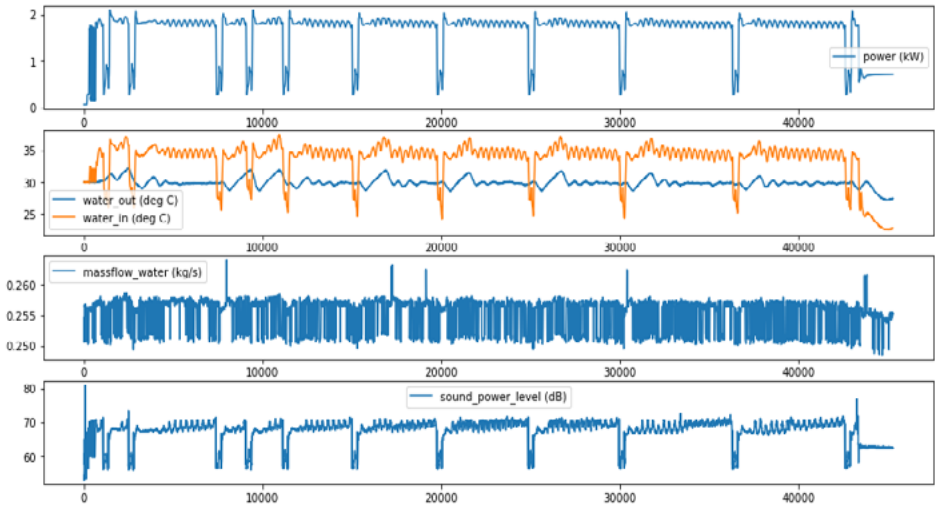

Fig. 2: Transient thermodynamic and acoustic data during a typical experiment. These measurements results are the basis of the following implementation.

In order to use these experimental sound power level results as basis for ESC, we re-write them according to their dependency of fan speed and index of third octave band. This allows us to couple the presented energetic model to its acoustic signature at a rotational speed. Additionally, increasing simulation speed, we use a fitting procedure to describe the dependency of sound power level on the rotational speed at a certain octave band. The fitting procedure increases calculation speed at an accuracy of $RMSE = 0.66$, which is within measurement uncertainty.

Using the AIT's Sound Source Extension Library (SSELib) [13], the energetic model can be extended by an acoustic interface. The library has components that can be used to determine the propagation of sound in air, the effects of silencers and the location. In addition, several sound sources can be superimposed. In order

to couple acoustic measurement data with an energetic simulation model, the acoustic signature is correlated with the rotational speed of the respective component.

This coupling of energetics and acoustics enables us to underline the conflict between energy efficiency and sound emissions. Regarding a common operating point at an air temperature of 7 °C and a water temperature of 50 °C (short: A7W50), our model is now able to calculate its energetic and acoustic performance, which are shown in Figure 3. According to a fixed heat demand as discussed in Chapter 2 and in Burns and Laughman [2], there are many combinations of compressor speed and fan speed to match the demand. By increasing the fan speed at a constant heat demand, the heat transfered from the ambient to the refrigerant increases so that compressor speed can decrease. In addition, this causes an increase in *COP* (blue dashed line). Applying systems *COP* (blue line) one can observe an increase to a certain maximum. After that the system *COP* decreases again. This means up to this maximum the power consumption of the fan increases more than the power consumption of the compressor decreases. The maximum is the energetic maximum in this operating point.

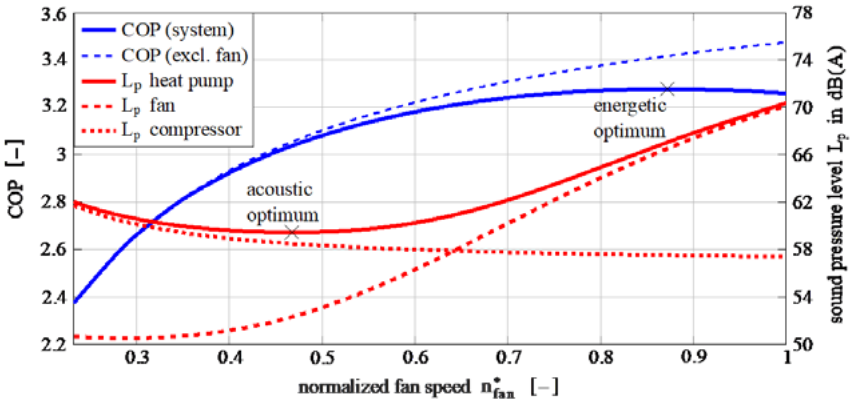

Fig. 3: The conflict of objectives between energetic efficiency and acoustic emissions of an air-to-water heat pump. The heat pump control provides constant heating output and a superheat of 5K. Above a threshold value, the increase in electrical power of the fan is greater than the resulting decrease in electrical power of the compressor. This point represents the energetic optimum of the system. The varying speeds of compressor and fan result in different acoustic emissions of the components. The noise level of a heat pump (compact design) is determined by the logarithmic addition of the compressor and fan emissions. For this operating point (A7W50), the acoustic optimum is at lower fan speeds compared to the energetic optimum.

The varying speeds of compressor and fan lead to different acoustic emissions of the heat pump as well. An increase in the fan speed leads to an increase in the sound pressure level caused by the fan. The effect of the compressor is the opposite: as the fan speed increases, the compressor speed and thus, also the emitted noise decreases. Both sound sources were added logarithmically. Since the components were measured individually and under the same structural conditions, this is permissible. Due to the acoustic dominance of the fan, the acoustic optimum lies at lower fan speeds. The simulation study shows that the operating points for the acoustic and energetic optimum do not coincide, resulting in a conflict of objectives.

Furthermore, the Figure shows a Pareto effect between energy efficiency and acoustic emission: A comparatively small deviation from the energetic optimum results in a disproportionately reduction of sound emission. For a normalized speed of n^*_{Fan} = 0.7, the coefficient of performance of the system is reduced from $COP_{Sys,energ.}$ = 3.27 to COP_{Sys} = 3.23. This means a reduction in energy efficiency by 1.22 %. The acoustic emission drops from $L_{p,energ.}$ = 67.24 dB(A) to L_p = 62.2 dB(A). Thus, by reducing the system efficiency by 1.22 %, the noise level emission can be reduced by ΔL_p = 5.04 dB(A). This Pareto effect is used in the following sections to achieve EAO.

The respective optima are strongly dependent on the ambient temperature and the heat demand. This results in the optima shifting during heat pump operation. In order to solve the conflict of objectives, a real-time-capable, adaptive optimization algorithm must therefore be selected. In addition, the procedure should be easy to implement and operate without complex measurement technology in order to enable economical application in new heat pump systems. One possibility is MPC. However, this technology has very high requirements on model accuracy and model speed, which makes practical implementation more difficult [14]. For this reason, research on model-free adaptive optimizers has intensified in recent years. This includes ESC, the suitability of which to solve the described conflict of objectives is examined in the following.

3.3. Extremum Seeking Control Design

In order to apply ESC, it is important to define a gradient estimator and an objective function. In our case, we use a simple benchmark model to identify the gradient estimator that fits best. Common gradient estimators are a combination of high-pass and low-pass filter (simple perturbation PB), a recursive-least-square method (RLS) and a Kalman filter (Kalman).

Former researches showed the functionality of a gradient estimator using a simple so called Hammerschmidt model [10]. Using this model, they were able to benchmark different gradient estimators.

The results of the three ESCs are shown in Figure 4. Models are started with a constant value of u = 2. After 100 s, ESC is activated and all ESCs converge to the optimum at y* = 1. The curves of the RLS-ESC and PB-ESC correspond to the literature [10]. The control signal u of the PB-ESC oscillates strongly according to its parameterization. This results in the oscillation of the output signal y. The control signals of the RLS-ESC and the Kalman-ESC also oscillate. Due to the lower magnitude of their amplitudes, this is not visible in the Figure. The PB-ESC converges after 470 s (not shown in the Figure), whereas RLS-ESC and Kalman-ESC show similar convergence times about 35 s. Concluding this test, we use the Kalman filter as the gradient estimator in the following simulation studies.

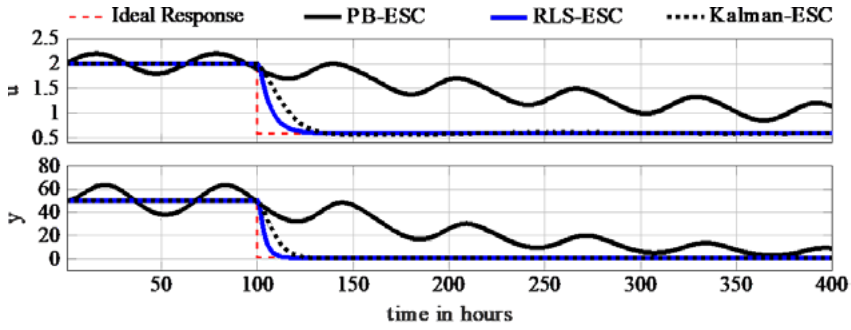

Fig. 1 Graph of the manipulated variable u and output variable y with ESC on a Hammerstein model. PB-ESC has a significantly slower convergence time than RLS-ESC and Kalman-ESC. RLS-ESC and Kalman-ESC show simuliar performances with convergence times about 35 s.

Additionally, ESC requires an objective function to be implemented. In order to consider the compromise between energetic efficiency and acoustic emission in the simulation model, a corresponding objective function is defined (Equation 3). The *COP* is not suitable to evaluate the energetic efficiency of the heat pump, as the transferred heat output at the condenser must be determined for this purpose. The flow temperatures and the mass flow of water must be known (or alternatively the condensation temperature and the mass flow of the refrigerant) respectively. Measuring the mass flow is particularly complex and therefore expensive. With respect to our optimization problem, electrical power data of compressor and fan, on the other hand, have the same informational content to implement the target function. In addition, the electrical power of both can easily be measured or recorded without great effort, which makes this approach favourable. Therefore, the minimization of compressor's and fan's power consumption defines the first part of the objective function. The acoustic emission of the heat pump is specified by the sound pressure level and depends on the design. We distinguish design between compact and split design as it is common in air-to-water heat pumps. Regarding both, the target function (TF) is defined as follows:

$$TF = \min a \underbrace{\frac{\sum_i P_{\mathrm{el,i}}}{\sum_i P_{\mathrm{el,max,i}}}}_{\text{Energetic}} + (1-a) \underbrace{\frac{\sum_i L_{\mathrm{p,i}}}{\sum_i L_{\mathrm{p,max,i}}}}_{\text{Acoustic}} \tag{3}$$

The left term contains the energetic evaluation of the current operating point and the right term contains the acoustic information. The terms are normalized with their maximum values for comparability. With the parameter a, which assumes values between zero and one, the operating point to be controlled can now be specified:

- a = 1: Energy-optimal operating point
- a = 0: Acoustically optimal operating point

Setting a = 1, the ESC will converge to the energy-optimal solution, while for a = 0, the quietest operating point is set. For values 0 < a < 1, a continuous weighting between energy-optimal and acoustically-optimal operating point is possible.

In general, objective functions for ESC need to be convex to ensure optimization. Figure 5 shows the objective functions for split and compact design. Compact design (left) is composed of the acoustic emission of compressor and fan. The acoustic emissions of the split design (right) are determined solely by the fan. Obviously, both are convex, since the terms used to describe energetics and acoustics are convex as well.

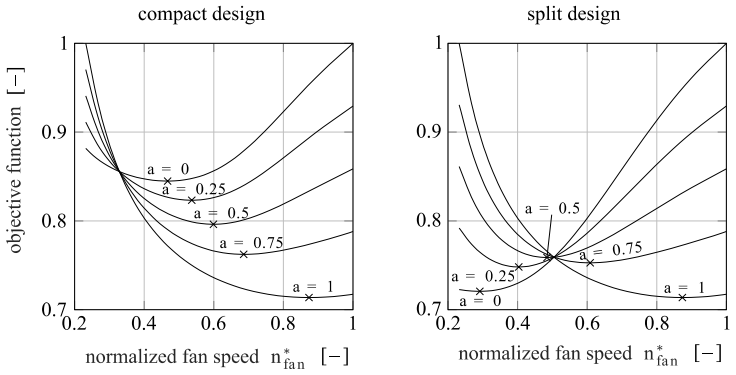

Fig. 5 The target function of the ESC at A7W50. With parameter “a”, a continuous trade-off between energy-optimal (a = 1) and acoustically-optimal operation (a=0) can be achieved.

4. **Simulation Study**

Applying ESC to our heat pump model, we use two setups. First use a fixed condition setup to evaluate the functionality of ESC. Therefore, we choose the operating point A7W50 as it was discussed in Chapter 3 as well. After proving functionality, we discuss a use case with realistic and highly dynamic boundary conditions.

4.1. Fixed Condition

First, the general functionality of the ESC is to be tested using Kalman-filter as a gradient estimator. For a constant operating point (A7W50), the models are initialized with constant fan speed. After 200 s ESC is activated with different values of EAO factor “a”. In addition, the manipulated variable n^*_{Fan} is perturbed with a square wave oscillation with an amplitude of A = 0.02 and a frequency of f = 0.06. The frequency of the oscillation is set to 0.06. The frequency of the square wave oscillation is set to 0.02. The amplification factor K is set to K = -0.0075.

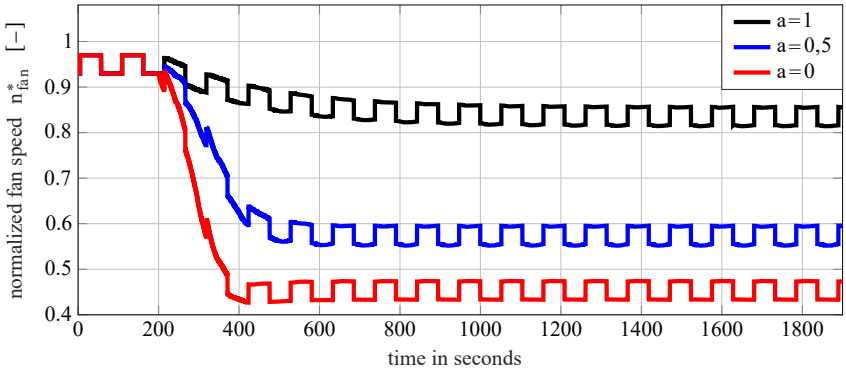

Fig. 6 Kalman-ESC with different values for parameter “a” at A7W50 and compact design. ESC is activated after 200 seconds and the steady-state values correspond to the optima in Figure 5.

According to Figure 6 energetic optimal control (a=1) fits to the corresponding energetic optimum at $n^*_{Fan} = 0.873$ resulting in a *COP* =3.27 and L_p=67.1 dB(A). Setting a=0 (acoustic optimal control), ESC finds the acoustic optimum at $n^*_{Fan} = 0.467$ with *COP*=3.04 and L_p=59.46 dB(A). In between, setting a=0.5, EAO is determined by ESC to be at $n^*_{Fan} = 0.598$ resulting in a *COP* = 3.19 and L_p=60.2 dB(A). All in all, this Figure shows a successful implementation of ESC to enable EAO.

4.2. Realistic Condition

After the basic functionality of ESC has been demonstrated, the acoustic and energetic effects for a realistic 24-hour operation will be quantified. The heat demand which is to be covered by the heat pump is shown in the Figure below (Figure 7). The ambient temperature varies between 2°C and 6°C. The maximum flow temperature is 58 °C.

Three scenarios are compared with each other for this purpose. First, the ESC is deactivated and the fan speed is set to nominal fan speed (1000 rpm). For the other two scenarios, the ESC is activated and the parameter "a" is set to constant a=1 in one scenario. This results in energy-optimal operating points. At last, the parameter "a" is varied depending on the time of day. Therefore, this day is split in three parts. At night (10 pm to 6 am), we define a silent mode at a=0.4. In the morning (6 am to 8 am) and in the evening (8 pm to 10 pm) we increase energy efficiency by setting a=0.8. At the rest of the day (8 am – 8 pm) we set a=1. The results of ESC are shown in Figure 7.

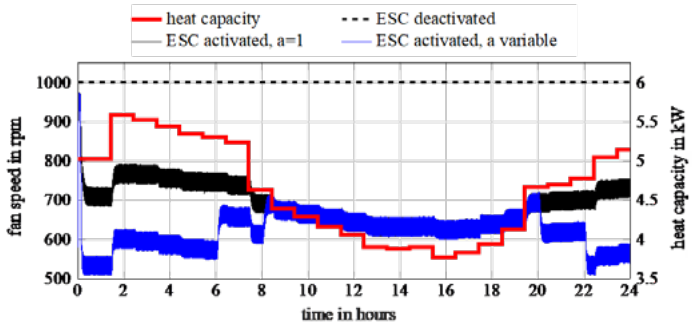

Fig. 7 ESC at variable operating conditions (24-hour heat demand profile). Fan speed curves for three different scenarios: Constant nominal fan speed (black, dashed), active ESC with constant a = 1 (blue), active ESC with daytime-dependent values for parameter "a".

When ESC is active, the fan speed is always significantly lower than the nominal speed. For scenario 3, the fan speed is lower in the morning, in the evening and at night than in the energy-optimal scenario. During the day (8 am to 8 pm), the rated speeds of scenario 2 and 3 are identical, as both are approaching energy-optimal operating points. For the scenario with constant fan speed, the compressor power is consistently lowest and the electrical consumption of the fan is constant at 200 W. If the heat output is provided in an energy-optimal way, a higher compressor output is required than in scenario 1, but therefore the fan power can be reduced significantly. For example at 4 am, the compressor power differs from scenario 1 to 2 by $\Delta P_{el,comp.}$ = 71 W, while the fan power decreases by $\Delta P_{el,Vent.}$ = 115.5 W. The comparatively high difference between the fan outputs of the two scenarios is based on the cubic relationship between fan output and fan speed. The maximum saving is 98 W. Over the entire period 1.63 kWh can be saved, which corresponds to a reduction in electrical energy consumption of 3.75 %.

In nominal operation (scenario 1) the sound emissions vary between 70.6 dB(A) and 70.9 dB(A) and are dominated by fan emissions. While the fan emissions are constant, the compressor emissions fluctuate with the heat demand. In energy-optimized operation, less noise is emitted due to the reduced fan speed. The sound pressure level varies between 65.1 dB(A) and 60 dB(A), which represents a volume reduction between 5.8 dB(A) and 10.9 dB(A). This leads to a reduction of the subjectively perceived volume by up to half. The acoustic emissions can thus be significantly reduced without the acoustics having any weight in the target function of the ESC. In this scenario, the fan is the dominant component for noise emissions. In scenario 3, noise emissions can be further reduced compared to energy-optimal operation. The sound pressure level fluctuates between 62.6 dB(A) and 59.7 dB(A). In periods where the parameter "a" does not assume the value one (0-8 h and 20-24 h), the compressor is the dominant component in noise emission.

5. Discussion

The challenges of the presented procedure lie in the implementation and parameterisation of ESC in a real heat pump. Since heat pumps have time delays due to the thermal intertia of the heat exchangers, the convergence time of the algorithm is limited. The achieved convergence times are not yet representative due to the simplified dynamic modelling of the heat exchangers. In the experiment, it has to be shown that the convergence time of the algorithm is fast enough to ensure economic use.

Experiments from the literature show convergence times between one and three hours. However, a comparison is difficult because these are largely dependent on the distance between the initial manipulated variable and the optimum manipulated variable. If it can be excluded that ESC changes the manipulated variable against the optimization direction due to measurement errors or incorrect parameterization, ESC leads to an improvement of the current state, even if the algorithm has not yet converged to the optimum.

In addition to the convergence time, the parameterisation of the gradient estimator on a real heat pump is also challenging since the dynamics of the heat exchangers slow down the parameterisation process. Because these dynamics are not yet realistically represented by the simulation model, the parameters of the gradient estimator used in this paper probably deviate from test bench parameters. It is expected that the frequency must be reduced in order to counteract the slow dynamics and a possibly poor controller design. Due to loss mechanisms, interference influences and measurement uncertainties, the course of the system output cannot be attributed exclusively to the perturbation of the manipulated variable. In order to quantify the influence of perturbation, the amplitude of the perturbation must therefore be increased if necessary.

Depending on the heat pumps surrounding's, further improvements of factor "a" estimation can additionally be deduced. Therefore, we suggest installing an internal heat pump microphone. This microphone is on the one hand able to measure the heat pump's acoustic environment. The factor "a" can be set to a reasonable value depending on environment's acoustics. On the other hand, a high frequent microphone yields to applications of predictive maintenance because high frequency changes can indicate aging effects.

6. Conclusion and further work

In this work, the conflict of objectives between energetic efficiency and acoustic emission is addressed. The analysis is based on the fact that a constant heat demand at the condenser can be realized by a multitude of combinations between fan power and compressor power. A simulation study shows that the acoustically optimal combination of compressor and fan power does not correspond to the energetic optimum, thus creating a conflict of objectives. A comparatively small deviation from the energetic optimum can reduce the noise emission disproportionately. This Pareto effect is used to achieve optimal energetic-acoustic operation. With the help of the adaptive, model-free Extremum Seeking Control, any states between energetic and acoustic optimum can be realized by means of an objective function. For the first time, acoustics is implemented as a variable to be optimized. The energetic and acoustic effects are quantified based on a realistic 24 h heat demand profile. Compared to nominal operation, the energy efficiency of the system can be increased by 3.75 % with ESC, while at the same time the noise emission decreases by up to 10.9 dB(A). This means that the subjectively perceived volume is halved.

This procedure increases the two system efficiency and user comfort. This work, thus, contributes to the development of new control concepts, which, in addition to energy efficiency, can also optimize and evaluate the sound emission of heat pumps. No additional measurement technology needs to be installed on the heat pump to apply the presented method. However, an experimental evidence is necessary to take heat exchanger dynamics into account.

For the next steps, a microphone can be attached to the heat pump to improve the assessment of acoustic emissions. This allows location-dependent factors, such as the installation location, to be considered within the optimization process. High-frequent microphones can also be suitable for predictive maintenance.

Abstract

Decreasing carbon dioxide emissions in heat supply of buildings, heat pump systems (HPS) allow the replacement of conventional technologies that utilize fossil-based energy sources. Increasing HPS market penetration, investment and operational costs need to be reduced significantly.
Recent studies show cost reductions by solving optimization problems and considering operation already in the design process. However, many studies assume systems linear in order to simplify optimization procedures. Therefore, we investigate the applicability of a hybrid approach to design simultaneously heat pump, heating rod, space heating and domestic hot water tank considering their nonlinear interactions introduced by operation. We achieve this by combining dynamic simulation models with a multi-objective genetic algorithm using annualized costs and annual emissions as target functions.
Optimal designed systems reduce annualized costs by installation of smaller heat pumps and larger storage tanks compared to normative design standards. In addition, a reasonable larger heating rod ensures annual reliable supply. Thus, total annualized costs can be reduced by up to 12 %. The design highly depends on heat pump modelling and input weather data though.

Keywords: Heat pump design; design optimization; genetic algorithm; multi-objective optimization

1. Introduction

The building energy sector requires significant ecological improvements to meet political goals until 2050. Within this sector, the main contributor to its emissions is the supply of space heating and domestic hot water. Typically, conventional technologies like gas-fired or oil-fired boilers are used to meet the demand. Exchanging boilers with heat pump systems (HPS) can reduce heat supply related emissions. In general, however, HPS have higher costs than conventional systems. Hence, HPS need a cost reduction.
Costs mainly consist of investments and operating costs. Investment costs relate to system's component sizes whereas operational costs belong to the electricity costs to operate the system. Investments and operational costs are mutually depend and their interdependencies are nonlinear. Nevertheless, conventional design processes do the component design first and regard operation by designing the controller afterwards. Therefore, transient interdependencies of design and operation are neglected. Thus, in order to reduce total costs, there is a potential for advanced design processes that simultaneously take component design and operation into account.

In this study, HPS consists of a heat pump, an electric backup heater and two thermal storages: one for space heating and one for domestic hot water. In the literature, we mainly found two approaches that describe the design processes of these components. On the one hand, there are conventional design processes that design component sizes for steady-state operating points. This procedure is either traditional by applying standardized rules or more advanced by using optimization functions in order to define component sizes. On the other hand, first approaches dealing with simultaneous design of component sizes and controller exist. These use optimization procedures to organize the design process. In order to apply deterministic optimization procedures,

*Corresponding author. Tel.: +49 241 80 49786; fax: +49 241 80 49769.

systems often are linearized. Therefore, nonlinear interactions are neglected as a compensation to determine an optimal solution. However, Dongellini et al. [1] and Naldi et al. [2] show that interactions between component size and control influence considerably each other. In addition, Maier et al. [3] prove that interactions are nonlinear as well. Within this work we, therefore, contribute to the establishment of design procedures that consider nonlinear interactions between components. This design procedure introduces a simulation-based optimization method in order to design component sizes simultaneously including operation:

- In Chapter 2, we give an overview about design methodologies regarding conventional design standards as well as improved procedures.
- Our simulation-based optimization approach is introduced in Chapter 3. We distinguish between three steps. First, we show our data processing procedure to generate the algorithm's input data. Afterwards, we describe our system model and highlight nonlinearities introduced by dynamic simulation models. Lastly, we explain the optimization process.
- We show optimization results in Chapter 4. On the one hand, we compare our results with a German normative design standard. On the other hand, we discuss the influence of different boundary conditions.
- A detailed discussion of all results is done in Chapter 5.
- Finally, in Chapter 6, we conclude our work and give an outlook for further investigations.

2. Literature review

Replacing gas-fired or oil-fired heating systems by HPS, there is an urgent need to reduce heat pump system's costs. Costs depend on component design and operation, which again are mutually dependent. Common design procedures, however, are either conventional, sequential ones or linearly simplified to ensure optimal solutions.

Within this work, we define a heat pump system as a heat pump, an electric backup heater, a space-heating tank and a domestic hot water tank according to [3]. These components need to be designed and operated related to a building demand.

In Germany, there is a normative design standard DIN EN 15450 that describes the design process of HPS. It uses simple design rules to successively define the component's sizes. Applying these rules, a heat pump system is specified that ensures reliability of supply [4]. On the one hand, this procedure has the advantages of simple application as well as a repeatable methodology. On the other hand, it is obvious that these rules design all sizes very conservative to ensure system's reliability.

Dongellini et al. [1] and Naldi et al. [2] introduce and discuss advanced design procedures, which take interdependencies of components and operational aspects into account. While Dongellini et al. prove in [1] the dependency between heat pump sizing and its consequence on system performance, Naldi et al. show in [2] that system's efficiency is closely linked to considered climate and heat pump type. Therefore, it is promising to apply simulation-based approaches in order to design HPS considering system interdependencies as well as different climate conditions.

Designing HPS using simulation-based approaches is straight forward, respectively. However, if boundary conditions are insufficiently chosen, this approach will not lead to mathematical optimal designs. Therefore, Wolisz et al. [5], Schütz et al. [6] and Bischi et al. [7] introduce mixed integer linear programs (MILP) as deterministic optimization design procedure. This leads to optimal design results for mathematical linearized systems. According to Maier et al. [3], however, some nonlinear interactions exist. Concluding these insights, MILP procedures demonstrate design trends accurately. Deducing conclusions is hardly possible regarding reasonable system dynamics. Therefore, combined approaches, which find optimal solutions considering system dynamics are necessary.

Solving nonlinear problems, a trade-off between solution's optimality and dynamics accuracy leads to further design approaches. Therefore, Nguyen et al. present in [8] a review on simulation-based optimization methods. They suggest genetics algorithms (GA) to optimize the design of building energy systems stochastically. Additionally, they show that multi-objective optimization leads to reasonable designs that take costs and for example thermal comfort into account. Fazlollahi et al. confirm in [9] using combined approaches is promising.

The literature review shows great potential to optimize the design process of HPS by simultaneously considering dynamic operation. A contribution that optimizes component sizes at minimal costs and emissions was not identified, yet. Therefore, we show in Chapter 3 the methodology to apply our simulation-based optimization algorithm in order to minimize total costs and emissions.

3. Simulation-based optimization algorithm

Within this work, we introduce a simulation-based optimization algorithm, which includes a multi-objective genetic algorithm (MO-GA). In order to design heat pump heating systems, we need three calculation procedures according to Fig. 1. These three steps are data processing, simulation and optimization. Executing the data processing step, external inputs of location and building characteristics are necessary. Regarding the optimization part, user settings are additionally required. Developing an efficient optimization procedure, all models need to be both fast and accurate.

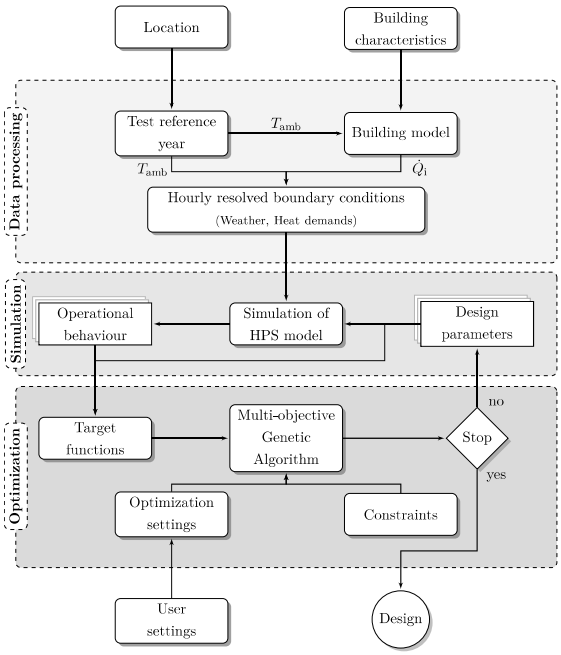

Fig. 1. Superstructure of developed simulation-based optimization algorithm. The algorithm is divided in three parts. Within data processing, the simulation model inputs are prepared. During the simulation, different designs are used to calculate operation behavior. The optimization part improves systems design regarding annual emissions and annualized costs.

3.1. Data processing

Within the data processing, we accumulate few input data in order to estimate the building's energy demand. Based on location, weather data of German weather service (DWD) will be used providing hourly resolved weather conditions in shape of different test reference years (TRY) [11]. Weather data serves as input for thermal building model simulation as well as for HPS model simulation.

Using a high-order building model from the open-source AixLib Library [10], building's demand is calculated hourly resolved. Both time series, weather data and energy demand, are simulation inputs. By taking this step, we neglect the interaction of heat supply system and building's hydraulics in order to increase simulation speed significantly. Simultaneously, we consider hourly resolved system dynamics regarding heat demand, which is reasonable because of large time constants in buildings. For the presented study, we exemplarily use a building located in Aachen, Germany, with a net area of 150 m², year of construction about 1960, insulation standard according to WSchV1984 at normal and cold TRY.

Regarding short time constants, profiles for domestic hot water (DHW) supply are applied according to the German normative standard DIN EN 16147. Within our study, we calculate profile XL, which is common in the heat pump system design process.

In Aachen, normal and cold TRY are summarized in Table 1. In the normal TRY, operating hours below 0 °C arise 313 hours a year, which is only about 4 % of the year. By reducing this temperature by another 2 K, the operating hours decrease to 80 h, which are about 1 %, respectively. The overall mean temperature is 11.48 °C at a lowest temperature of -5.7 °C. This temperature distribution results in a building heat demand of about 63.2 GJ.

In the cold TRY, operating hours below 0 °C are almost doubled with 863 h, which is about 10 % of a year. Operating hours between -2 °C now take 5 % of a year, which means 490 h, respectively. As consequence, the annual mean temperature decreases to 10.66 °C and the lowest temperature is -7.5 °C. With respect to the normal TRY, the building's heat demand increases by about 50 % to 93.4 GJ.

Table 1: Properties of different TRY. Data is proved by DWD. The normal TRY represents the last 20 years best for one region, whereas the cold TRY offers extreme conditions.

Studied year	Hours below 0 °C	Hours below -2 °C	Mean temperature in °C	Coldest temperature in °C	Resulting heat demand in GJ
Normal TRY	313	80	11.48	-5.7	63.2
Cold TRY	863	490	10.66	-7.5	93.4

Comparing both TRYs, the difference of temperatures and heat demands becomes clear. According to Naldi et al. [6], these differences will lead to different system designs as well as system efficiencies and emissions. Both TRYs and hourly resolved building energy demands serve as input for subsequent HPS simulation.

3.2. Heat pump system simulation

As already introduced, HPS consist of a heat pump, a heating rod, which generate heat (Fig. 2). Additionally, there are two storage tanks: one for space heating (Thermal Energy Storage: TES) and one for DHW, which are interconnected by a hydraulic system. These build the distribution system. In combination with a controller, the generation system and the distribution system match the consumer's heat demand.

For the simulation of the HPS, simulation models need to meet different requirements: simulation speed, simulation stability, simulation accuracy. Therefore, we assume reasonable simplifications.

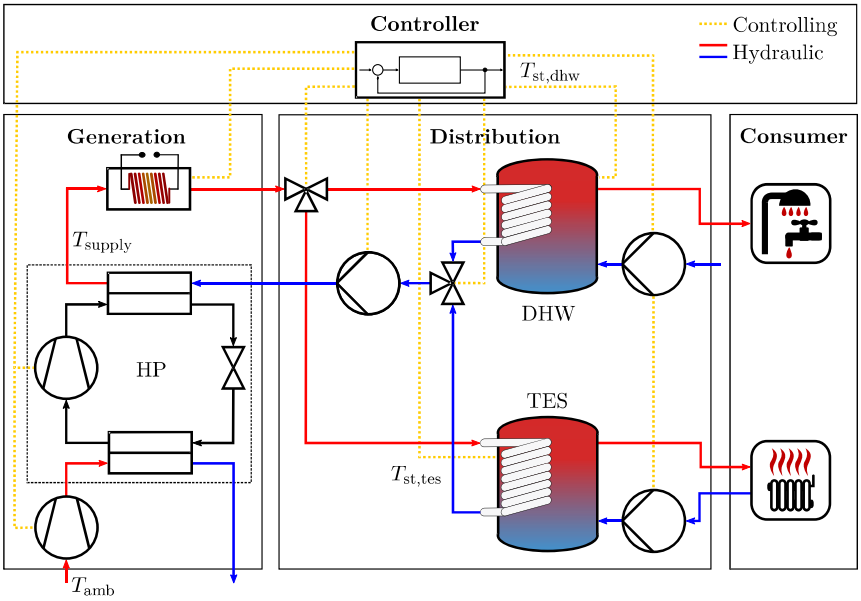

Fig. 2. Schematic structure of used heat pump system models. The system is divided into four subsystems: generation, distribution, consumption and controlling. Generation consists of a heat pump and a heating rod. Within the distribution subsystem storages and the hydraulic system are located. Consumer regard demands for space and hot water heating.

Heat generation:

Instead of using a physical heat pump model with its four components, we summarize its behavior in a characteristic map according to Fig. 3. Using this map, we neglect time delays between two operating points, which means quasi steady-state operation. Therefore, the heat pump is assumed speed controlled between 50 % and 120 % of nominal load according to [12]. We consider start-up losses according to Maier et al. [3] while neglecting defrosting due to missing data. The heating rod has a thermal efficiency of 0.97.

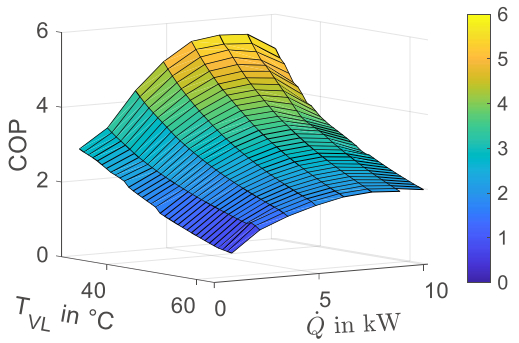

Figure 3: Efficiency map of the heat pump for an ambient air temperature of 0 °C. Within simulations, a three dimensional performance map summarizes dependency of ambient air temperature, supply temperature and condenser heat flow rate.

Distribution system and consumer:

The use of storage tanks is crucial for overall system performance. With respect to implemented models, two target quantities are addressed in the simulation. On the one hand, we define the capacity of a storage by its volume. Both volumes are optimized by the implemented MO-GA. Simplifying the geometry, we assume both storages a cylinder with constant height (h) to diameter (d) ratio of $h/d = 2$. On the other hand, heat losses scale with the surface of the storage tank and heat transition coefficients. Heat transition is calculated assuming free convection on the inner ($\alpha_i = 100\ W/m^2$) and outer side ($\alpha_o = 10\ W/m^2$). In between, heat conduction through insulation is taken into account by $k = 0.045\ W/mK$ and a thickness of $s = 0.12\ m$.

Simple pumps with constant isentropic efficiency are modelled and stratified storages with indirect loading procedure are used in order to match the heat demand of the consumer. As discussed before, the consumer is described by an hourly-resolved data set. Hence, user comfort cannot be measured, yet.

Controller:

Within the scope of this work, we demonstrate that design optimization considering operational dynamics is possible and promising. Therefore, we do not optimize the controller settings for different designs, yet. The controller is a simple heating curve function, which is state of the art. We implement a hysteresis band in order to decrease on/off switches. In addition, DHW has charging priority to increase user's comfort. We do not define a bivalence temperature but use the heating rod, if the lower hysteresis temperature is hurt for more than 20 min. Using this simulation model, the optimization method can be introduced.

3.3. Optimization method

Within this work, we apply a multi-objective genetic algorithm (MO-GA) based on Deb's NSGA-II [13]. In order to adapt it to our design procedure, two further extensions are implemented: The first one is local search in order to improve optimization performance around pareto-optimal solutions [14]; secondly, we use death penalty to deal with constraint hurting solutions [15].

Regarding very extreme demands at normative ambient temperature, thermal power of heat pump and heating rod have to meet normative heat demand according to DIN EN 12831-1, which is 9.7 kW at -12 °C in our use case.

The target functions are annual costs defined by annuity method and annual emissions: costs are defined by the combination of investment costs (according to [3]) investment specific maintenance costs and electric costs (constant specific value of 0.3048 €/kWh in Germany); emissions: specific emissions of German electricity grid (473 g/kWh).

4. Optimal design results

Using the simulation-based optimization approach, we design different systems. In Chapter 4.1 we show the difference between optimized designs compared to normative design standards. Afterwards, we study the effect of different boundary conditions that serve as input for the data processing procedure.

4.1. Comparison of normative and optimized design

When applying the simulation-based optimization algorithm, a pareto front according to annual costs and annual emissions will be calculated. The results are shown in Fig. 4. We discuss three highlighted ones compared to the normative design standard.

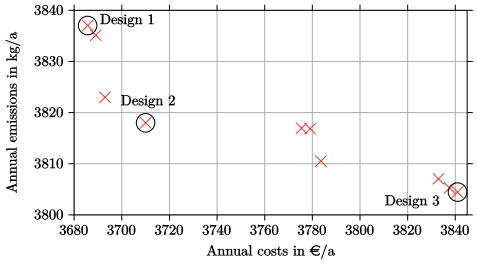

Figure 4: Resulting optimization pareto front using normal TRY. Three designs will be studied more thorough. Design 1 represents the cost optimal solution, design 3 the emission optimal solution and design 2 shows a trade-off between both targets.

Design 1 represents the cost-optimal, design 3 the emission-optimal and design 2 the solution that provides the best trade-off between the two target functions. Table 2 shows the component dimensions of the three optimizations. In addition, the design in accordance with DIN EN 15450 is shown. The corresponding values of the target functions were determined with the aid of an annual simulation in order to allow comparison.

Table 2: Design and performance parameters of optimization and normative designs. Design 1 represents the cost optimal solution, design 3 the emission optimal solution and design shows a trade-off between both targets.

Design label	Heat pump size in kW	Heating rod power in kW	TES volume in l	DHW storage volume in l	Costs in €/a	Emissions in kg/a	SCOP
Cost Optimal	3.95	7.83	578	269	3841	3804	2.76
Cost and Emission	4.03	7.77	412	77	3710	3818	2.74
Emission Optimal	4.18	7.76	257	50	3688	3837	2.72
Normative design	8.25	6.64	193	100	4206	4551	2.39

The three optimised designs show only minor differences in the heat generators' thermal performance. The heat pump thermal power is rated at approximately 4 kW and the heating rod at about 7.8 kW. The cost-optimized solution provides a heat pump's thermal power that is about 5 % greater. In the case of storage tanks, on the other hand, the differences are greater. With a TES of 257 l and a DHW of 50 l, the cost-optimal solution delivers the smallest and the emission-optimal solution the largest storage tanks with 578 l and 269 l, respectively. It is noticeable that the dimensions of the other pareto-dominant optimization solutions for each component lie between the two optimal solutions for a target function. Overall, the different interpretations lead to a difference of 4 % in cost function and about 1 % in annual emissions.

Compared to the normative design, larger differences are identified. This results in a cost savings potential of up to 12 % and a savings potential for emissions of up to 16 %. This is also accompanied by larger differences in the components' sizes. The normative standard designs the heat pump up to 50 % larger. Ensuring reliable supply, the thermal power of the heating rod can be decreased by about 20 %. In addition, an up to three times smaller TES is installed, whereas the dimensioning of the DHW, apart from the emission-optimal solution, lies between the interpretations of the normative standard. Overall, smaller design leads to a reduction in investment costs.

Due to the illustrated design changes, system behaviour varies overall. The efficiency of the system can be illustrated using the seasonal coefficient of performance (*SCOP*). It represents the ratio of the heat provided over the year and the electrical energy required. The *SCOP* of the overall system is 2.39 for the normative design, whereas the *SCOP* varies between 2.72 and 2.76 when using the optimization results. Consequently, *SCOP* can be increased by up to 15 % when using the simulation-based optimized design.

Main contributors to the improved overall efficiency are the changes of TES volume and heat pump capacity. Due to a reduced capacity, the heat pump can be operated more frequently and for longer periods. Therefore, losses related to switching can be decreased by up to 50 % since heat pump starts are reduced. Furthermore, increased full load operation due to larger TES volume is possible, so that efficiency losses in partial load operation are reduced.

In addition, the heating rod provides about 4 % of total heat. Within the scope of reference values according to DIN EN 15450, this result is reasonable, because the use of heating rods should not exceed 5 % of total heat. Hence, it is conspicuous that the heating rod is almost not used during system simulation of normative designed system. The share of the heat supply is below 1 %. Several possible reasons exist for this finding. Either the heat pump is oversized in the normative design or the normal TRY represents a comparatively warm year with a high mean temperature. In order to investigate the influence of different weather data sets, the cold TRY is applied to the algorithm.

4.2. Influences of different weather data sets

We distinguish between optimized design 1 (Opt.1), optimized design 2 (Opt. 2) and normative design (Norm). Case Opt. 1 is the optimized design already presented in Chapter 4.1. Regarding the normal TRY (Fig. 5, red bars), this case shows the optimal solution compared to the other design as expected. In Opt. 2 the design is optimized according to the cold TRY (blue bars). Obviously, Opt. 2 shows the best design compared to the others for both costs and emissions.

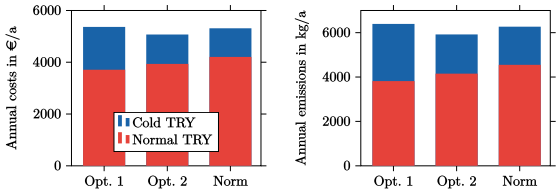

Figure 5: Target functions for the trade-off solutions of optimizations using different TRY as well as the normative design. Opt.1 represent optimization using the normal TRY and Opt.2 represent optimization using cold TRY.

With respect to the normal TRY, normative design rules perform worse. In case of the cold TRY, the normative design procedure nearly obtains the results compared to Opt.1. In Table 3, the component sizes of all design procedures are shown.

Due to the increased heat demand during the cold TRY, the heat pump within Opt. 2 is designed about 60 % larger than in Opt. 1. At the same time, heating rod power can be reduced by around 14 % while satisfying used boundary conditions. In addition, TES is designed at half the volume, whereas the DHW is increased by 10 %. Overall, significantly smaller deviations of the individual components from the normative design procedure can be detected compared to Opt. 1, which reduces potential savings. Nevertheless, the optimized annual costs are about 5 % below the normative design.

Table 3: Optimal designed systems regarding a normal TRY (Opt. 1) and a cold TRY (Opt. 2) compared to a normative designed system. Opt. 2 designs a heat pump with a 60 % higher thermal power and therefore with a reasonable smaller heating rod. Both storage tank volumes are in between Opt. 1 and normative design.

Design label	HP size in kW	HR size in kW	BS volume in l	DHW volume in l	SCOP (standard year)	SCOP (cold year)
Opt. 1 (normal TRY)	4.03	7.77	412	77	2.74	2.24
Opt. 2 (cold TRY)	6.45	6.60	224	93	2.58	2.48
Normative design (Norm)	8.25	6.64	193	100	2.39	2.37

Increasing comparability between the results, operation of all designs is calculated for both weather conditions. For this purpose, annual simulations with both TRYs as boundary conditions are created. Table 3 provides the *SCOP* of the respective simulation and Fig.5 displays each target function.

Opt.1 shows the greatest potential for savings in terms of both costs and emissions compared to normative design. Best results can be observed when using the normal TRY, which leads to a *SCOP* of 2.74. The same design, however, also leads to the lowest *SCOP* during a cold winter. Main reason is the increased operation of the heating rod. When using cold TRY, the heating rod provides about 8 % of the heat demand which requires 20 % of the total primary energy due to its low efficiency. Therefore, both costs and emissions increase significantly.

Opt. 2, on the other hand, provides a lower overall savings potential, but improves target functions by up to 9 % under both TRYs. Consequently, the choice of weather data during the design process has a direct influence on the dimensioning of the components.

Furthermore, Figure 5 shows similar trends for both target functions investigated. This suggests a correlation between the two target functions and can be explained by the predominant influence of operational costs and emissions as a function of power consumption. The operational electricity costs account for between 60 % and 80 % of the total costs. The share of emissions is even higher with up to 90 %. As a result, subsequent work should revise target functions and make it possible to decouple the two goals.

5. Discussion

In contrast to the normative designs, HPS is designed that it ensures just reliable supply when normative heat demand is needed, which reduces heat pump's thermal power and increases the TES volume for space heating. The ecological optimum of the optimization delivers in each case the design with the smallest heat pump and the largest thermal storage. This coincides with the findings according to [3] where an bigger sized TES leads to a continuous improvement in the final energy consumption which is equivalent to a reduction in indirect emissions.

Due to downsizing heat pump's capacity, the optimized designs include an increased heating rod power, so the reliability of supply is ensured even at very low ambient temperatures. Accordingly, the heating rod must be operated earlier, whereby the bivalence temperature shifts towards warmer temperatures. Since the bivalence temperature is dependent on the installed heat pump power, it should be optimized in further studies.

The optimized designs highly depend on the boundary conditions and used models. In particular, changing the weather data by using an extreme year instead of an average one with a 50 % increase in heat demand shows large differences in the design. Due to the increased heat demand, heat pump capacity is increased by 60 % compared to other optimization calculations. There are two major reasons for the different heat pump size. Firstly, the general share of total costs accounted by operation increases when using a higher heat demand. Within the normal year, investment costs account for 34 % of the total annual costs, which drops to only 20 % when using the cold TRY. As a result, operational improvements are weighted more strongly than investment costs accompanied by increasing heat pump capacity. Secondly, the inefficient operation of the heating rod is reduced, which improves the overall operation.

When designing HPS under normal weather conditions, the overall efficiency of the system can drop below the efficiency of a system designed using normative design procedure in years with lower mean outdoor temperatures. In contrast, designing for cold boundary conditions shows an economic and ecological improvement compared to normative design at both low and high mean annual temperatures. Consequently, the cold TRY should first be used during the design process. However, further work should investigate to what extent the extreme TRY is necessary when designing HPS and if a trade-off between the two investigated designs can be made. For this purpose, the optimization should be carried out for different locations.

6. Conclusions

In this work, we investigate a simulation-based optimization algorithm to design HPS. The introduced approach improves the component dimensioning of HPS. As a basis for comparison, the design according to the German standard DIN EN 15450 is used. In order to estimate the improvement potential, an optimization algorithm is developed. It consists of a MO-GA, which optimizes HPS models regarding annualized costs and annual emissions. Optimization results are compared with the normative method by using annual system simulation. A potential for improvement regarding the annual costs of up to 12 % and with regard to emissions of up to 16 % is shown. The results of the optimization are influenced by several factors. Among other things, the weather conditions have great influence on the designed system.

If a year with a cold winter is used instead of the normal TRY of the DWD, where heat demand is about 50 % greater, the heat pump capacity increases by up to 60 %. A comparison of system simulations of both designs under different weather conditions shows that the design using the normal TRY is less efficient than the normative design at low annual mean temperatures. Only the cold TRY optimized system guarantees improved operation regardless of weather conditions. Consequently, it must be investigated which weather conditions are required for the design in order to ensure an optimal design. For this purpose, further locations should be included in the comparison in order to validate the statements.

Combined Heating and Cooling in District solutions

Jussi Alpua*, Martti Kukkola

Oilon Oy, Niittytie 25 A, Vantaa 01300, Finland

Abstract

Energy companies can now produce energy efficient cooling with heat pumps outside of the traditional district cooling network. Property-specific heat pumps can be used to provide cooling services to customers within the energy company's district heating network. This concept makes it possible to offer energy efficient cooling services to customers without having to build a district cooling network. In property-specific cooling, the heat pumps are installed in the customer's property produces cooling and transfer the generated heat into the district heating network. The cooling service offered to the customer acts as decentralized heat source for the district heating network. In this Combined Heating and Cooling (CHC) concept, energy is not wasted. In many commercial and office buildings, hospital, datacenter as well as apartment buildings can be changed environment friendly cooling in future.

1. Introduction

The low carbon roadmap published by the European Commission in December 2011 aims at a near-zero emission energy system by 2050. For example, Finland's long-term goal is to reduce greenhouse gas emissions by 80 % by 2050. These more stringent political climate goals, increasingly volatile and lower wholesale electricity prices, and customer awareness of the need for renewable energy production forms to combat climate change are driving district heating companies to look for new energy sources and heat production forms. The use of heat pumps in a district heating system enables the utilization of a wide variety of different heat sources and increases the flexibility of the district heating system and the share of renewable energy production. According to the study, heat pumps could produce between 3 to 4 terawatt hours (TWh) of district heat per year, which would represent 9-13 percent of the annual sales of district heat in Finland. Current district heat production from heat pumps in Finland is about 0.6 TWh, which is around 1.7 percent of the total district heat production. In Sweden, for example, about 7.4 % (4.0 TWh) of district heat is generated by heat pumps [1].

This article looks at property cooling solutions implemented with heat pumps. In the implemented solutions, the cooling energy (cold water) required by the property is produced by heat pumps and the condensate energy generated in the production of cooling energy is transferred to the district heating network for further utilization of thermal energy. Typically, the cooling of the real estates is implemented with a cooling solution, in which the condensate energy generated during the cooling is not utilized and condensate energy is lost through outdoor condensers to the air.

* Corresponding author. Tel.: +358-44-337-4475; fax: +358-3-857-6239.
E-mail address: jussi.alpua@oilon.com .

The implemented solution can be applied and is sensible to apply to large properties that require cooling and are not able to be connected to the district cooling network and have been connected or will be connected to the district heating network. A large property here refers to a property with a design cooling power greater than ~ 30 kW.

2. The principle of cooling the property by heat pump

Figure 1 presents a cooling solution to a property, in which the condensate heat generated during cooling is transferred to the district heating network by use of a heat pump (lower example). Figure 1 also shows a conventional cooling solution in which condensate energy generated during cooling is transferred to the outdoor air via a heat transfer fluid (upper example). Heat pump and water chiller unit share similar operation principles. The temperature level of the water/liquid leaving from heat pump is high enough to utilize the condensate energy to the heat sink. For example in this figure 1 only adding 100 kW of electricity, there can be heat recover 600 kW high temperature water, instead of losing 500 kW to the air with chiller.

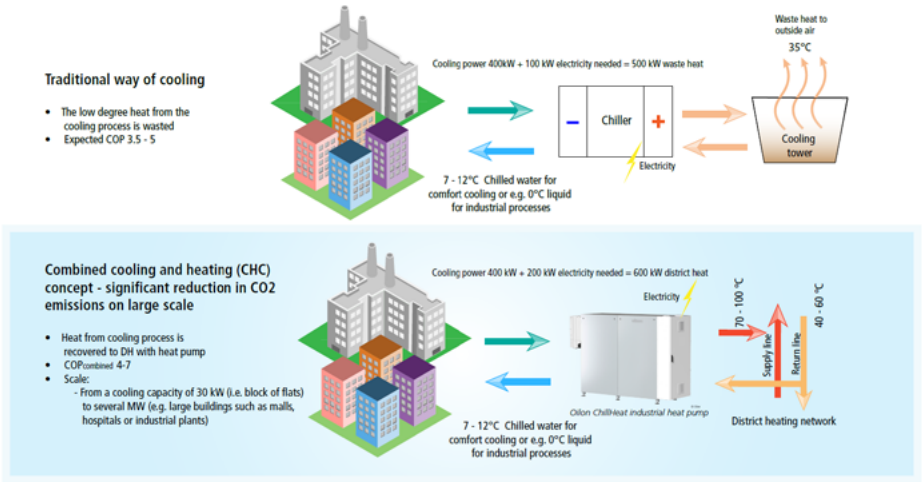

Fig. 1. Above is a traditional cooling solution in which condensate energy produced by cooling is transferred to the outdoor air via a heat transfer fluid. Below is a real estate cooling solution with a heat pump, where the condensate heat generated during cooling is transferred to the district heating network

The combined heating and cooling (CHC) system is not tied to any specific constant temperature like district cooling networks are. For example, the system can produce cooling liquid of -5 ˚C while recovering heat to the district heating network. In addition, the system can be installed in a small space. This is an advantage when operating normally on the client's existing premises.

Heat pump energy balance is:

$$Q_H = Q_c + P_e - Q_q \quad (1)$$

where Qc = cooling energy of the heat pump (kWh)
Pe = electric energy consumed by the heat pump compressor(s) (kWh)
QH = condensate energy of the heat pump (kWh)
Qq = heat losses of the heat pump to the environment (kWh)

The heat losses of the heat pump to the environment (engine room) are typically about 3 % of the electric energy with compressors equipped with semi-hermetic frequency converters.

The energy efficiency of cooling processes can be examined with the so called cooling efficiency factor (ε), defined by the formula:

$$\varepsilon = \frac{Q_c}{P_e} \tag{2}$$

The cooling efficiency of the cooling process depends on the temperature of the water (liquid) leaving the evaporator and condenser. The larger this temperature difference, the worse the cooling efficiency of the cooling process. The so called overall efficiency of the process can be determined to the cooling process, in which the condensate energy can be utilized:

$$\varphi_{tot} = \frac{Q_c + Q_H}{P_e} \tag{3}$$

If all the condensate energy generated by the cooling process is utilized, the overall efficiency as a function of the cooling efficiency is:

$$\varphi_{tot} = 2\varepsilon + 1 \tag{4}$$

3. The cooling solution for the property with a heat pump implemented in 2017

In 2017, a heat pump system was delivered for cooling the property, in which the condensate energy generated during cooling is transferred to the district heating network for further utilization according to the principle shown in the figure 1 (lower example). The design cooling capacity of the property to be cooled was calculated to be approximately 500 kW. Cooling water is utilized for cooling the property during warm periods and for condensate heat recovery of the year-round commercial refrigeration.

Two serial connected Oilon ChillHeat heat pumps were selected, based on the design cooling capacity of the property. Figure 2 shows the performance of the selected heat pump. Cooling water outlet is 10 ˚C and heating side outlet is 80 ˚C. Calculated total COP is 5,4. The heat pump performance is calculated using the Oilon Selection Tool program developed by Oilon Oy.

The selected heat pumps each have three piston compressors. In one heat pump two compressors are equipped with frequency drives (VFDx2). The six compressors in total achieve stepless cooling capacity control in the range of 8 %...100 %. Due to the control method of the heat pump, the efficiency of the heat pump remains almost constant throughout the power control range. In the implemented project, the heat pump and the cooling system require good adjustability, since the need for the cooling capacity of the property varies greatly e.g. depending on the outdoor temperature.

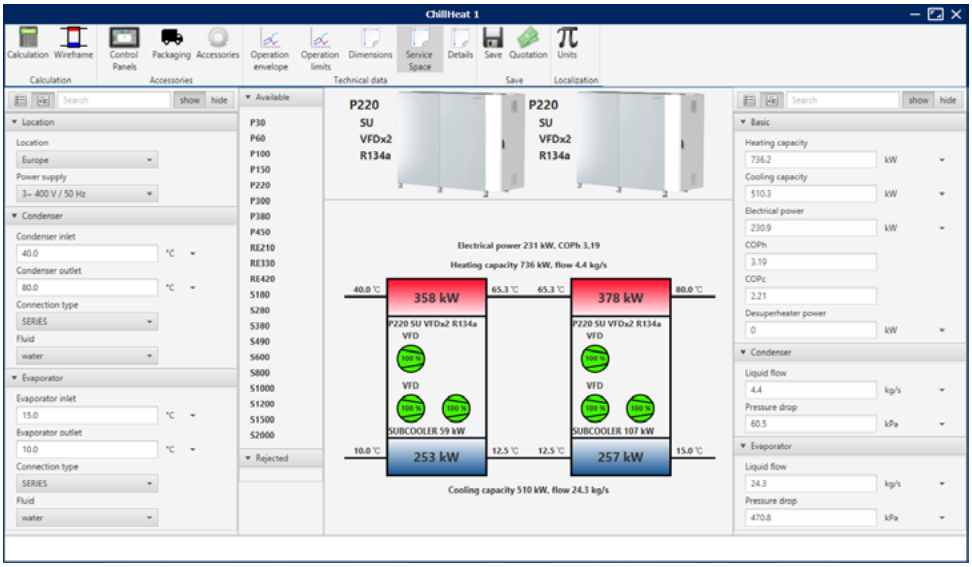

Fig. 2. Design information for the heat pump. The heat pump performance is calculated using the Oilon Selection Tool program

3.1. System description

The principle PI diagram of the system is presented in the figure 3. The system consists of the following main components:

- heat pump and automation (1)
- storage tank for the cooling circuit (2)
- cooling circuit circulation pump with a frequency converter (3)
- energy metering of the cooling circuit (4)
- district heating circuit pump with a frequency converter (5)
- district heating energy metering (6)
- district heating circuit 2-way control valve (7)
- district heating circuit check valve (8)
- filters (9)
- Electrical cabinet (10)

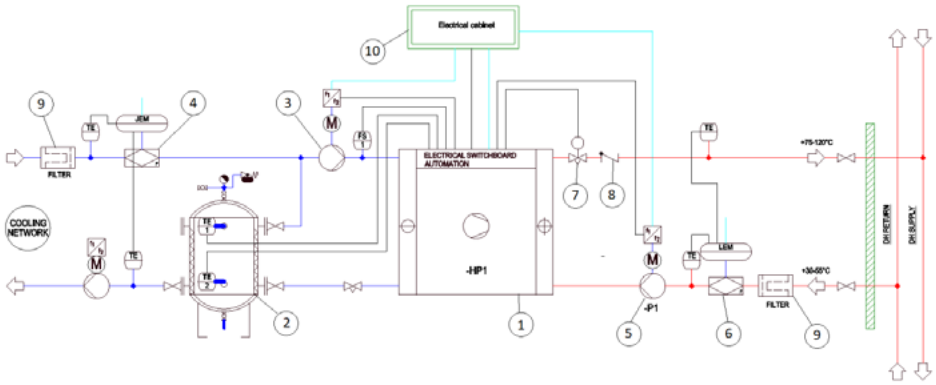

Fig. 3. Principal PI diagram for combined heating and cooling solution

The system does not need external control or automation to operate. The heat pump receives a running permission according to the lower temperature of the cooling accumulator. First, the circulation pumps (3 & 5) are started, both in the cooling and heating circuit. The cooling circuit is equipped with a flow switch (FS1) which detects the flow. When the flow is detected, the heat pump (1) can start.

The cooling power is controlled by adjusting the heat pump power, (1) and the temperature to the cooling network is controlled by changing the flow rate of the circulation pump (3). A set value for the outgoing water in the heating circuit is also set to the heat pump automation. This temperature is controlled by changing the flow rate with the frequency controlled pump (5) and the control valve (7). The control valve control is used when the circulation pump control range runs out. This ensures that the water entering the network is at the set point temperature. The heat pump will shut down after a delay when the power requirement is so low that it does not correspond to the minimum load on the unit.

3.2. Implemented system running in year 2019

This implemented solution was producing cooling approximately 850 MWh in year 2019. Heat pumps were consuming electricity 373,8 MWh and 80 ˚C hot water were produced 1 224 MWh. Total COP was 5,55. So the COP is higher than calculated COP. Note that this COP doesn't include circulation pumps electric consumption.

The system is owned by an energy company. Energy company is responsible for the running costs electricity and maintenance. Customer pays for the cooling energy. They also receive a compensation for the recovered heat. The energy company has not announced the price of sold cooling energy. Electricity price in Finland is typically 80-100 €/MWh without taxation. This size CHC solution installation costs are typically 450-480 €/kW (cooling). This price doesn't include pipe work from district heating network to machine room.

4. CHC in the future

The future looks pride for the CHC solutions. Last two years Oilon has supplied more than 20 CHC solutions in Nordic countries. This is just a start. For example energy companies in Finland have begun to open district heating networks, so that third party can access networks if the agreements can be settle.

Moving to 4th generation district heating networks give also more advance to CHC solution. In 4th generation district heating networks supplied water temperature will be low as 70 ˚C and even lower. Decentralized large scale heat pump systems are named one of the heat sources to the 4th generation district heating networks. Heat pumps can produce heating to the buildings as well as they can be used for 2-way district heating as CHC is. [2]

Lower network temperature will increase the CHC system efficiency and decrease the capital costs. Also lower temperature gives better possibility to use CHC solution storage tanks as heat storage when cooling is not needed. This of course needs some modification for the current system piping.

Maybe the best efficient way to use CHC is 5th generation district heat networks. This generation is using heat sharing networks where the temperature is near ambient ground temperature. Heat pumps are installed in customer buildings, as in CHC concept. Heat sharing networks can be used as heat source for the heating as well as for rejecting the heat to the network when a building needs cooling. This increases the CHC efficient, because the heat pump condensing temperature can be much lower. [3]

5. Summary

The low carbon roadmap published by the European Commission in December 2011 aims at a near-zero emission energy system by 2050. Finland's long-term target is to reduce greenhouse gas emissions by 80% by 2050. Cooling large buildings with heat pumps enables the condensate energy generated by cooling to be utilized in the district heating network, which reduces the amount of district heat produced by fossil fuels in the district heating network.

Combined Heating and Cooling solution (CHC) is simple, functional and effective system. Heat pump total COP can be over 5,5 when producing 10 ˚C cooling and 80 ˚C hot water. These systems can be implemented in new and existing properties.

CHC potential can be seen to increase in future. District heating companies are more and more opening the networks to third parties. Also moving forward to use 4th and 5th generation district heating networks increases the use of CHC's. Lower network temperature, decentralized sources and 2-way network will increase the benefits of using heat pump systems like CHC.

Experimental investigations of two types of the dual-loop heat pump systems for ventilation heat recovery

Guoyuan MA*, Lei WANG, Anna MA, Xiaoya JIA, Yu LIU, Feng ZHOU

College of Environmental and Energy Engineering, Beijing University of Technology, Beijing 100124, China

Abstract

Heat recovery capability of ventilation system can be effectively improved by using multiple loop independent heat pump cycles. This paper focus on how to further improve the performance in the heat pump system under constant loop number and compressor displacement. The heat recovery performance differences between two types of the dual-loop heat pump system were compared through experimental testing. Results show that COP of the system in which the displacement in the low-pressure loop is twice of that in the high-pressure loop can be increased by 14.78% comparing with the system in which the displacement in the low-pressure loop is half of that in the high-pressure loop. Especially, the COP of the former system is even higher than that of the triplex loop heat pump system under some operating conditions. Therefore, in multi-loop heat pump system for ventilation heat recovery, it is more significant to increase the circulating flow rate of the working fluid in low-pressure loop.

Keywords: heat pump ; ventilation heat recovery ; dual loop; displacement ratio

1. Introduction

According to statistics, the energy consumption of buildings accounts for more than 40% of the total energy consumption in the European Union [1]. As the largest developing country in the world, the energy consumption of civil buildings accounts for about 25% of the total energy consumption in China [2]. Reducing the building energy consumption caused by ventilation system is an effective way to reduce building energy consumption [3-4]. Relevant studies have also confirmed that heat recovery from indoor exhaust air can greatly reduce the energy consumption of buildings [5-6].

The recovery efficiency of heat pump heat recovery system can reach 100% [7]. Some scholars have analyzed the energy-saving buildings using heat pump for ventilation heat recovery, and considered that the heat pump system has excellent performance, and the heat pump system has a better application prospect for ventilation heat recovery [8-9]. However, with the decrease of outdoor temperature in cold climate, the circulating mass flow rate of refrigerant will gradually decline in the heat pump system, and the excessive attenuation of circulating mass flow rate is not conducive to the heat recovery of exhaust air. Therefore, in order to improve the performance of the system at low outdoor temperature, some scholars have proposed a solution of multi-loop compression cycle [10].

The multi-loop heat pump ventilation heat recovery system proposed in reference [10] has excellent heat recovery performance with the same compressor displacement in each loop. Whether the displacement distribution of loops has influence on the performance of the system has not been studied. Therefore, this paper proposed two kinds of dual-loop heat recovery system. The total displacement of the compressors in the two systems is the same, but the displacement ratio in the high- and low-pressure loop is different. The performance

* Corresponding author. Tel.: +86-010-67391613.
E-mail address: magy@bjut.edu.cn.

of different dual-loop systems is analyzed by experiments, and the difference of displacement ratio for influence the performance of system is summarized and analyzed.

2. Method

2.1. System principle

Compressors A, B and C with the same specifications were used for experiments. Dual-loop system I represents a dual-loop system with a displacement ratio of 2 between high- and low-pressure loop, the system scheme is shown in Fig. 1. Compressors A and B were connected in parallel in the original experimental platform, so that the displacement in the high-pressure loop was twice as large as that in the low-pressure loop. At the same time, heat exchanger # 1 and # 2 were paralleled used as the condenser of high pressure-loop, heat exchanger # 4 and # 5 were used as the evaporator of high-pressure loop. Low-pressure loop was driven by compressor C. Heat exchanger # 3 and # 6 were used as condenser and evaporator of low-pressure loop, respectively. The low-temperature outdoor fresh air first passed through the low-pressure loop composed of compressor C, and then heated by the high-pressure loop composed of compressor A and B in parallel, finally sent into the indoor.

Dual-loop system II represents a dual-loop system with a displacement ratio of 0.5 between high- and low-pressure loop, the system scheme is shown in Fig. 2. The low-pressure loop was driven in parallel by the compressors B and C. At the same time, the heat exchangers # 2 and # 3 were used as the condenser of the low-pressure loop, the heat exchangers # 5 and # 6 were used as the evaporator of the low-pressure loop. High-pressure loop was driven by compressor A. Heat exchangers #1 and # 4 were used as condenser and evaporator of high-pressure loop, respectively. The low-temperature outdoor fresh air first passes through the low-pressure loop composed of compressors B and C, and then heated by the high-pressure loop composed of compressor A, finally sent into the indoor.

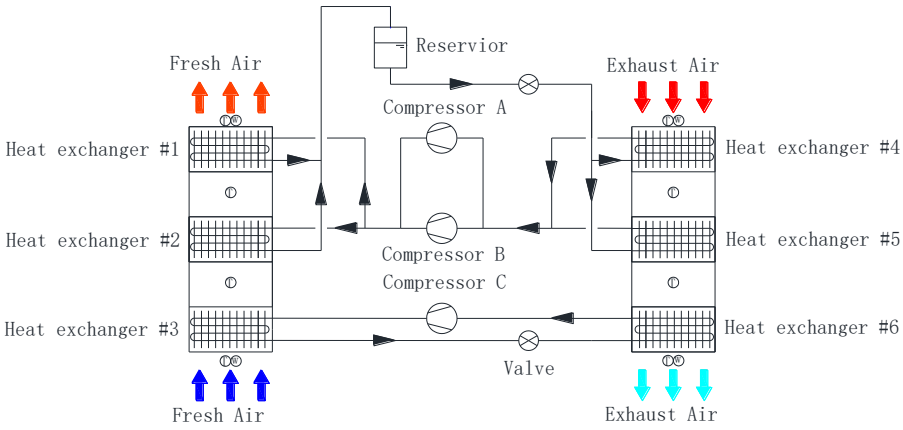

Fig. 1. Dual-loop system I: Displacement ratio between high-pressure loop and low-pressure loop is 2.

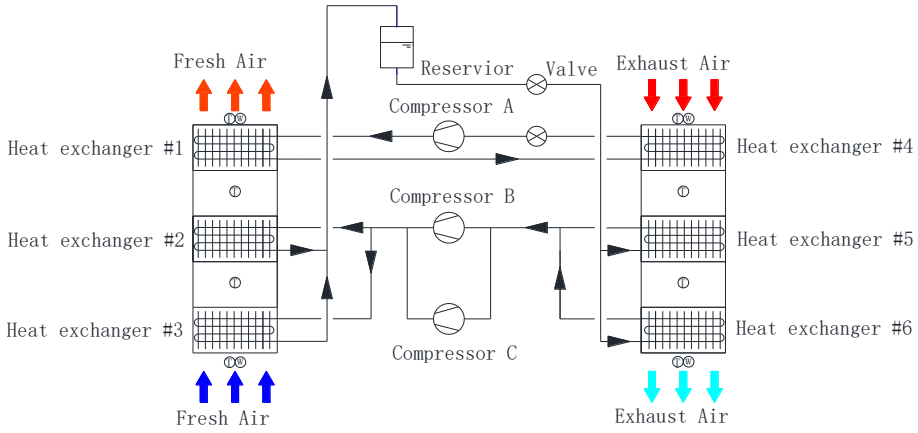

Fig. 2. Dual-loop system II: Displacement ratio between high-pressure loop and low-pressure loop is 0.5.

Fig. 3 is the representation of dual-loop heat pump ventilation heat recovery system on P-h diagram. The dual-loop system on the P-h diagram is composed of two independent cycles. A1-A2-A3-A4-A1 stands for low-pressure cycle, B1-B2-B3-B4-B1 stands for high-pressure cycle. There is no heat or mass exchange between the two cycles.

When the relatively low-temperature fresh air first enters the condenser of the low-pressure loop, the condensing pressure of the loop is lower because of the low air temperature. The air is gradually heated when flowing through the condensers. When fresh air entering the condenser of the next loop, the air temperature is already high. So the condensing pressure of this loop is higher than that of the low-pressure loop. When the exhaust air with high temperature enters the evaporators, the evaporating pressure of the loop which contact exhaust air first will relatively high, and then the evaporating temperature and evaporation pressure of the next loop are lower because the air has been cooled. This is the principle of the formation of high-pressure loop and low-pressure loop in dual-loop system. The two loops are combined in a step by step way to recover heat from exhaust air. C1-C2-C3-C4-C1 represents the system cycle in which the traditional heat pump ventilation heat recovery system works in a large temperature and pressure range.

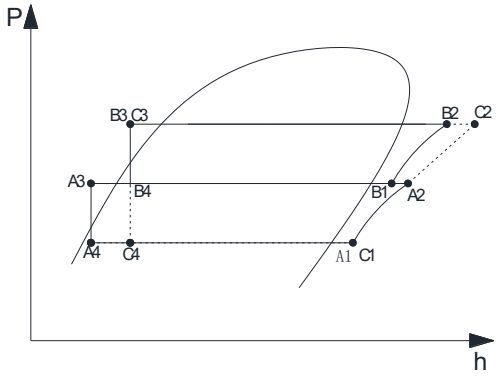

Fig. 3. P-h diagram of the dual-loop system cycle

2.2. Experimental procedure

Fig. 4 shows the photo of the experimental platform. The compressors used in the experiment are three GMCC rotary compressors of the same specification, the frequency is 50Hz, and the refrigerant used is R410A.

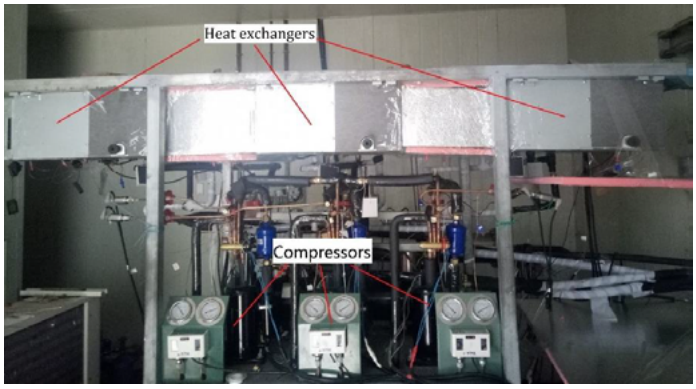

Fig. 4. Photo of the experimental platform

The fresh air heat exchangers (condensers) and the exhaust air heat exchangers (evaporators) of the experimental platform are respectively arranged in the outdoor environment simulation room and the indoor environment simulation room. The working environment of the ventilation heat recovery device can be realized by adjusting the temperature of the simulation rooms. The experimental test conditions are shown in Table 1.

Table 1. Test conditions

Test conditions	Indoor temperature (℃)	Outdoor temperature (℃)
Winter	20	15,10,5,0,-5,-10,-15,

3. Results and discussion

Fig. 5 shows the heating capacity changes for fresh air in different systems. From the point of view of the heating capacity to the fresh air, with the decrease of outdoor temperature, the heat obtained by the fresh air also increases gradually. The heating capacity of dual-loop system II is higher than that of dual-loop system I, which the growth amount can be up to 11.21%. That is, the heat recovery ability of dual-loop system II is higher than that of dual-loop system I. With the decrease of outdoor temperature, the fresh air temperature entering each heat exchanger is gradually declined. The temperature difference between the discharge temperature of the compressor and the fresh air temperature at the inlet of the condenser corresponding to the loop is gradually increased. The increase of the temperature difference between the refrigerant and the air will increase the heat transfer capacity of the heat exchanger to a certain extent. Therefore, with the decrease of outdoor temperature, the heating capacity of systems will gradually increase.

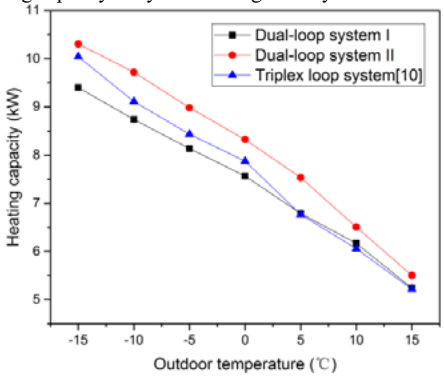

Fig. 5. Heating capacities of heat pump systems.

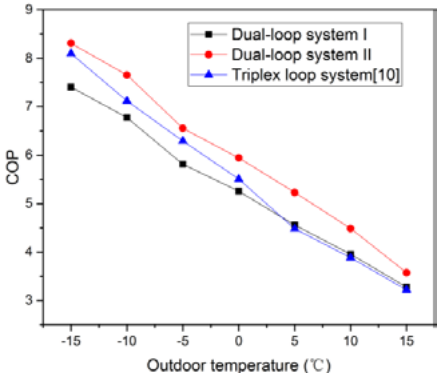

Fig. 6. COP of the heat pump systems.

The changes of system COP under each test condition is shown in Fig. 6. With the decrease of the outdoor temperature, the COP of the various systems are gradually increasing. The COP of dual-loop system II is higher than that of dual-loop system I at all test conditions, and the improvement can reach a maximum of 14.78%. The COP of the dual-loop system II is 2.61%~16.69% higher than that of triplex loop system as well. This is mainly because that the higher heating capacity and lower power input has been attained in dual-loop system II. This method to enlarge the displacement in the low-pressure loop can significantly improve the system performance while reducing the loop numbers and simplifying the composing for multiple loop heat recovery system as much as possible.

In general, heating capacity and COP of heat pump increase with increase of outdoor temperature, but the results of this study are opposite. This is actually the difference caused by the application of heat pump system in different occasions. When the heat pump system absorbs the heat from the low temperature outdoor air and then releases it to the high temperature indoor air, the heat source temperature in this condition is lower than the heat sink temperature. So the heating capacity and COP increase with the increase of the outdoor temperature. When the heat pump system is used for ventilation heat recovery, the system absorbs heat from the exhaust air（heat source） and then releases heat into fresh air（heat sink）. In this application, the temperature of the heat source is higher than that of the heat sink in winter. Operating condition is just opposite to an ordinal heating condition, so the heating capacity and COP decrease with the increase of the outdoor temperature. Of course, this trend will change with the heat transfer limit of the device and the deterioration of the operating environment.

4. Conclusion

In this paper, based on the theory of multiple loop heat pump ventilation heat recovery system, the influences of two dual-loop systems with different displacement ratio on heat recovery performance were analyzed and compared by experiments, and the following conclusions were drawn:

(1) COP of dual-loop system with a displacement ratio of 0.5 in high- and low-pressure loop can be 14.78% higher than the dual-loop system with a displacement ratio of 2, and the heating capacity can be 11.21% higher.

(2) Compared with dual-loop system with a displacement ratio of 2 in high- and low-pressure loop, system performance in dual-loop system with a displacement ratio of 0.5 is better in system performance, which indicates that increasing the displacement ratio of the low-pressure loop is more beneficial to the performance improvement of the multiple loop system.

Abstract

Heat pumps represent ideal systems to exploit the energy flexibility potential of buildings and their embedded thermal storage possibilities, particularly when they are operated by intelligent management systems such as model predictive controllers (MPC). The present study proposes to evaluate in an experimental setup the performance of an MPC controller used to control an air-to-water, variable speed heat pump for a residential building. In particular, the impact of the forecast quality is investigated, since MPC relies on the access to forecasts of the disturbances (weather, price, occupancy…) to perform its optimization. Two experiments of three days were thus repeated, the first one with a real weather forecast retrieved periodically from a commercial service, while the second one considered a perfect forecast. In cooling mode, the case with imperfect forecast resulted in an increase of the electrical energy use of the heat pump of 5.8%, corresponding to a cost increase of 11.2%, compared to the case with perfect forecast. These experimental results highlight the importance of the forecast quality on the performance of model predictive controllers for heat pumps.

Keywords: model predictive control; weather forecast; experimental study; residential applications; space cooling.

1. Introduction

With the growing penetration of wind and solar plants in our energy mix, the need for demand-side flexibility is becoming more and more relevant to maintain a proper operation of the power grids. In particular, the heating and cooling loads of buildings can be regarded as flexible demand, since they can be shifted in time to a certain extent, by exploiting their embedded mass as thermal storage. Heat pump systems enable firstly to electrify this demand, and secondly to make it more flexible, if operated by smart controllers.

In this regard, model predictive controllers (MPC) have shown a growing interest in recent years to exploit the energy flexibility of buildings [1]. Such control strategies rely on an optimization problem solved periodically, making use of a forecast of the external disturbances and a model of the dynamic systems to project their behavior over a certain finite horizon in the future, and thus find the optimal control sequence. MPC usually provides greater benefits in terms of savings, comfort or energy flexibility (depending on the chosen objective), than simpler strategies such as rule-based controls, even though its development costs are higher. The performance of MPC depends highly on its formulation, the reliability of the model used, and the accuracy of the disturbances forecast, which most commonly consists of weather predictions. About this last point, little literature was found about the influence of the forecast quality on the performance of MPC used in building climate control. A summary of existing articles and their learnings is presented hereafter.

The literature on the subject often uses a “performance-bound MPC”, sometimes also called “perfect MPC”, “optimal MPC” or “optimal policy”, as a benchmark for other control strategies [2]. It is an “idealized” MPC, which creates a perfect agreement between predictions and reality. Such studies are possible in computer

simulations where the future evolution of the exogenous parameters can be known beforehand, but could not be applied to field tests. It enables to see the upper limit of the benefits that MPC could ideally provide, if it had a perfect knowledge of the future. Mendoza-Serrano et al. [3] compared for instance different configurations, with the MPC provided either with a perfect forecast (full future information), either with zero future information. The first case lead to savings of 31% compared to a standard reference case, while the second one lead to savings of only 27%. The authors highlighted the fact that the savings strongly depend upon the level of information provided to the MPC algorithm. Similarly, Allen et al. [4] reported savings of -13% on the total energy costs with a perfect forecast, and -11% with an imperfect forecast. Rolando et al. [5] developed a predictive rule-based control, and found that the system energy consumption was reduced of about 15% when the control logic utilized the information of the perfect solar radiation forecast, over the entire heating season. Lazos et al. [6] also commented that weather variables are significant components of the evolution of building energy systems and minimizing the uncertainty in predicting their evolution can lead to significant savings, usually in the range of 15–30% compared to a deterministic and non-weather sensitive control approach. Lohr et al. [7] compared a controller when fed with a perfect forecast, or with the data of the previous day used as predictions for the next day (yesterday-based predictions). They found that the performance decreased only slightly, if historical data is chosen as forecast for the upcoming day, but the proposed controller performed well in both cases.

Most of the reviewed literature agrees on a significant influence of the forecast quality over the MPC performance. However, it remains unclear how much better the MPC can perform with a perfect knowledge of the future, compared to other imperfect methods used to predict the future evolution of the disturbances. In fact, a complete absence of knowledge of the future is as unrealistic as a perfect knowledge: since weather parameters have a certain inertia, and repeat daily and seasonal patterns, a certain approximation of the next day weather can always be estimated. Furthermore, most of the reviewed articles resorted to simulation work, and did not consider the application on real systems like heat pumps operated in a realistic setup. The present work intends to fill this gap by proposing a comparative study which shows the performance of an MPC controller on a real heat pump operated in a semi-virtual laboratory setup. The experimental nature of the study considers all practical aspects related to applying MPC as a heat pump supervisory control, and enables to obtain more realistic results than previous simulation-only work. In this study, the MPC was run firstly in real time, using weather forecasts updated every hour from a commercial service, while the current weather was also measured in parallel. In a second experiment, the recorded weather conditions were reproduced in a climate chamber where the heat pump outdoor unit is placed, also providing this information as a perfect forecast to the MPC controller. In this way, the performance of the MPC with a perfect or with an imperfect, but real-life forecast could be compared with the same boundary conditions.

2. Methods

2.1. Experimental setup: semi-virtual environment and heat pump system

The tests were performed in a semi-virtual environment setup in a laboratory, according to the schematic of Figure 1. The real heat pump is an air-to-water, reversible model of 11 kW capacity, able to regulate the speed of its compressor (variable speed). Its outdoor unit is placed in a climate chamber where the air temperature and relative humidity can be accurately controlled to reproduce the desired climatic conditions in a dynamic manner. Two thermal benches emulate the thermal loads from the building according to the simulation made in real time with the TRNSYS software: the first thermal bench emulates the space cooling load, by controlling the return temperature from the emission system that goes back to the heat pump. The other thermal bench schedules the tapping of DHW from the storage tank, according to a fixed and predefined schedule.

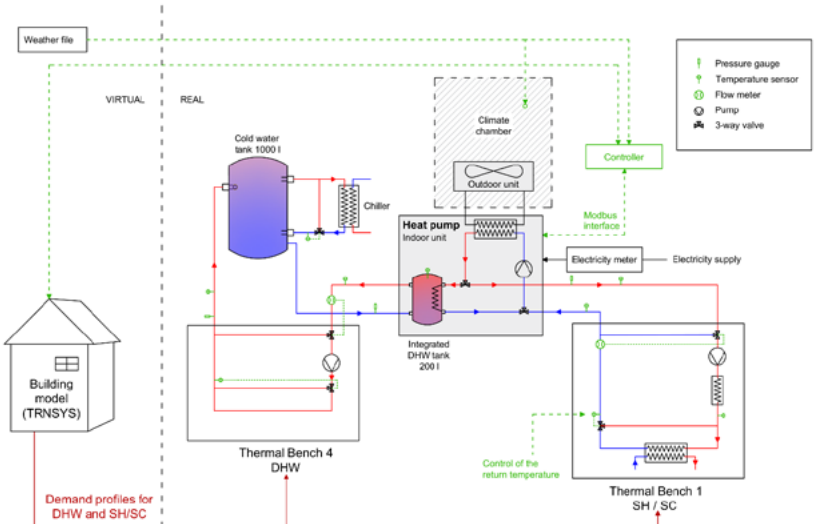

Figure 1. Schematic of the laboratory setup, applying the concepts of semi-virtual environment and hardware-in-the-loop.

2.2. Study case and utilized models

The control configurations have been tested on a building study case representative of the climate of the Catalonia region in Spain. It is a flat of 110 m^2 with 3 bedrooms, occupied by a family of 4 and conditioned by a circuit of eight Fan-Coil Units (FCU) supplied by the air-to-water heat pump. The flat is modelled in TRNSYS as a detailed white-box model. The occupation of the apartment is modelled stochastically, with a profile of the heat gains from people and equipment. The climate files used for the tests originate from a weather station situated in Tarragona (Spain), see also next section 2.4 about the forecasts on this matter.

In the present case, only a period of the cooling season was chosen for the tests. In this configuration, the heat pump functions in cooling mode to provide space cooling (SC), and in heating mode to produce Domestic Hot Water (DHW) stored in an integrated tank. Only one mode is allowed at any time, with DHW having priority over SC. The experiments carried out cover three days of September 2018, from the 13th to the 15th included, with a sufficiently high cooling load.

2.3. Model predictive controller

The controller tested in this study is a model predictive controller whose formulation is presented hereafter. The MPC formulation is summarized in this section; for any doubt or for further details, the reader is referred to previous publications [8], [9], and to the nomenclature at the end of this paper.

Objective: $\min_{u,\delta} J = [\alpha_\varepsilon J_\varepsilon + \alpha_{\Delta u} J_{\Delta u} + (1 - \alpha_\varepsilon - \alpha_{\Delta u}) J_{cost}]$

Subject to, $\forall k \in [\![1, N]\!]$:

Model:

$$\begin{cases} \boldsymbol{x}(k+1) = \boldsymbol{A} \cdot \boldsymbol{x}(k) + \boldsymbol{B_u} \cdot \boldsymbol{u}(k) + \boldsymbol{B_e} \cdot \boldsymbol{e}(k) \\ \boldsymbol{y}(k+1) = \boldsymbol{C} \cdot \boldsymbol{x}(k) \end{cases}$$

Constraints on the inputs:

$$\begin{cases} \delta_{SC}(k) \cdot \underline{Q_{SC}} \leq Q_{SC}(k) \leq \delta_{SC}(k) \cdot \overline{Q_{SC}} \\ \delta_{TES}(k) \cdot \underline{Q_{TES}} \leq Q_{TES}(k) \leq \delta_{TES}(k) \cdot \overline{Q_{TES}} \\ \delta_{SC}(k) + \delta_{TES}(k) \leq 1 \end{cases}$$

Constraints on the outputs:

$$\begin{cases} T_{int}(k) \leq \overline{T_{int}}(k) + \varepsilon(k) \\ \underline{T_{TES}} - \varepsilon(k) \leq T_{TES}(k) \end{cases} \qquad (\varepsilon \geq 0)$$

The cost function is multi-objective: it combines a comfort objective J_ε, a smoothing objective $J_{\Delta u}$ (which aims at avoiding too frequent changes in the frequent actions), and a cost reduction objective J_{cost}. These conflicting objectives have been balanced by choosing appropriate values for the weighting coefficients α_ε and $\alpha_{\Delta u}$.

The MPC controller projects the behavior of the systems on a horizon of 24 hours in the future (denominated N), using a simplified model of the building. This model is a resistance-capacitance grey-box model which represents the building envelope and the capacity of the thermal mass of the building to store energy. The model is expressed here in a state-space format (matrices A, B_u, B_e and C), using two different kinds of inputs: the vector $u(k) = [Q_{SC}\ Q_{TES}]^T$ contains the thermal powers of the heat pump for either space cooling or DHW production operation. These are the decision variables of the MPC. The vector $e(k) = [T_{amb}\ I_H\ Q_{occ}\ Q_{DHW}]^T$ contains the exogenous, non-controllable variables (also called disturbances), that must be forecasted for the MPC to be able to make its projections in the future. The ambient temperature T_{amb} and the solar irradiation I_H represent the weather forecast: this is where different forecast strategies have been tested in the present work. The heat gains from occupants and equipment Q_{occ} and the DHW tapping profile Q_{DHW} represent the other disturbances.

The constraints on the inputs ensure that the thermal power chosen by the MPC stays within the operation limits of the chosen heat pump system, between the minimum $\underline{Q}$ and the maximum $\overline{Q}$. The binary variables δ_{SC} and δ_{TES} allow the MPC to decide whether to operate the heat pump in SC or in DHW mode, and the last input constraint guarantees that only one mode is activated at a time. The output constraints ensure the provision of comfortable conditions to the occupants. The indoor temperature T_{int} is thus limited below the limit of $\overline{T_{int}} = 25℃$ and the tank temperature T_{TES} above the limit of $\underline{T_{TES}} = 50℃$. These constraints are softened by the slack variable ε, which is included in the objective J_ε. In this way, the constraints can sometimes be violated, but at a certain cost reflected in the objective function.

Finally, the cost objective is formulated as shown in Equation (2). A simplified model of the heat pump enables to estimate its power consumption P_{el} in function of the thermal power Q, the ambient temperature T_{amb} and the supply temperature T_{sup}. This power consumption is then multiplied at every time step by the price of electricity c_{el} which varies hourly but still presents two distinct periods with high and low tariffs.

$$J_{cost} = P_{el}(Q, T_{amb}, T_{sup}) \cdot c_{el} \tag{1}$$

The MPC controller is called every hour, and only the first control actions are sent to the real heat pump, before another instance of the MPC is formulated and solved.

2.4. Forecasts

In this study, the forecasts used within the MPC controller play an important role. Two configurations have been developed and tested: with perfect or imperfect forecast. During the days of September 13th to 16th of 2018, the outdoor temperature and solar irradiation were measured from a weather station situated in Tarragona (Spain). In parallel, every hour a forecast of these two weather parameters for the next 24 hours was retrieved from an external service and stored. It is a commercial service available online through an API [10], which enables the automatic download of the weather forecast periodically. This information was then used as input for the MPC.

The case with perfect forecast uses the actual measurements as forecasts, therefore it has a perfect knowledge of the future. It should be noted that the forecasts used are in fact a resampled version of the real measurements, to fit with the discretization time step of the MPC optimization problem (12 minutes). For this reason, the forecasts are slightly smoothed but have a very similar shape than the measurements.

The case with imperfect forecast uses the successive forecasts, as it would happen in a real operation on site with an actual building. The MPC runs its optimization every hour, therefore it updates with the best forecast information that it can have at the present moment.

The measurements and forecasts are presented in Figure 2. In the case of solar radiation, it appears that the forecasts did not take into account the cloud coverage, and only offered an estimation of the solar irradiation based on the location and hour of the day. This forecast matches well with the reality in the first day, as the sky was cloud-free, however it produces an important error on the third day, where the day was cloudier. The irradiation forecast does not actually change from one forecast to the next retrieved one hour later, for this reason all the curves are superposed. It should be noted that the weather forecast chosen was a free service, for this reason it is of poor quality, but it represents an actual service available on the market, for this reason it is interesting to investigate how the MPC would perform with such input.

In the case of the ambient temperature, the forecasts are shown on the bottom of Figure 2, and they provide a better estimation of the future evolution of the outdoor temperature, compared to the measurements carried out afterwards. The forecast is updated regularly, for this reason we observe a stack of curves. The forecast is relatively good although for instance in the third day it shows more uncertainty, probably due to the more irregular weather of that day.

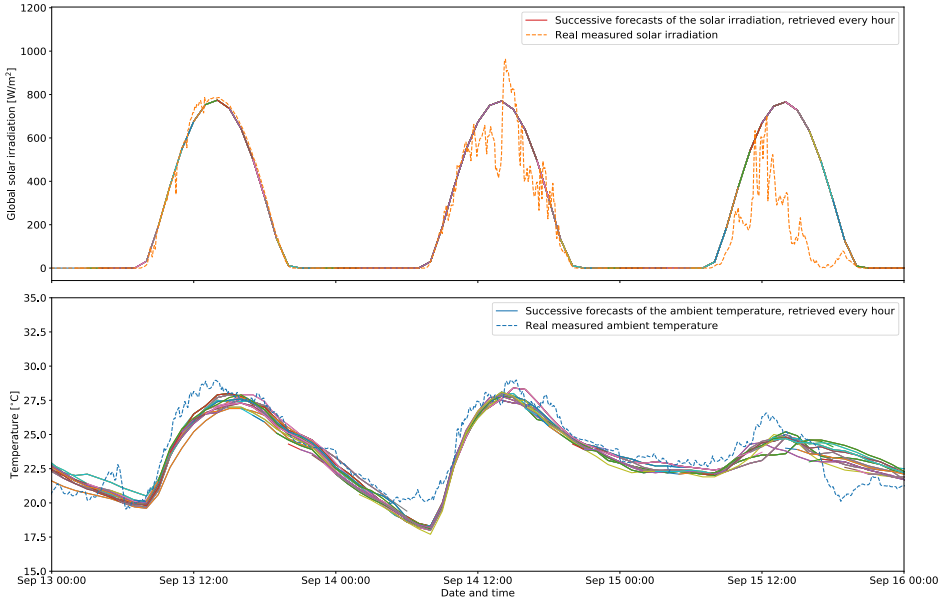

Figure 2. Measurements and successive forecasts of the solar irradiation and the ambient temperature in Tarragona (Spain) during three days of September 2018.

2.5. Performance indicators

The performed tests are analyzed in the view of different performance indicators. The summed energy values constitute the first series of indicators: the thermal energy produced by the heat pump, and the electrical energy that it used, over the three days of experiment. It should be noted that the thermal energy is always counted positive, whereas it is cooling energy like in space cooling operation, or heating energy like during DHW production (both of them are then summed to obtain the total thermal energy). The ratio of these two quantities (thermal and electrical energy) represents the efficiency of the heat pump, also called coefficient of performance (COP). Next, the costs incurred by the use of the heat pump are computed: the calculation consists in an integration of the electrical energy over the three days, weighted at each time step by the price of electricity in EUR/kWh at that time step, using for this purpose an hourly price profile available for small consumers in Spain (PVPC) [11]. This electricity tariff has a higher price period in the afternoon, therefore the economic MPC strategy tends to avoid the heat pump operation during these hours.

To evaluate the comfort conditions in the building, the average indoor temperature is calculated, as well as the percentage of time spent in Category I according to standard EN15251 [12], the category of highest comfort. Finally, an indicator able to estimate if the control strategy is able to shift the loads towards low-price periods is chosen. The flexibility factor is a performance indicator that reveals if the heat pump has used more energy during low price hours (up to a value of 1) or during high price hours (down to a value of -1) [13]. Its formula is indicated in Equation (2), where P_{el} represents the electrical power of the heat pump, and lp and hp the low and high price periods respectively.

$$FF = \frac{\int_{lp} P_{el} dt - \int_{hp} P_{el} dt}{\int_{lp} P_{el} dt + \int_{hp} P_{el} dt} \quad (2)$$

3. Results

The main results of the two experimental cases are presented in Table 1, in terms of summed energy values, average COP and comfort conditions, as well as with the chosen flexibility indicator.

Table 1. Summed or average values of several performance indicators over the three days of experiment in the two cases. The variation of the imperfect forecast case with respect to the perfect forecast case is indicated in absolute and/or relative terms.

Parameter	Unit	PERFECT	IMPERFECT
Thermal energy	**[kWh]**	**94.4**	**99.9**
Absolute variation	*[kWh]*		*+5.5*
Percentage variation	*[%]*		*+5.8%*
Electrical energy	**[kWh]**	**40.4**	**42.8**
Absolute variation	*[kWh]*		*+2.3*
Percentage variation	*[%]*		*+5.8%*
COP	**[-]**	**2.3**	**2.3**
Absolute variation	*[-]*		*+0.0*
Cost	**[EUR]**	**4.1**	**4.6**
Absolute variation	*[EUR]*		*+0.5*
Percentage variation	*[%]*		*+11.2%*
Average zone temperature	**[°C]**	**24.7**	**24.7**
Absolute variation	*[°C]*		*+0.0*
Time in Comfort Category I	**[%]**	**91.5%**	**95.0%**
Absolute variation	*[%]*		*+3.5%*
Flexibility factor cost FF	**[-]**	**0.5**	**0.3**
Absolute variation	*[-]*		*-0.2*

To evaluate the performance of the two configurations comparatively, the energy costs constitute the most interesting indicator, since this is the declared objective of the MPC controller. In this regard, the case with imperfect forecast performs worse than the case with perfect forecast, resulting in an increase of 11% of the costs. It thus appears that knowing an accurate forecast of the weather conditions in advance constitutes an important advantage for the controller. The thermal energy delivered and the electrical energy used by the heat pump both also increase when the forecast is imperfect, but in a less important manner, by 5.8%.

Next, the impact of the control configurations on the load shifting towards low price periods is investigated. Although the price forecast is equal in both cases, the case with perfect forecast managed to shift a greater proportion of the loads towards the periods of low price, reaching a value of $FF = 0.5$, while with imperfect forecast it stayed at a value of $FF = 0.3$.

The different strategies had little impact on the comfort of the occupants: the average temperature within the inhabitable zone is equal in both configurations, with a value 24.7°C. The percentage of time spent in comfort category I (i.e. with temperatures below 25.5°C in cooling mode for residential buildings) increased a little in the case of imperfect forecast, with 95%, while the case of perfect forecast only had 91.5% of the time in Cat. I, which is still entirely satisfactory, given that Cat. I represents the highest level of expectation. The extra energy spent thus enables to slightly improve the comfort conditions.

To understand better the dynamic behavior of the two configurations of the MPC controller, the time series of Figure 3 are plotted. The two versions of the controller behave in general similarly, for instance they tend to precool the building before the price increase happening every day, so as to limit the energy expenditure during the period of expensive electricity. However, some discrepancies are also observed, which explain the different results previously presented. For instance, on the third and last day, the imperfect forecast anticipated a large solar irradiation during the afternoon, while in fact the sky happened to be cloudy with low incoming solar radiation. Because of its overestimation, the MPC with imperfect forecast decided to cool the building in the early afternoon, anticipating an incoming solar radiation that never actually occurred, and so as to stay within the imposed comfort boundaries. On the other hand, the MPC with perfect forecast knew that the solar radiation would stay at a low level, and that active cooling would not be necessary to stay within the comfort zone. Since this difference in behavior occurred during a high price period, it had an important impact on the final energy costs, as can be seen in the end of the cumulative cost curves (third graph from the top). This

illustrates perfectly the importance of an accurate forecast for an MPC controller, and explains why the MPC with perfect forecast performed significantly better.

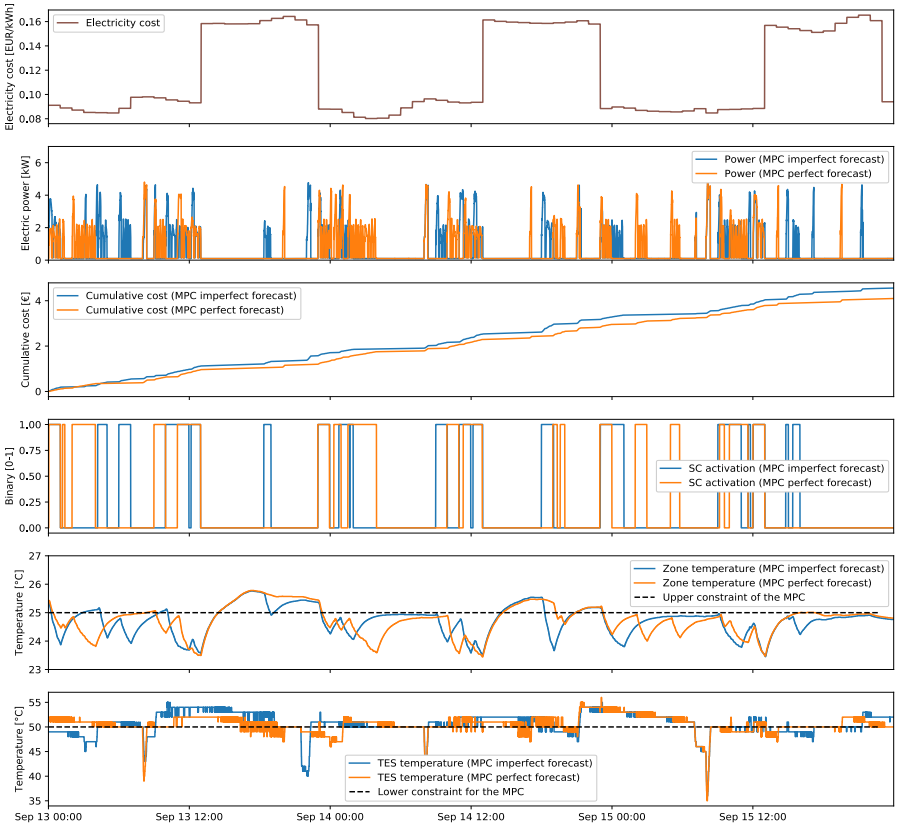

Figure 3. Time series comparing the dynamics of both studied configurations along the three days of the experiments.

4. Conclusions

In this study, an MPC controller was tested on a real heat pump system in an experimental laboratory setup, following the hardware-in-the-loop principles. Two experiments of three days duration were performed, one where the MPC controller was provided with a perfect forecast of the weather conditions for the next day, and the other where it used an imperfect forecast retrieved from an external service. When operated by the MPC with perfect forecast, the heat pump used 6% less electricity, which resulted in 11% savings on the energy costs, compared to the case with imperfect forecast. In the two experiments, the weather in the climate chamber where the heat pump is placed was identical, only the weather forecasts for the MPC was changed, which enabled to perform a thorough comparison on the MPC performance, when provided with a different forecast input. The results corroborate the learnings of the existing literature, highlighting the influence of the forecast accuracy on the savings achieved by the MPC. Additionally, the experimental nature of the work gives further reliability to the presented results, since few experimental studies on this topic had been carried out so far. From the obtained results, it can be concluded that a special care should be given to the choice of the weather forecast service when designing and implementing MPC in real buildings for climate control.

The weather forecasts used in this study originated from a commercial API available online, which gave a real-life example of service that could be connected to an MPC. However, it proved to be significantly inaccurate, especially regarding the solar irradiation. Better forecast service could have been used and would probably have reduced the difference with the perfect forecast case. Another idea for further research could be

to study separately the influence of the forecast of the ambient temperature and the solar irradiation, to understand if there exists any difference in their impact, or if one of those parameters could be forecasted more loosely than the other without significant loss of performance. Finally, the presented study only presented real-life cases of three days duration in cooling mode: these results could be extrapolated by performing longer experiments or simulations, also considering heating mode to find out whether the impact of the disturbance forecast changes seasonally. For instance, it appears that it was particularly important to forecast well the solar irradiation in cooling mode, since it is responsible for important heat gains and thus of the cooling demand, but on the other hand in heating mode, the ambient temperature might be the most important parameter to forecast accurately. These constitute interesting topics for further research.

Nomenclature

$J, J_{\Delta u}, J_{\varepsilon}, J_{cost}$	Global objective function, and subobjective terms, respectively for smoothing, comfort and cost reduction.
$\alpha_{\varepsilon}, \alpha_{\Delta u}$	Weighting coefficients of the sub-objectives
A, B_u, B_e, C	Matrices of the state-space building model (parameterized with resistance and capacitance values)
x, y, u, e	Vectors of the states, outputs, controllable inputs, and exogenous inputs
$T_{amb}, I_H, Q_{occ}, Q_{DHW}$	Exogenous inputs: ambient temperature, solar irradiation, heat gains from occupants/equipment, heat losses from DHW tapping
$\delta_{SC}, \delta_{TES}$	Binary variables for the activation of SC or DHW
Q_{SC}, Q_{TES}	Thermal power for SC or DHW operation of the heat pump
$\underline{Q_{SC}}, \overline{Q_{SC}}, \underline{Q_{TES}}, \overline{Q_{TES}}$	Lower and upper limits of thermal power in SC or DHW modes respectively
$\overline{T_{int}}, \underline{T_{TES}}$	Comfort constraints (upper constraint for the room temperature and lower constraint for the DHW storage tank temperature)
ε	Slack variable to relax the comfort constraints
T_{sup}, T_{int}	Supply temperature of the heat pump, indoor temperature of the building
P_{el}	Electrical power use of the heat pump
FF	Flexibility factor

Model Calibration of an Air Source Heat Pump System for Transient Simulations in Modelica

Philipp Mehrfeld[a,*], Markus Nürenberg[a], Dirk Müller[a]

RWTH Aachen University, E.ON Energy Research Center, Institute for Energy Efficient Buildings and Indoor Climate, Mathieustrasse 10, 52074 Aachen, Germany

Abstract

Within the scope of HVAC and building performance simulations, 74 % perform manual calibrations whilst the remaining 26 % aim for a fully automated process. Nonetheless, with focus on detailed grey-box simulation models for complex HVAC systems, such as a heat pumps (HP), a full automation might lead to several assumptions and, thus, to inaccuracies regarding the calibration results in terms of its misfit measures. Therefore, we define clear requirement specifications for an experimental design in combination with a semi-automated calibration procedure for an electrically driven air source HP system. The device under test is located in a climatic chamber and coupled to a hydraulic test bench, representing the source and sink of HP, respectively. As software toolchain, we use a combination of Python-based framework and Modelica-based simulation model library. We define the objective function as a chained and weighted KPI consisting of the normalized misfit measure CV(RMSE) of supply temperature and consumed electrical power. In a three-day long test with realistic dynamic boundary conditions, covering a comprehensive spectrum of inputs, we validate the calibrated models. The validation misfit measures show a deviation of 1.6 %.

1. Introduction

Electrically driven heat pumps (HPs) are a main rising technology in the building energy sector. With a growing share of renewable energy sources in the current mixture of electricity, HPs are the most promising energy conversion system to convert electricity efficiently into thermal power. This work will focus mainly on air source heat pumps as they have a higher market share than ground source HP [1].

As the computing power has massively increased over time, HVAC plant simulation models represent an ever-increasing approach to predicting system performance using transient simulation. There are different approaches, ranging from white-box to grey-box to black-box modelling. Anyway, in every case adequate parameterization is necessary so that the simulation model is able to represent a real plant. In addition to parameterization with the aid of manufacturer data sheets, a semi-automatic calibration of a grey-box air-source HP (ASHP) model is used in this paper. Semi-automatic in this case means that besides a manual aggregation of existing model classes in the modelling language Modelica, an individual preprocessing of used input time series data takes place. The rest of the calibration process is fully automatic.

A well calibrated model of the HVAC system is necessary, for example, to:

- predict system performance for e.g. one year using a simulation with a suitable sink model (building + e.g. underfloor heating and dynamic user boundary conditions)
- derive a model for inclusion in an MPC algorithm [2, 3]

E-mail address: pmehrfeld@eonerc.rwth-aachen.de.

- test functionalities of the system and the controller virtually (model in the loop) and thus save cost-intensive hardware tests

For this reason, measurement data is extracted from a 3-day dynamic test for an ASHP. About 60 % of the time series data is used for training and 40 % for validation purposes.

This paper deals with a developed framework consisting of a python-based and a modelica-based part. Figure 2 shows an overview of the process. The use case applied represents the calibration of an ASHP from existing time series data. In order to keep further influences to a minimum, the domestic hot water preparation and the control system are left out, although both were part of the experiment that provides the measurement data.

2. State of the art and initial condition

2.1. Calibration

Calibration is the variation of model parameters so that the difference between simulated and measured data is as small as possible [4]. A challenge in the field of modelling is the divergence between simulated and practical behavior [5]. In order to make building energy simulations a reliable tool for analyses regarding energy saving potentials or operational optimizations, there is a great interest in a correspondence between simulated and measured values of technical systems [6].

Within this framework, a model calibration in its core describes the parameterization of a model so that generated simulation results fit the measurement results of real systems. Before this, sensitive model parameters can be identified by sensitivity or uncertainty analyses and afterwards applied to the calibration process. [6]. However, we skip this step in the context of this work, since we know the model sufficiently well to determine the tuner parameters ourselves.

The mathematical methods differentiated Coakley et al. [7] in optimization methods and alternative modeling techniques. The optimization procedures are based on an objective function that evaluates the difference between measured and simulated data in the form of a statistical indicator or misfit measure. The optimization problem is formulated as a minimization problem, since this difference has to be reduced. The practical implementation typically takes place via the coupling of a simulation software with an optimization algorithm.

2.2. Measurement Data

To calibrate a model, it is vital to have extensive measurement data. In the scope of our case study, we obtained the dataset from a hardware-in-the-loop experiment [8, 9]. Figure 1 shows test bench arrangement of the ASHP system mentioned above and locations where the monitoring equipment are mounted. The HP is inverter controlled. While the outdoor unit of the split HP was positioned in a climatic chamber, the indoor unit was connected to a hydraulic test bench in order to emulate the outside air conditions and heat sink, respectively. With heat sink it is meant that simulation models of the hydronic network, the radiator heat transfer system and the building shell of a single family house were running during the experiment and values were interchanged online. Since a feedback of the simulation influences the hardware setup and vice versa, this explains the origin of the term hardware-in-the-loop. Tests with a monitoring frequency of 1 s represent the measurement database for the later performed calibration.

Uncertainties of measurements are evaluated for the supplied thermal energy and electrical energy consumption from a set of 11 reproducibility tests [10]. Results show a maximum uncertainty of 1.85 % for the thermal and 0.87 % for the electric energy.

Furthermore, we apply highly dynamic user profiles to the building model during the hardware-in-the-loop experiment. In terms of user profile we mean internal Gains up to 700 W, air change rates up to 0.8 1/h and room set temperatures up to 24 °C in the bathroom. The combination of all these boundary conditions and general heat losses of HVAC components like the buffer storage lead to a certain heat demand even during warmer days.

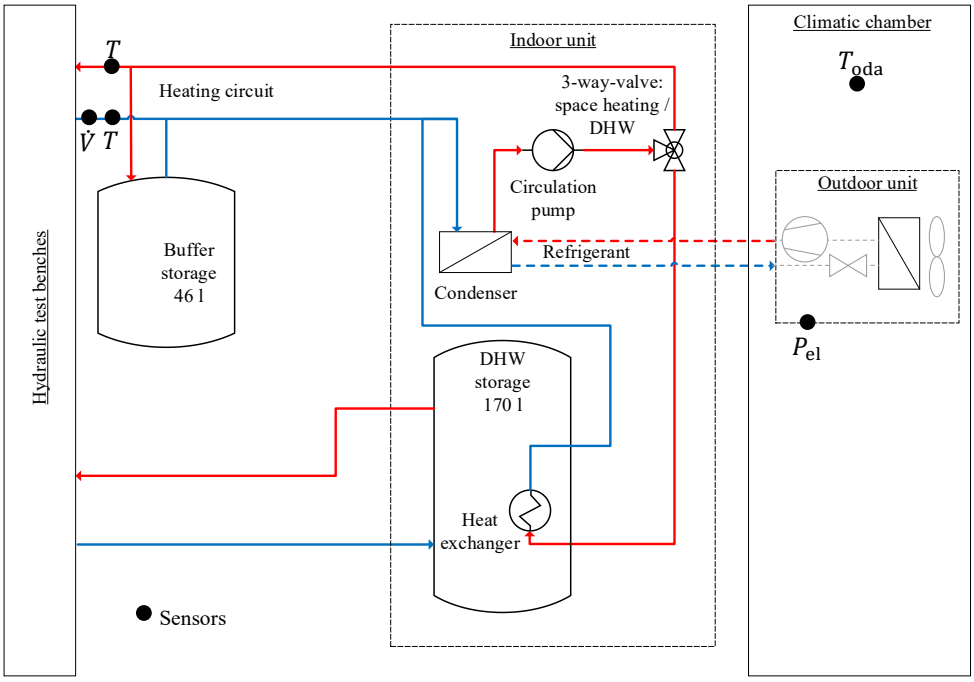

Figure 1: Experimental setup of hardware-in-the-loop experiment

2.3. Models

Throughout this work, we use the open-source and object-oriented language Modelica to model and run building performance and HVAC simulations. Modelica is specially designed for modeling physical systems [11]. To perform the required simulations for this work we use the freely model library AixLib [12] [13], which is a part of the IBPSA Project 1 [14] (former IEA EBC Annex 60 [15], therefore some models will be found as well in the main library IBPSA [14]. The HP model depends on tabulated data as stated by EN 14511 [16]. The model uses both black-box and grey-box modeling approaches. The first is used for the refrigerant circuit, whilst the latter is used for the remaining model parts. This means that thermal capacities, heat losses and pressure drops of the heat exchangers at both sides of the heat pump, condenser (con) and evaporator (eva), are implemented as grey-box approach in the model. A variable compressor speed signal represents one mandatory and time variable input to the model. A PT1 element of the model characterizes the dynamic behavior of start-up and shut-off phases of the compressor. The heat losses at the condenser to the atmosphere is parametrized by the combination of a thermal resistance-capacity model. Furthermore, in order to be able to model the temperature change due to heat losses in connected piping – even when there is no circulating fluid – a time constant in the temperature sensor can be defined in the corresponding Modelica model.

Furthermore, the simulation setup, consists of the HP model and the following three main components. The models are a 46 l buffer tank for hydraulic decoupling between the loading and the heating circuit (HC), a loading pump that allows the heating water to flow through the condenser, and a fan on the evaporator side. The storage model is discretized into three volumes.

2.4. Framework

As described above, this work is primarily concerned with structuring a calibration process based on Modelica models. For this reason, a two-part internal institute framework consisting of a Python-based and a

Modelica-based part was set up. The Python part is called AixCaliBuHA and stands for "**Aix** (from French Aix-la-Chapelle) **Cali**bration for **Bu**ilding and **H**VA**C** Systems". The Modelica part is a library of templates called MoCaTe and stands for "**Mo**delica **Ca**libration **Te**mplates". The template models of the library allow to be filled with arbitrary models, but designate certain inputs and outputs, which are needed for each calibration procedure (compare Figure 2). In the general pre-processing phase e.g. low pass filters or moving averages can be applied to the time series data. In terms of variable declaration, a fixed naming specifies the following three vectors, which contain the variables necessary for calibration and occur in every calibration: „Measured inputs" (mi), „Target values measured" (tv_{meas}) und „Target values simulated" (tv_{sim}). The latter two are compared in the objective function to be minimized and a misfit measure is formed. AixCaliBuHA allows the following misfit measures by default: Mean-absolute error (MAE), mean-square error (MSE), root-mean-square error (RMSE), coefficient of variation of the RMSE (CV(RMSE)), normalized RMSE, coefficient of determination (R^2). In the case of the present work it is the weighted chaining of CV(RMSE) [17]. The CV(RMSE) is defined as follows:

$$CV(RMSE) = \frac{\sqrt{1/n \cdot \sum_{j=1}^{n} (tv_{meas} - tv_{sim})^2}}{\overline{tv}_{meas}} \tag{1}$$

With n as the number of data points in the time series and $\overline{tv}_{\mathrm{meas}}$ as the arithmetic mean of the measured time series.

The parameterization of AixCaliBuHA provides for the definition of time segments and the definition of tuner parameters for these time classes with associated constraints in the form of minimal and maximal values. Start values can also be assigned. The core of the framework is the optimization of an objective function under consideration of the mentioned constraints. This objective function always calls the simulation necessary for the aimed period, extracts the simulated target values and compares them with the measured target values as calculation of an integral misfit measure. In the scope of this work this is the CV(RMSE).

The currently implemented optimization algorithms are dlib.find_min_global [18] and scipy.optimize.minimize [19], which in turn allows multiple algorithms. The non-linear optimizer dlib was used in the work. It is important to note that the optimizer cannot only optimize linear problems, since the behavior of the models used is usually non-linear.

In order to describe the dlib library, which provides a Python application programming interface, I quote the description from the website [18]: "Dlib is a modern C++ toolkit containing machine learning algorithms and tools for creating complex software in C++ to solve real world problems. It is used in both industry and academia in a wide range of domains including robotics, embedded devices, mobile phones, and large high performance computing environments. Dlib's open source licensing allows you to use it in any application, free of charge."

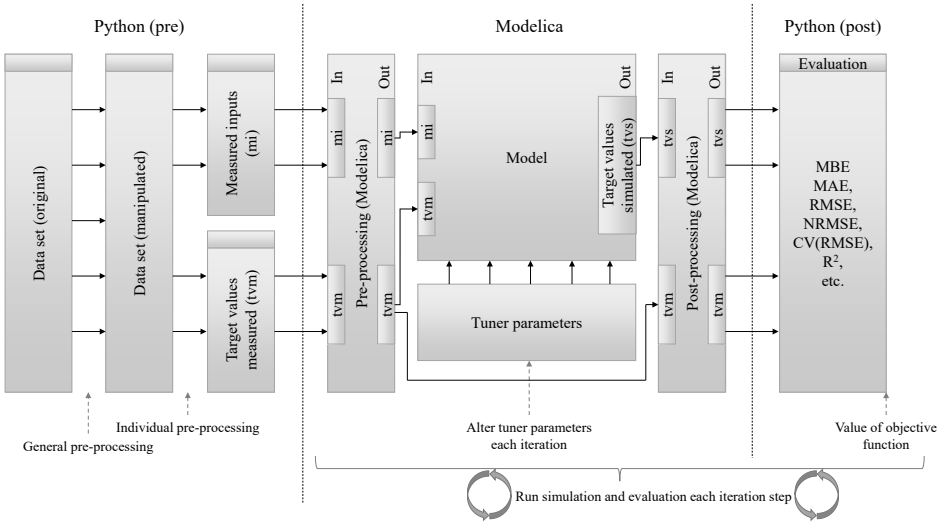

Figure 2: Overview and temporal representation of toolchain

In Modelica, the explicit statement "Evaluate=false" must be in the annotation of all tuner parameters. This ensures that the compiler excludes the parameter from the symbolic pre-processing. In some cases, however, this is not possible, namely when so-called structural parameters are involved which change the system of equations in a structural way. In these cases, the entire model must be recompiled each time in each iteration step of the optimization, which results in a significantly greater expenditure of time. The framework checks if all tuner parameters can be excluded from the symbolic pre-processing of the compilation and informs the user if this is not possible.

Finally, it should be said that the partial framework AixCaliBuHA can be fed with arbitrary forms of models. The use of Modelica models is only the choice during this work. It is therefore conceivable to use Functional Mock-Up Units [20] or models written in other programming languages that can be placed in the AixCaliBuHA framework via defined inputs and outputs.

3. Carrying out the calibration

The target values (tv) are on the one hand the **heating circuit flow temperature** $\boldsymbol{T_{HC,flow}}$ and on the other hand the total **electrical power consumption** $\boldsymbol{P_{el}}$ of the system including powers consumed by fan, pump, controller unit and compressor. The total objective function to be minimized is composed of the chain approach:

$$min \sum f_{tv_i} \cdot CV(RMSE)(tv_i) \;\forall\; tv_i \in \{T_{HC,flow}, P_{el}\} \tag{2}$$

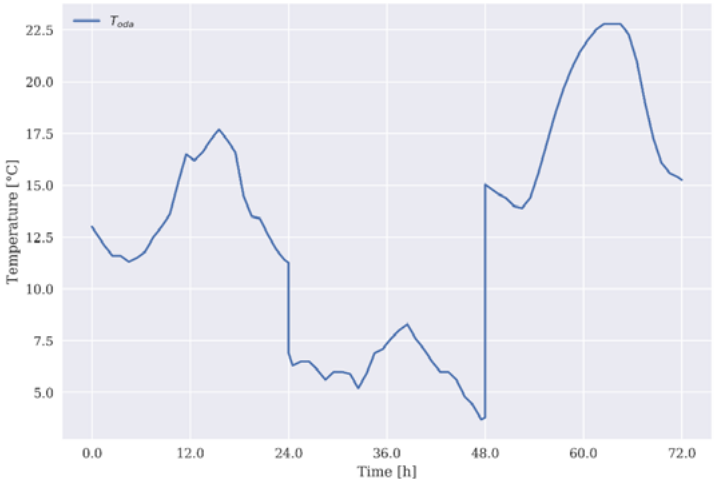

Figure 3: Outdoor air temperature T_{oda} that was emulated by the climatic chamber

Under the premise that the sum of all f_{tv_i} equals 1. The aim is to weight the two targets equally. For this reason, both terms must be in the same order of magnitude, for which a sensible choice of the factors f_{tv_i} is done. For this purpose, we conducted a preliminary investigation that the order of magnitude of $\mathrm{CV(RMSE)}(T_{\mathrm{HC,flow}})$ lies at approximately 0.01 and that of $\mathrm{CV(RMSE)}(P_{\mathrm{el}})$ is about 0.2. Therefore, the factors are $f_{T_{\mathrm{HC,flow}}} = 19/20$ and $f_{P_{\mathrm{el}}} = 1/20$, in order to ensure approximately equal weighting.

The time series data refer to three experimental days in the hardware-in-the-loop test mentioned above. Figure 3 displays the curves of the outside temperature, emulated by the climatic chamber. The test days come from an autumn, winter and summer day and are representative and realistic.

The following variables represent time series variables as „Measured inputs“ given with a brief description each:

- `nSpeedFanEva_1_0`: Relative fan speed (either 0 or 1)
- `TEva_K`: Outdoor air temperature emulated and measured in climatic chamber
- `THCRet_K`: Return temperature of heating circuit measured at hydraulic test bench
- `nSpeedPumpCon_1_0`: Relative pump speed of supply / loading pump near condenser (either 0 or 1)
- `m_flowHC_kg_s`: Mass flow rate through heating circuit measured by hydraulic test bench
- `nSpeedHP_invCtrld_0_1`: Relative and variable compressor speed with a minimum threshold of 25 %

The following variables represent the „Tuner parameters“:

- `scaleHPQCon_nominal`: Scaling factor for tabulated data of default thermal powers for the HP model
- `scaleHPPEl_nominal`: Scaling factor for tabulated data of default electrical powers for the HP model
- `mCon_flow_nominal`: Nominal mass flow rate on water side of the condenser (condenser model derives nominal pressure drop and heat transfer capabilities from this value)
- `mHC_flow_nominal`: Nominal mass flow rate on air side of the evaporator (evaporator model derives nominal pressure drop and heat transfer capabilities from this value)
- `fQWarm`: Additional scaling factor for thermal powers in the range of $T_{\mathrm{oda}} \geq 12\ °\mathrm{C}$
- `fQMed`: Additional scaling factor for thermal powers in the range of $2\ °\mathrm{C} < T_{\mathrm{oda}} < 12\ °\mathrm{C}$
- `fQCold`: Additional scaling factor for thermal powers in the range of $T_{\mathrm{oda}} \leq 2\ °\mathrm{C}$
- `fPWarm`: Additional scaling factor for electrical powers in the range of $T_{\mathrm{oda}} \geq 12\ °\mathrm{C}$
- `fPMed`: Additional scaling factor for electrical powers in the range of $2\ °\mathrm{C} < T_{\mathrm{oda}} < 12\ °\mathrm{C}$
- `fPCold`: Additional scaling factor for electrical powers in the range of $T_{\mathrm{oda}} \leq 2\ °\mathrm{C}$

- `T_fixAmbTestHall`: Assumed temperature in the test hall, wo which indoor unit, most piping and sensors were exposed to and transferred heat to as losses
- `lambdaIns`: Thermal conductivity of buffer storage envelope
- `tauVolCon`: Time constant that scales the assumed condenser volume of the HP model

In terms of the measured inputs, we conduct chosen individual pre-processing like in the step in Figure 2 states. This is necessary since we do not have all the necessary knowledge of all operational states of the HP For example, we derive the fan speed `nSpeedFanEva_1_0` as well as the pump speed `nSpeedPumpCon_1_0` from one phase of the monitored electrical power consumption. This means the fan and pump is enabled when the power consumption exceeds a threshold of 0.5 % of maximal power. Furthermore, we gain the relative and modulating compressor speed `nSpeedHP_invCtrld_0_1` by normalizing the total electrical power between its maximum and minimum for each day. It is necessary to distinguish between the days and, thus, in a certain way between the outdoor temperature since this mainly determines the level of power consumption.

4. Results

4.1. Training

The plot of the objective function's values in Figure 4 shows that already from approximately iteration 50 onwards the deviation mainly lies below 0.02.

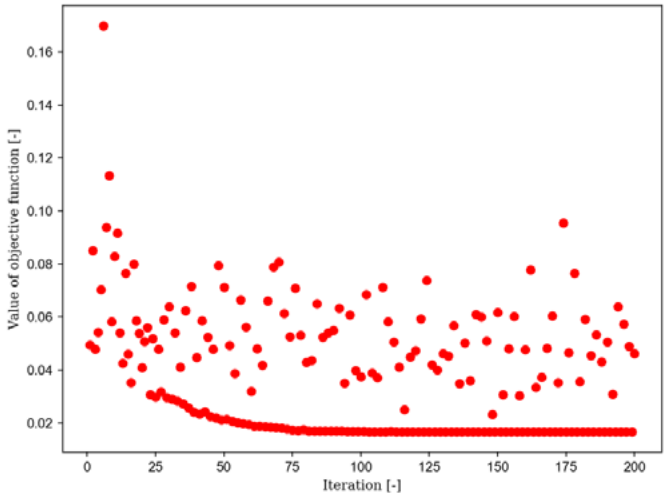

Figure 4: Progress of the objective function's values over iteration steps (training phase)

Figure 5 shows the measured and simulated target values for the 1.5 day-long training phase. The behavior of the dynamics fits predominantly well. In particular with regard to $T_{\mathrm{HC,flow}}$, in some places deviations become apparent, which can be explained with a high degree of probability by the control that was not transferred from real experiment into the simulation domain. In contrast, during the experiments the control of the HP system was active, including pump's pre- and post-run times, heating rod control, partial DHW tank charging. For the calibration, a speed control for the inverter-controlled compressor was derived from the power consumption only. The following target value function results from a quantitative point of view:

$$\left[f_{T_{HC,flow}} \cdot CV(RMSE)\left(T_{HC,flow}\right) + f_{P_{el}} \cdot CV(RMSE)(P_{el})\right]_{Training} \tag{3}$$

$$= \frac{19}{20} \cdot 0.0090 + \frac{1}{20} \cdot 0.1463 = \mathbf{0.0158} \tag{4}$$

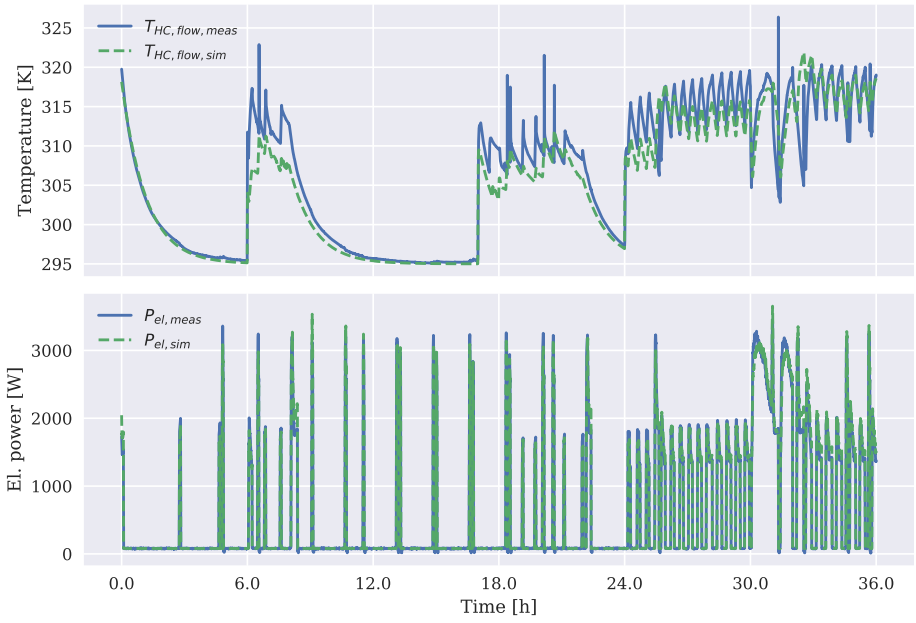

Figure 5: Curves of target values plotted for training data (day 1 and first half of day 2)

Table 1 shows the finally selected tuner parameters' values that the optimization algorithm found. The development of the tuner parameters' value search displays Figure 6.

Table 1: Final values of optimized tuner parameters

scaleHPQCon_nominal [-]	**scaleHPPEl_nominal [-]**	**fQWarm [-]**	**fQMed [-]**	**fQCold [-]**	**T_fixAmbTestHall [K]**	
0.82	0.70	0.77	1.31	1.76	295.45	
mCon_flow_nominal [kg/s]	**mHC_flow_nominal [kg/s]**	**fPWarm [-]**	**fPMed [-]**	**fPCold [-]**	**lambdaIns [W/m/K]**	**tauVolCon [s]**
0.34	0.49	1.97	1.77	1.94	0.15	150.00

4.2. Validation

The data set for the validation consists of two partial days. On the one hand from the second half of the winter day (day 2) and on the other hand a part from the summer day (day 3), since this has a similar behavior to the transition day (day 1). However, the first 25 % of the summer day were excluded from the validation data as there is an incomprehensible discrepancy between measured and simulated values of the target values. This probably stems from a control strategy such as the use of the heating rod, which we could no longer clearly prove from the experimental documentation at the time of calibration. The hardware-in-the-loop tests were performed several months before calibration and the system was already dismantled. The experiments were selected because of their very high measurement resolution of 1 s, as they provide a good basis for calibrating transient models. However, we did not conduct the experiments with this aim in mind.

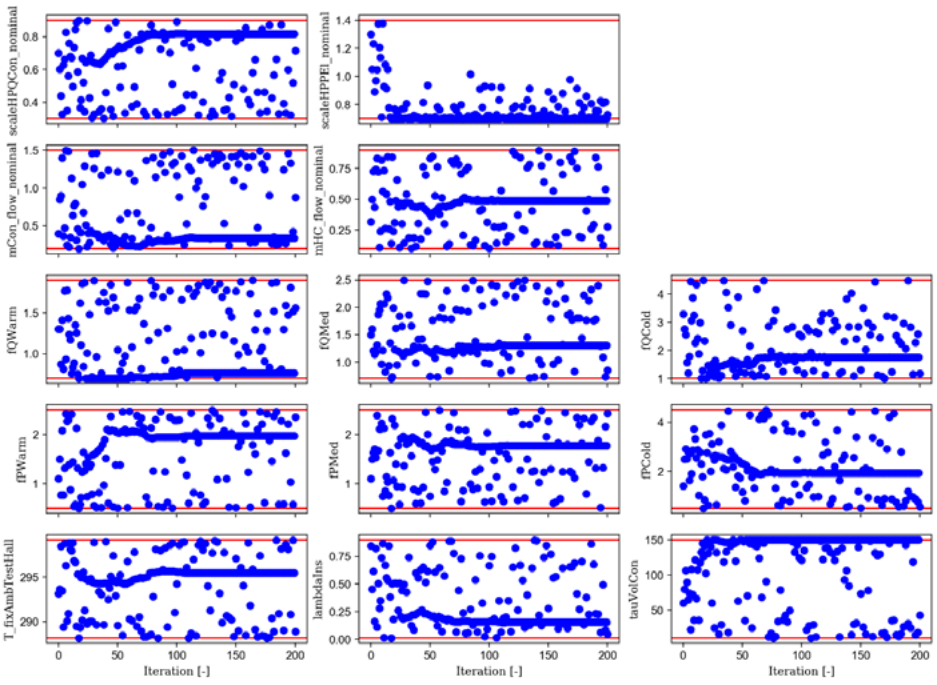

Figure 6: Process of the tuner parameters' value during optimization (red lines: minimal and maximal boundaries)

Figure 7 shows the measured and simulated target values for the two periods mentioned above. Hereby, the time series parts of day 2 and day 3 are concatenated.

The calculation of the value of the combined objective function looks as follows:

$$\left[f_{T_{HC,flow}} \cdot CV(RMSE)\left(T_{HC,flow}\right) + f_{P_{el}} \cdot CV(RMSE)(P_{el})\right]_{Validation} \tag{5}$$

$$= \frac{19}{20} \cdot 0.0085 + \frac{1}{20} \cdot 0.1343 = \mathbf{0.0148} \tag{6}$$

5. Conclusions

In the scope of this work, we develop and present a toolchain to calibrate transient simulation models of HVAC plants. This framework is preliminary based on the programming language and can be interfaced to a sub-framework of the simulation model. In the case of this work this is the open-source and object-oriented modelling language Modelica. The calibration framework provides general as well as individual pre-processing possibilities and multiple evaluation strategies with focus on time series data. These evaluation strategies create key performance indicators by comparing the measured to the simulated time series of defined target values. These key performance indicators are meant to be minimized by one of the implemented optimizers.

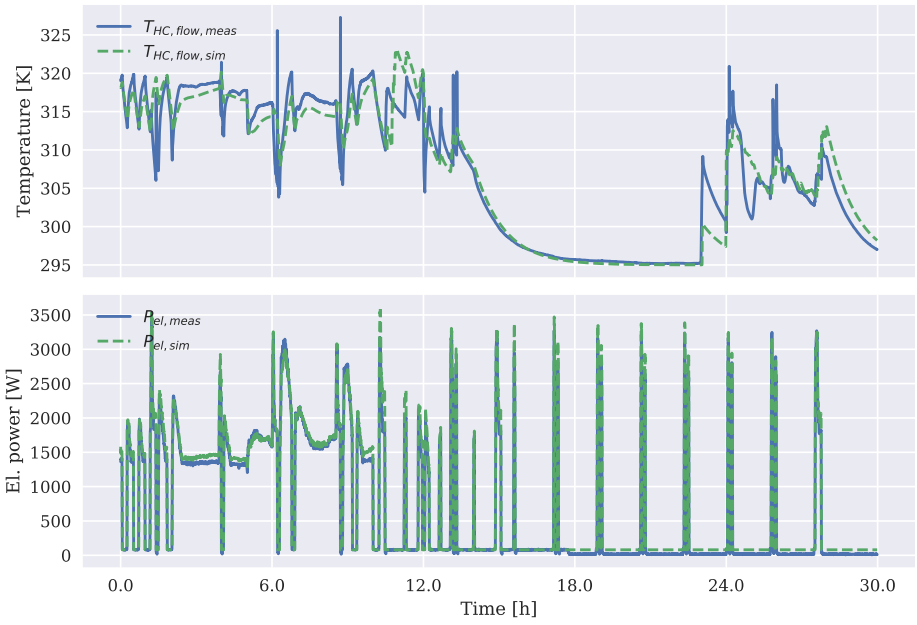

Figure 7: Curves of target values plotted for validation data (part of day 2 and 3 concatenated)

The use case is the calibration of an air-to-water heat pump, of which we gained high-frequent measurement data of a hardware-in-the-loop test that we conducted in our institute's laboratory. Since the boundary conditions of this 3-day long experiment are volatile and covering a broad range, e.g. in terms of outdoor air temperature, the data suits well for the application in a calibration process.

To calibrate the air-source heat pump we split the measurement time series into 60 % training and 40 % validation data. With 200 Iterations for calibrating the model on the basis of the chosen training set, we achieve a coefficient of variation of the root-mean-square error CV(RMSE) = 0.0158. For this purpose, we use 13 tuner parameters. The validation reaches an even better value of CV(RMSE) = 0.0148. Whilst the target value P_{el} (electrical power consumption) shows a satisfying congruence in terms of dynamics and level of the values, the other target value $T_{HC,flow}$ (heating circuit's flow temperature) displays in the time series plot solely in terms of dynamics good results. Offsets within certain time spans are probably due to neglecting control phenomena during the calibration process.

Especially the latter mentioned effect asks for further improvement of the process. The suggestion is to have individual calibrations for individual components like the heat pump unit itself, the hot water storages and the controller. For this reason, monitoring equipment must be installed with focus for a feasible calibration. Furthermore, the calibration of a controller is a challenging task due to lots of binary states like mode for domestic hot water or space heating.

High temperature heat pumps for drying – first results of operation in industrial environment

Veronika Wilk[a*], Franz Helminger[a], Michael Lauermann[a], Andreas Sporr[a], Bernd Windholz[a]

[a]AIT Austrian Institute of Technology GmbH, Giefinggasse 2, 1210 Vienna, Austria

Abstract

Heat pumps make an important contribution to increasing the efficiency of industrial processes and avoiding CO_2 emissions and therefore are considered as an important element for industrial heat supply by valorizing waste heat. Heat utilisation temperatures above 120°C will significantly expand the field of application for heat pumps in industry. This article presents the first results of operation of the H2020 project DryFiciency. Closed loop high temperature heat pumps with a heating capacity of 400 kW and heat supply temperatures up to 160°C are being developed, built and operated. The heat pumps are integrated in industrial drying processes recovering waste heat available on site. In this article, a first assessment of the operation of the heat pump for brick drying at Wienerberger AG in Uttendorf (Austria) is presented.

Keywords: High temperature heat pumps; industrial application; drying; HFO refrigerant; demonstation

1. Introduction

Decarbonization of industrial production is a key element to achieve the climate goals of the European Union. This requires drastic reduction of energy consumption and CO_2 emissions, as well as the transition to renewable energy supply. Increasing energy efficiency of industrial processes will contribute significantly to achieve these goals, however, new processes are also needed, such as electrification to replace fossil energy supply. Industrial heat pumps enable both, efficiency increase and electrification and will therefore play a major role in the future energy system.

Although heat pumps are an established technology for domestic heating and hot water preparation, integration of heat pumps into industrial processes is still in an early diffusion phase. Currently, there is no statistical data available on how many heat pumps are already applied in industry. In the framework of the collaborative IEA HPT Annex 48 project, more than 300 application examples for industrial heat pumps were collected from 7 countries. [1] These heat pumps are applied in many different industrial sectors. For example, in Austria a large number of examples is reported for the food industry, utilities and metal processing industry. The heat supply temperatures of the heat pumps in the examples are in the range of 45-95 °C, which corresponds to the products available on the market. Heat pumps supplying that temperature range have been available on the market for many years. [2]

In the last years, new developments have raised the heat supply temperature to more than 100 °C. With heat pumps that deliver high temperature heat up to 160 °C, a larger range of applications in industry can be covered. However, there are some barriers that still slow down the diffusion of heat pumps in industry despite the great application potential. Arpagaus [3] summarized the findings of several studies on market barriers for industrial heat pumps: There are important economic barriers, such as stringent expectations of short payback periods

E-mail address: veronika.wilk@ait.ac.at

by industry and competing heating technologies based on fossil fuels at low energy prices. But there are also barriers related to knowledge and trust in a new technology: low level of awareness of the technical possibilities due to further development, lack of knowledge about the integration into industrial processes and lack of pilot and demonstration systems. [3]

Industrial demonstration projects are an important step to address the knowledge-related barriers. Within DryFiciency, an H2020 project, heat pumps for drying processes are developed, constructed and operated in a real industrial environment. Drying processes are among the most energy intense processes; they are wide spread in industry and mostly fired with fossil fuels. The heat pumps are used to recover waste heat that is available at the industrial sites and upgrade it to process heat for drying at temperatures up to 160 °C. In the project, different types of heat pumps are developed: heat pumps for air drying processes based on a closed loop vapor compression system and heat pumps for steam drying based on an open loop mechanical vapor recompression system. The heat pumps for air drying are demonstrated in a starch drying process of Agrana Stärke GmbH, an Austrian company specialized in processing and refining of agricultural raw materials such as corn, wheat and potatoes; and in a brick dryer of Wienerberger AG, the world's largest brick producer. The open loop heat pump for steam drying is demonstrated in a batch dryer for sludge of Scanship Holding AS in Drammen/Norway. First, the industrial drying processes were analyzed in detail, then, the heat pumps and their system integration were designed. A special focus was placed on the selection of materials and compounds to ensure stability and reliability at the demanding conditions of the high temperature applications. The heat pumps were constructed and integrated at the industrial sites. Commissioning of the heat pumps started in November 2019. In this work, a first assessment of the operation of one of the DryFiciency heat pumps are presented: the closed loop heat pump for brick drying at Wienerberger.

2. Brick drying process with heat pump

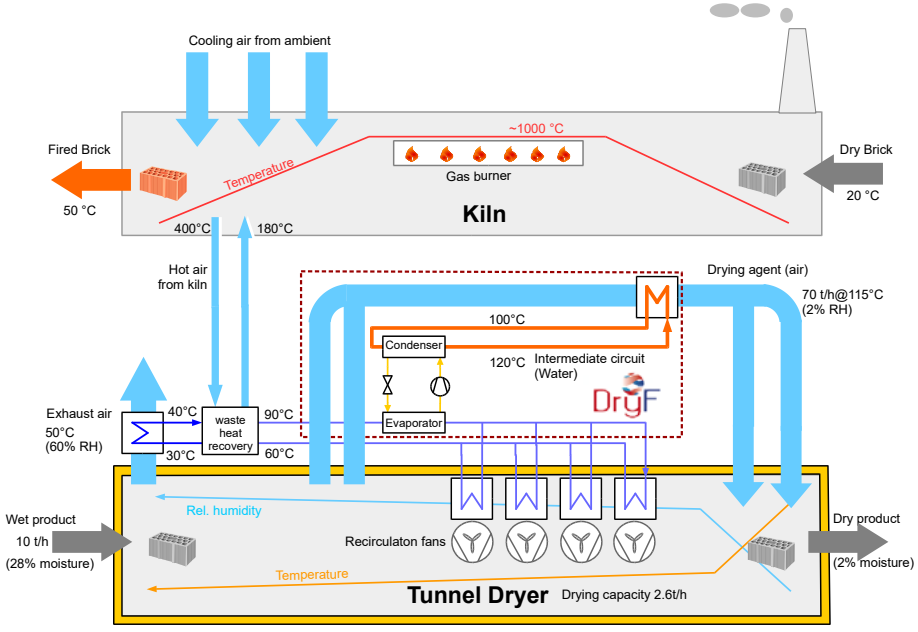

Fig. 1. Illustration of brick drying process at Wienerberger with the DryFiciency heat pump, the indicated temperatures values of the intermediate circuit and the drying agent show the design operating point for the DryFiciency heat pump, the thin red line in the kiln indicates the temperature profile in the kiln, the thin blue and orange lines the temperature and moisture profile in the tunnel dryer.

Wienerberger operates approx. 200 brick dryers in its manufacturing units worldwide. The DryFiciency heat pump was integrated at the production site in Uttendorf in Austria.

In general, the production of bricks and other clay products can be divided into several steps: preparation of the raw materials, shaping of the bricks, drying and firing. The drying process prepares the bricks for firing by extracting moisture from the soft shaped bricks. The shaped bricks (so-called "green" bricks) with a

moisture content of around 28 % are dried to a moisture content of 2 % required at the entrance of the kiln. Drying is the most energy intensive step in the brick production process.

The dryer, the kiln and the heat pump are illustrated in Fig. 1. It is a continuous drying process in a tunnel dryer using air as drying agent flowing counter-currently to the bricks. Drying air is heated by internal heat exchanger surfaces in the tunnel, which are supplied with water with 90 °C by a heat recovery cycle. The heat pump also uses the heat recovery cycle as the heat source. The evaporator of the heat pump is installed before the heat exchangers. The heat pump provides hot air via an intermediate circuit, heat supply temperatures up to 160 °C can be reached there. The hot air is fed into the outlet zone of the tunnel dryer, where the highest temperatures are required. The heat pump acts as a booster for the heat recovery cycle. It replaces a natural gas burner, that was used for that purpose.

2.1. Heat pump and integration infrastructure

The heat pump is designed as a closed loop compression heat pump with a heating capacity of up to 400 kW. R-1336-mzz(Z) by Chemours is used as refrigerant, it is based on HFO (hydrofluoro-olefins). The refrigerant has been already successfully tested at AIT in a lab-scale heat pump prototype for high temperature applications up to 160 °C. [4]. It has a low GWP value of 2 (global warming potential) and is non-flammable, non-toxic and not subject to the F-gas regulation.

The piston compressors integrated in the demonstrator were developed and supplied by Viking Heat Engines AS. The compressor design is based on an ORC (Organic Rankine Cycle) expander used for heat recovery applications with an overall design temperature of 215 °C. The expander has already been extensively tested at high temperatures and achieves high efficiencies. The compressor designed is 90 % the same as the ORC expander and built on the same piston bottom-end, only the cylinder head is different. Over the past five years the piston expander has undergone a comprehensive development program to achieve a long service life and high durability at very high temperatures. Today, this piston machine technology is equally capable of operating in organic Rankine cycles (ORC) as well as vapor compression heat pump systems. The compressor is designed for use with R-1336-mzz(Z). A single piston compressor has a swept volume of 55 m^3/h at 1800 rpm. A total of eight compressors arranged in two modules of four are used. Fuchs Schmierstoffe GmbH has developed a suitable lubricant for the compressors, which fulfils all necessary requirements regarding lubrication, viscosity, and thermal and chemical stability together with the refrigerant.

The heat pump is designed as a twin cycle system consisting of two refrigerant cycles (see also Fig. 5). The condensers of the two cycles are connected in series. Thus, the temperature lift from the heat source to the heat sink is reduced to a certain extend for one of the two cycles and about one half of the heating capacity is provided at a higher COP (coefficient of performance). In each refrigerant cycle there is one compressor module with four compressors. Due to the thermodynamic properties of the refrigerant, an internal suction gas heat exchanger is used to ensure dry compression.

The heat pump is placed in a container with approximately 8 m in length and 3 m in height and width. It is equipped with eight doors to enable easy access and if necessary, replacement of components of the heat pump. It contains all piping and other connections that are needed to connect the heat pump with the integration infrastructure at the brick dryer. Fig. 2 and Fig. 3 show the heat pump container from the outside and with open doors. The heat pump itself consists of hundreds of single parts of the following main component categories:

- Components for the refrigerant cycles such as piston compressors, condensers, evaporators, etc.
- Components for water distribution for the heat source and heat sink including control and safety valves, metal bellows compensator, etc.
- Housing including refrigeration machinery room equipment like ventilation, leakage detection system and warning devices
- Control system including cabinet, programmable controller, frequency converters, electrical fuses, control transformer, visualization, data logging and data transfer equipment to allow profound monitoring activities
- Measurement devices

Fig. 2: Heat Pump Container (outside)

Fig. 3: Heat Pump Container (inside, before insulation)

As illustrated in Fig. 1, the heat pump is integrated into the drying process by an intermediate water circuit. The water circuit allows testing a wide range of heat supply temperatures from 110 – 160 °C. In the intermediate circuit, a pressure holding device including a circulation pump and a water-to-air heat exchanger (air register) are installed.

2.2. Measurement equipment

Monitoring, data logging and data transfer are separated into two parts, one with the existing process control system of Wienerberger, where also the integration infrastructure (intermediate water circuit, air register and heat source) belongs to, and the other one of the DryFiciency heat pump. Both process control systems have their own measurement points and separate data transfer to AIT.

The heat pump is equipped with numerous sensors for data monitoring. Temperature sensors are integrated at all important parts of the refrigerant cycles, for example at the condensers, the internal heat exchanger, the expansion valve, the evaporators and the compressors. Pressure sensors are located among others before and after the compressors, at the inlet of the condensers and before the expansion valves. Electricity consumption of the motors is measured in terms of power, energy, voltage, current and power factor. In addition, heat meters to monitor the heat source and the heat sink are integrated.

Numerous parameters of the drying process from the existing process control system are used to determine the impact of the heat pump on the brick production process. The following parameters from the tunnel dryer are used: Volume flow of drying air into the dryer, inlet and outlet conditions of the air in the dryer, inlet and outlet temperature and mass flow of hot water used in the heat exchanger to heat the tunnel dryer, mass flow of wet bricks, mass reduction of bricks from inlet to outlet of the dryer.

3. Results

During commissioning, a trial operation of the heat pump system is carried out to provide proof of operational safety and functional capability. Also, the quality of the heat pump system is assessed based on fundamental functional tests according to predefined operating conditions to test the control algorithms, compressor lubrication, oil separation, operating temperatures of the compressors the suction gas super heating and part load conditions. The successful completion of the trial operation is the end of the commissioning and an important prerequisite for the subsequent long-term monitoring. Four different operation conditions are described in more detail that are characterized by different heat supply temperatures: 120, 140, 150 and 160 °C (Table 1).

Table 1: Operation points during trial operation

Operation point	Heat sink inlet temp., °C	Heat sink outlet temp., °C
1	95	120
2	110	140
3	120	150
4	130	160

Fig. 4 illustrates the heat source and heat sink inlet and outlet temperatures for the four operation points. The yellow area indicates the preparation phase, the green area stationary operation. For OP1, 2 and 3, stationary operation lasted more than three hours and did not show any fluctuations in the heat source and heat sink. For OP4, operation was shorter and lasted about one hour. The heat source inlet temperature was 88 °C for all operation points. The complete heat source mass flow was used for the heat pump without flow regulation, as a result, the heat source was cooled by 3 – 6 K.

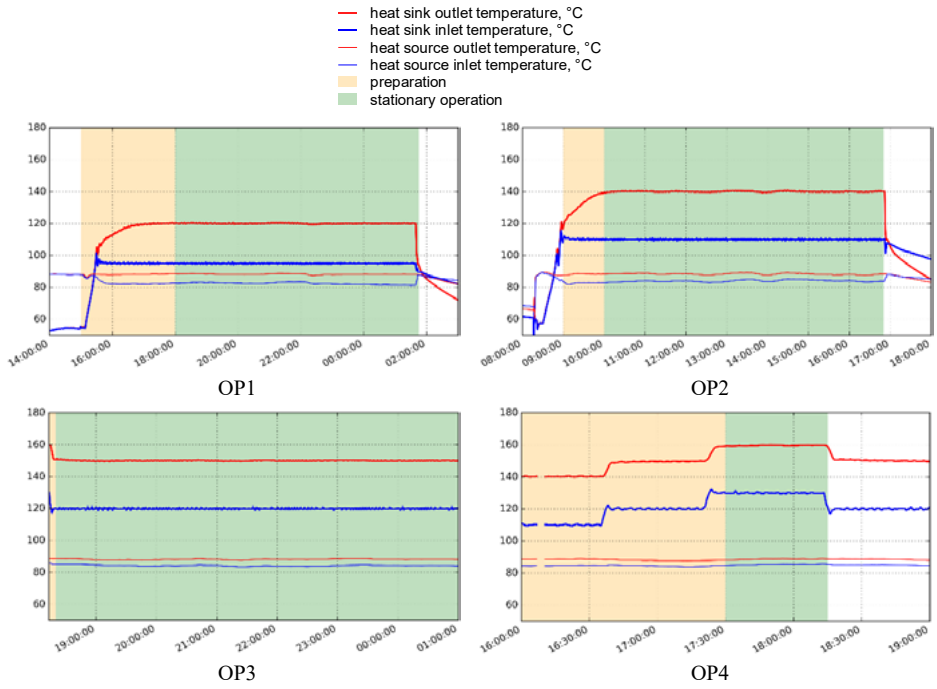

Fig. 4: Time series diagrams for four different operation points (120, 140, 150 and 160 °C)

As previously mentioned, the DryFiciency heat pump is designed as a twin cycle system consisting of two refrigerant cycles. The layout is shown in Fig. 5. The condensers of the two cycles are connected in series, therefore the condensation temperature of cycle 1 (yellow) is lower than the condensation temperature of cycle 2 (orange). The evaporators can be either operated in series or parallel. For the trial operation, they were operated in parallel. Fig. 6 shows the log(p)-h diagram for both cycles for OP1 (120 °C). The section 1-2 takes place in the compressor, 2-3 in the condenser, 3-4 in the sub-cooler, 4-5 at the hot side of the internal heat exchanger (IHX), 5-6 in the expansion valve, 6-7 in the evaporator and 7-1at the cold side of the internal heat exchanger. Due to the sub-cooler, more heat can be supplied to the industrial process. The sub-cooler is integrated between the condenser and the internal heat exchanger (not illustrated in Fig. 5). In cycle 2, more heat is provided in the sub-cooler than in cycle 1. For both cycles, the evaporation temperature amounted to 78 °C. As indicated by point 7, the refrigerant leaves the evaporator with super heat. The internal heat exchanger increases the efficiency by transferring heat from the high pressure side to the low pressure side of the heat pump. Point 1 and 2 indicate the satisfying function of the super heat control to ensure dry compression. The difference in condensation temperature between cycle 1 and cycle 2 was 10 K.

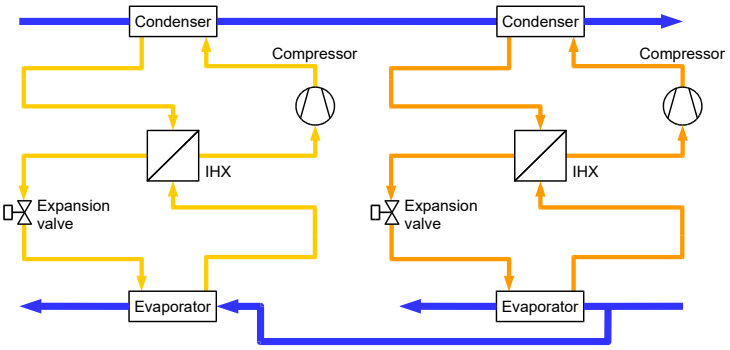

Fig. 5: Layout of the DryFiciency heat pump (yellow = cycle 1, orange = cycle 2)

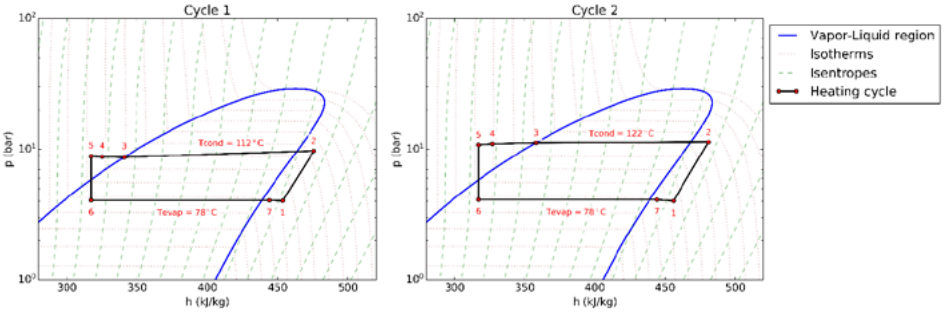

Fig. 6: Log(p)-h diagram for cycle 1 and 2 of the heat pump, OP1 (120 °C)

OP2, OP3 and OP4 show similar behavior as illustrated in Fig. 7, Fig. 9 and Fig. 10. With increasing temperature lift, more compressor work is needed to achieve higher discharge pressures. At a heat supply temperature of 160 °C, condensation takes place at the upper end of the vapor dome close to the critical point. With increase in supply temperature, the beneficial effect of the internal heat exchanger becomes more apparent. More superheat is needed at higher temperatures because of the shape of the vapor dome of R-1336mzz(Z).

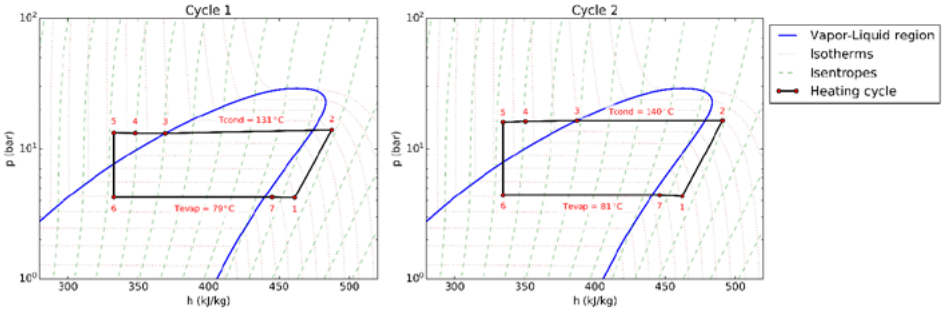

Fig. 7: Log(p)-h diagram for cycle 1 and 2 of the heat pump, OP2 (140 °C)

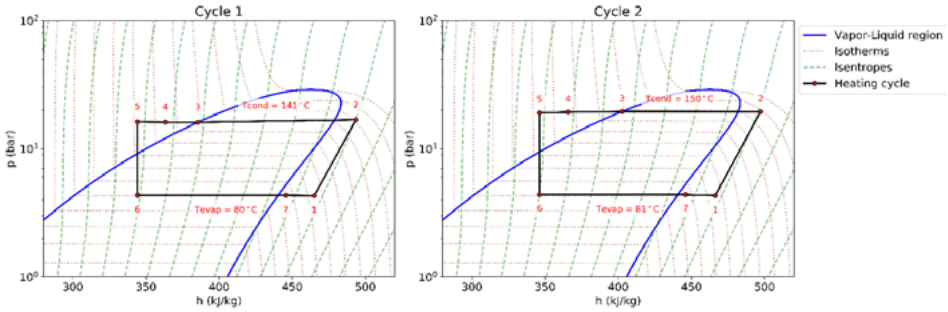

Fig. 8: Log(p)-h diagram for cycle 1 and 2 of the heat pump, OP3 (150 °C)

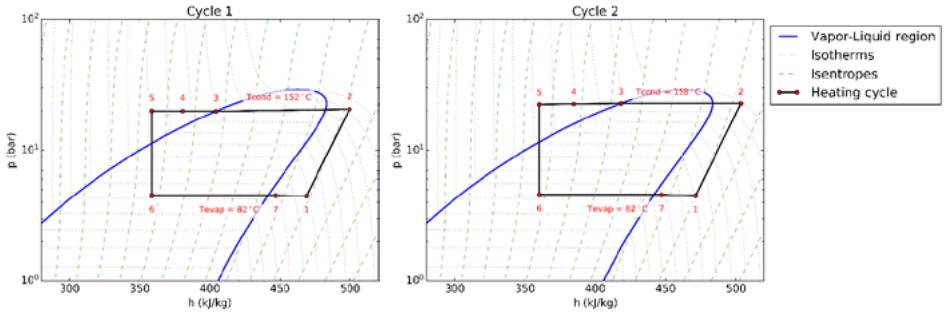

Fig. 9: Log(p)-h diagram for cycle 1 and 2 of the heat pump, OP3 (160 °C)

In Table 2, energy flows, mass flows and temperatures are compiled for the trial operation. The compressors were operated at 1500 rpm. Q_{heat} is the sum of the heat transferred to the industrial process in the condenser and in the sub-cooler, ranging from 200 – 300 kW for the trial operation. Q_{cool} is the heat extracted from the heat source in the evaporator, ranging from 150 – 240 kW. For OP1, the COP is the highest due to the smallest temperature lift of 40 K. It amounted to 4.65. At OP4 (heat sink outlet temperature of 160°C), the COP was 2.66.

In Fig. 9, the DryFiciency heat pump is compared with various other industrial high temperature heat pumps that were compiled by Arpagaus [3]. Data comprises heat pumps by different manufacturers, such as Kobelco, Viking Heat Engines, Ochsner, Friotherm, Combitherm, GEA, Star Refrigeration, etc. All these heat pumps have heat supply temperatures exceeding 90 °C covering the whole range of heating capacities from 30 kW to more than 10 MW. The lines in Fig. 10 indicate the COP of a heat pump with heat supply temperatures of 120 °C and 160 °C that reaches 50 % of the COP of the ideal Carnot process (Second law efficiency). The COP of the DryFiciency heat pump is in good agreement with efficiency data from the other industrial heat pumps and ranges among the higher values that were reported. The second law efficiency of the DryFiciency heat pump is in the range of 50 %. The comparison shows that the trial operation of the DryFiciency heat pump was highly satisfactory.

Table 2: Operation points during trial operation

OP	Qheat, kW	Qcool, kW	Pel, kW	COP	Vsink, m³/h	Vsource, m³/h	Tsink_in, °C	Tsink_out, °C	Tsource_in, °C	dTsource, K
1	281.7	239.0	60.6	4.65	9.9	33.3	95.8	120.9	88.3	6.5
2	254.0	208.5	68.5	3.71	7.5	45.5	110.7	140.9	88.4	4.2
3	221.2	174.3	69.6	3.18	6.5	37.6	120.7	150.9	88.4	4.3
4	195.9	148.4	73.8	2.66	5.9	42.3	130.7	160.7	88.6	3.3

4. Conclusion

In this article, a first assessment of the operation of the DryFiciency heat pump for brick drying at Wienerberger AG in Uttendorf (Austria) is presented. It was commissioned in November 2019 recovering waste heat at around 90 °C and providing hot air for the brick dryer. It is the first demonstration of a high temperature heat pump in real industrial environment providing up to 160 °C. During trial operation, the basic functionality of the heat pump was assessed. Four different operation points with varying heat supply temperatures were analyzed in more detail. Trial operation proved that the heat pump is working in stationary conditions without any fluctuations of the heat source or heat sink covering the whole range of 120 – 160 °C. Due to the twin cycle layout of the refrigerant cycle, the condensers are arranged in series with a temperature difference of 10 K in condensing temperature. Suction gas and discharge gas super heat are important to ensure dry compression because of the thermodynamic properties of the refrigerant. An internal heat exchanger provides the super heat and increases the efficiency of the refrigerant cycle. A comparison of the COP of the DryFiciency heat pump and various other industrial high temperature heat pumps confirms that the DryFiciency heat pump is among the most efficient devices. The results of the trial operation prove that brick drying is more efficient when using a high temperature heat pump, because it decreases energy consumption and provides a higher drying air temperature in the final drying zone in the brick dryer. Future work focuses on long term stability of the heat pump and its components such as refrigerant, lubricant and compressors.

Abstract

Passive houses linked to more efficient heating and cooling technologies have been one of the focus in last years. However, to close the loop of the building sector, there is still one open source: wasted heat from grey water. This paper addresses the potentiality of the wasted heat from grey water to produce domestic hot water (DHW) based on a heat pump system. A heat pump designed specifically for that application, a heat recovery heat exchanger and two variable volume storages tanks compose the system. The main objective of this work is to determine the potential of recovering this waste heat source in order to minimize the house energy consumption. An optimization of the size of the different elements and of the operation algorithm of the system has been performed in order to minimize the CO2 emissions and evaluate the maximum potential of the proposed strategy. The potential of using this type of waste heat as a source for heat pump system is demonstrated and could imply a recovery of available energy of up to 60%.

1. Introduction

In recent years, there has been a great effort in order to reduce the energy consumption in buildings. The main actions have been focused on both, the reduction of heating demand and on the improvement of the technologies used for heating and cooling ends. However, little attention has been paid to the reduction of the energy demand related to DHW production even though, in developed countries, accounts for approximately 15% [1].

Furthermore, 85-90% of the total energy dedicated to hot water production [2] is wasted to the ambient after its use and the recuperation of it has not been explored in depth.

Based on that, the use of high efficient technologies for water heating applications as well as the heat recuperation from warm wastewater can significantly contribute to the reduction of the energy consumption and the GHG emissions associated to the building sector. Heat pumps are the most suitable technology dealing with the mentioned two aspects: high efficiency and the use of medium-low temperature water flows as a heat source.

The main characteristic of this kind of systems are:

a. The heat sink has a high water temperature lift and a high demand variability.

* Corresponding author. Tel.: +34963879123
E-mail address: emilio.navarro@iie.upv.es

b. The heat source has slightly higher temperature than the water from the net (and stable through the year) and high variability.

In order to deal efficiently with the characteristics of the heat sink of this kind of system transcritical CO2 systems or subcritical with subcooling control systems has been used and usually they work against a tank which could absorb the variability. Regarding the other point, it is not so widely analysed in the litreature, heat pumps are able to work properly with the temperatures of the heat source and also a tank could respond to the variability of this source but based on the temperature level to include in the system a heat exchanger recuperator will increase the efficiency of the system. Considering all these factors, at this point, the most critical point about this part of the system is related with the amount of energy available and the optimum way to use it in order to satisfy the demand.

The control strategy plays a key role on the system efficiency. Most works dealing with HPs use pre-defined schedules function of electric tariffs and base their design on that, hiding the real potential of a HP system or even deteriorating the performance by simply avoiding energy aspects[3]. Furthermore, the solutions obtained in that way may be specific just for a specific case. For instance, in [4] the operation of the heat pump is directly driven by the off-peak electricity period or in [5] the majority of the production also takes place in these periods. In [6], the authors analyze under an energy and economic point of view the impact of the operation control of a HP-photovoltaic system concluding that the optimization of energy factors results in a degradation of the economic factor and viceversa. An approach to maximize the energy efficiency and then couple it with specific economic aspects may be more interesting.

The aim of this work is to analyze the influence of the available waste energy in the energy consumption of a DHW system based on heat pumps. To do so, a thermodynamic analysis of the most suitable system able to produce hot water depending on the heat source characteristics is done. As a proof of concept, 20 dwells have been used as an example to develop the proposed methodology. The study considers first an infinite availability of heat source. Thereafter, a finite but constant profile of grey water has been taken into account and finally, profiles based on the grey water produced by the dwells are studied and compared to previous cases.

The considered systems are composed of a heat exchanger regenerator, two water tanks and a heat pump using the control of subcooling to optimize the efficiency working with high water temperature lift in the condenser. The study includes the sizing of the different components (heat pump, recuperator, tanks) and the definition of the optimum control strategy of the system. The obtained results allow quantifying irreversibility added to the system by the use of low-grade heat sources, gives some guidance about its potential that could be used in other works and supplies an estimation about the expected differences in energy consumption associated to the system design and waste heat availability.

2. Methodology

2.1 Heat sink and heat source characterization

This study focuses on DHW production for residential sector. Thus, the heat sink is the end-user hot water demand. A yearly profile for 20 dwellings generated with the stochastic model, DHWcalc [7], has been used. The selected time step has been of 1 minute. This profile includes an estimation of socioeconomic factors and it has been validated with SynPro[8]. The profile is the same as the one used in [9]. The reader is referred to it for further details.

The daily DHW demand is 54.1 l. of water at 45ºC per person and per day. This represents an annual average energy consumption of 576kWh (for a net water temperature of 10ºC). That is, an average water consumption at 45ºC of 105.5 litre per apartment and a total mean water consumption of 2110 litre/day (for 20 dwells).The profile for the water inlet temperature has been determined following the methodology proposed in [10] and used in [8] based on Eq. 1.

$$T_{net} = \overline{T_{amb}} - 3 \cdot \cos\left(\frac{2\pi}{365}\left(n_{day} - n_{days,offset}\right)\right) \quad (1)$$

Where T_{amb} is the mean ambient temperature (10ºC), n_{day} is the day of the year and $n_{daus,offset}$ is the offset, set according to the coldest day of the year.

Regarding the heat source, the grey water production from 20 dwellings has been considered. Grey water includes all water consumptions in a house except that from toilets (black-water) collected before the general sewage system. Due to the scarce information about grey water in the litreature, the estimation of the profiles and its characteristics have been done based on the total average water consumption, the end-use, the typical

temperatures according to its use, the characterization of the DHW load profile and data found in literature.

Germany has been considered as the reference country for the grey load profile used. Furthermore, as the consumption in this country is rather conservative compared to other developed countries, for the potential estimation of heat recovery, which will imply that the obtained results would be conservative. According to [11], the average drinking water consumption in Germany is 123 litre per day and person (240 litre per day and apartment). The final end-mix for the grey water is based on [12]: 15% to shower, 25% to bath, 30% to flush the toilet, 13% to the clothes washing machine, 7% to dishwasher, 6% to hand wash, cleaning and gardening and 4% destined to cook. That is, grey water represents 70% of the total drinking water consumption (168litre per day and apartment).

Furthermore, both streams, DHW and drinking consumption, are related in terms that all DHW mass flow would be part of the grey water. Hence, as the daily average DHW consumption per household is 105.5 litre at 45ºC, the rest would come from the other uses except, toilets.

On the one hand, the grey water from DHW water has been considered to follow the same profile as the DHW but one-minute delayed (time considered between the hot water consumption and its availability as a grey source). These flows have been increased with drinking water (net water) up to the user final temperature demanded (45 ºC).

On the other hand, a profile representing the use of clothes and dish washing machines has been generated with DHWcalc software. Average flow rates, frequency and temperatures have been estimated according to the work presented in [13] and the mentioned drink water consumption.

Table 1 collects the main inputs used in DHWcalc software for the characterization load profile of the clothes and dish machines. An average consumption of 960litre/day, 20 dwells with a daily probability function based on a step function for weekends and weekdays, a 120% probability weekday/weekend and seasonal variations are accounted by means of sinusoidal function have been considered.

Table 1: Drink water use in appliances that do not require DHW inputs for DHWcalc.

Draw-off type	End-use temperature [ºC]	Mass flow [lpm]	Duration [min]	Probability [%]
Dishwasher	65	4.8	1	11
Hot rinse	50	4.2	1.5	15
Cold rinse	45	3.6	1	9
Cloth washer	37	10.2	3	65

From the available data, the authors consider as good estimation the values of the hot water temperature used in the work presented in [13] which have been obtained from a wide literature review and experimental measurements. Table 2 collects the temperature of the end-user used in this work for both types of streams.

Regarding to the temperature of the grey water at the drain, a drop of 7K from the end-user temperature has been estimated regardless the nature of the consumption. This value is based on the most conservative study performed [14].

The grey water load profile is obtained aggregating the DHW profile with one-minute delay, the profiles of the clothes and dish washing machines with a thirty-minutes delay generated with DHWcalc and mixed with cold water until the end-use temperature for an annual time-frame and one-minute step time. An average daily grey water availability of 3360litre (168litre/apartment) and an average grey water temperature of 32.8ºC is obtained out of that mix.

2.2 Model description

Figure.1 shows a scheme of the main components, water flows and average temperatures of the system.

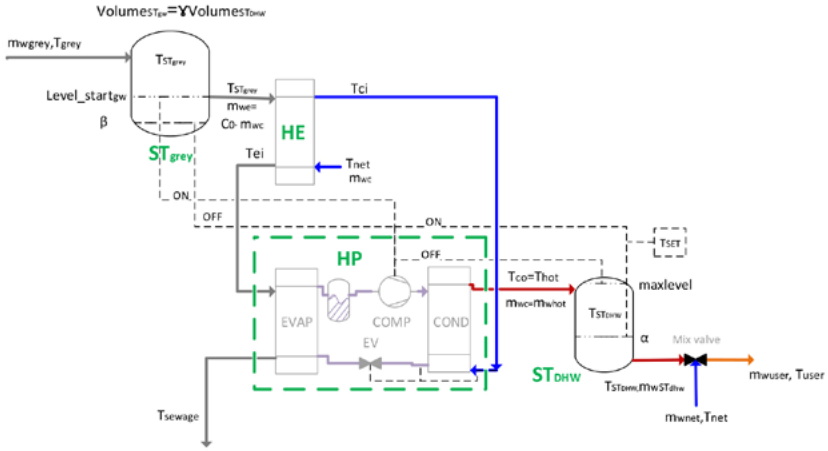

Figure.1: Lay-out of the system and average temperature conditions.

The main components of the system modelled are:

- Grey water storage tank (ST_{gw}): The variable volume storage tank modelled in Type 39 has been used. The size of the tank (Vol_{grey}) is one of the optimization parameters to minimize CO2 emissions.
  As conservative case, a geometric configuration that favours stratification has been used, that is H/D=4. The heat loss coefficient has been set to the one required by the Spanish legislation for DHW production, *RITE 07 IT 1.2.4.2.1.2,* that is 0.8W/m2K. An ambient temperature of 20ºC is set for all the simulations, as it is a typical value inside the houses through the year.
- Heat recovery heat exchanger (HE): Heat exchanger with an efficiency of 0.75 (type 5b). This heat exchanger will allow a first energy recovery.
- Water to water subcooled heat pump (SHP): This type contains a validated model of the subcooled heat pump [12].Due to its especial characteristics, a common HP type does not represent its behaviour properly and a new type was required. For further details about the developed type, the reader is referred to [15].
- DHW Storage tank (ST_{DHW}): For DHW Type 39 has also been used. As it is the case in $ST_{gw,}$ the size of the tank (Vol_{DHW}) is one of the optimization parameters to minimize emissions. The same insulation, geometry and characteristics used in the storage tank for grey water have been set in this case.
- Auxiliary water pumps and circuits: Types 742 with an efficiency of 0.3. Only the pressure drop of the heat exchangers were considered in order to evaluate their consumption.

Figure.2 represents the main inputs, outputs and optimization parameters of the model. In that scheme, scale is the size of the SHP, Volume is the size of the ST_{DHW}, γ indicates the proportion of the ST_{DHW} size and it is used for the ST_{gw} size ($Volume_{gw}$= γ·$Volume_{DHW}$). α is the ST_{DHW} level when the heat pump switches on, Tset is the ST_{DHW} temperature, Tco is the condenser outlet temperature and C_0 is related to the grey water mass flow rate (evaporator water mass flow rate) as a proportional value of the condenser water mass flow rate.

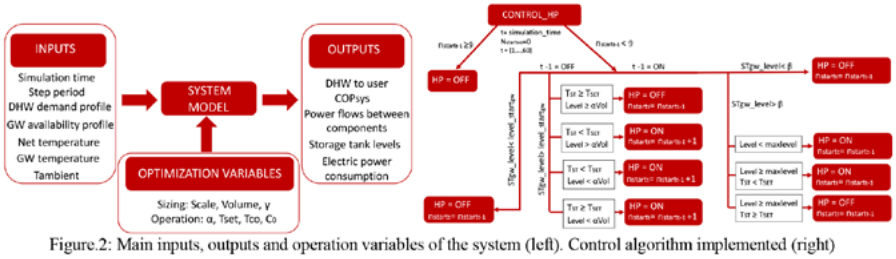

Figure.2: Main inputs, outputs and operation variables of the system (left). Control algorithm implemented (right)

The performance of the system (COP_{system}) is calculated according to Eq. 2

$$COP_{system} = Energy/Electric = \int_{t=0}^{t=simulationtime} (Q_{ST_{DHW_out}})/(W_{c_corr} + \sum W_{pumps}) \quad (2)$$

One should notice that the "useful energy" supplied by the system is the result of the heat exchanged in the HE and the heating capacity of the HP after the ST losses.

The scheme of the used control algorithm is presented in figure 5 (right) and it is based in the minimization of the time that the water is stored in the tank.In that figure *t* is the minute simulation time within each hour, T_{ST}, *Level*, *α*, *Vol*, T_{SET} and *maxlevel* refer to the DHW storage tank while subscript *gw* is used for conditions related to the grey water storage tank. It should be pointed out that once the HP is operating and while there is enough availability on the grey water storage tank, it keeps in the ON mode until the maximum level of the tank is reached or, in case it was already at that level, it keeps recirculating until the set point temperature (Tset) is reached. The used comfort criteria are based in two conditions, satisfy the demand 99% of the time and do not allow more than one-minute shortage at the same hour daily.

3. Performed Studies

Three cases based on the grey water conditions have been investigated and compared:

a) Infinite availability of grey water.
b) Finite availability of grey water and constant in time
c) Finite availability of grey water and no constant in time

According to [9], there is a set of system combination (size of the system componets and control) resulting in similar performances. Taking this point into account, the conditions b) and c) will be analysed in more detail for the solution corresponding to the smaller heat pump size (scale) and the solution with the smaller ST sizes (ST_{DHW}). Grey water energy available along the year is the same for the case 2 and 3 (the only change is when this energy is available). Table 2 shows the main inputs, variables used for limited m_{wgrey} availability based on the profiles of T_{net}, T_{grey} and m_{wgrey} presented in the methodology section.

Table 2: Main inputs used in each case

		T_{net} [ºC]	T_{gw} [ºC]	GW_{avail}	C_0 [-]
1	Infinite grey	10	33	∞	10
2a	Finite, $Scale_{min}$	10	33	Constant	2.27
2b	Finite, ST_{dhwmin}	10	33	Constant	2.27
3a	Design cond. $Scale_{min}$	7	25	Constant	2.33
3b	Design cond. ST_{dhwmin}	7	25	Constant	2.33
3c	Real cond. $Scale_{min}$	Profile	Profile	Profile	Opt.
3d	Real cond. ST_{dhwmin}	Profile	Profile	Profile	Opt.

a) Case 1: Infinite availability of grey water

This case will define the base case in order to evaluate the constrains imposed by limitations in the heat availability for the rest of the analysis. The methodology followed in [9] has been used. Notice that infinite availability of the heat source leads to the absence of the ST_{grey} and its derived variables.

Parametric studies have been done in order to obtain the map of possible solutions and the set of optimal combinations (heat pump size, Tank of DHW, alpha) that lead to minimum CO2 emissions satisfying the DHW demand under the comfort levels and operating constrains.

Figure 3 shows the parametric studies performed over the different design alternatives (heat pump size, storage tank size and control algorithm) for the available grey heat source (optimal m_{wevap}). This matrix comprises more than 4000 simulations

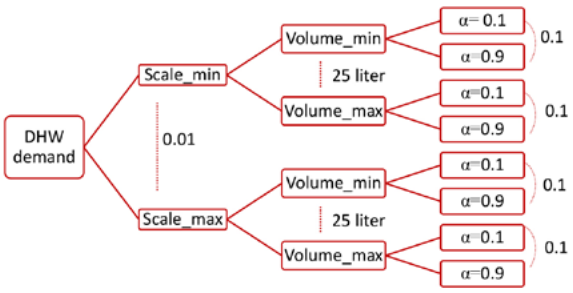

Figure 3: Parametric studies performed for available grey heat source based on variations of 0.01 in the scale of heating capacity, of 25litre in the ST_{DHW} tank and of 0.1 in α.

Where:

- *Scale* variation range: it has been expressed in terms of heating capacity (Q_{cond}) in the results section.
- *Volume* variation range: for each heating capacity, the maximum and minimum ST size that meet discomfort levels are investigated.
- *Alpha (α)* variation range: for each ST size, the variation of the control level in terms of a volume percentage.

b) Case 2: Finite availability of grey water and constant in time

The same parametric studies shown in Figure 3 have been performed. In order to compare this case with the case 1, two situations have been analysed quantitatively:

1. Case 2a: Solution with minimum heat pump size (scale factor).
2. Case 2b: Solution with minimum ST_{dhw}.

c) Case 3: Finite and not constant availability of grey water

Real applications introduce variability in three ways: time, temperature and quantity. These variables add complexity to the system and require the use of a ST_{gw}.

The main target of this study consists of analysing, on the one hand, the impact on efficiency of these limitations in the available energy compared to the previous cases and, on the other hand, the coupling of all the system components considering dynamic and real conditions from the system point of view. Hence, the use of a ST_{gw} and the definition of a proper operating strategy to integrate it in the system is necessary. In addition, this will help to get an estimation of the influence in the efficiency of the system design. Two subcases will be analysed in this part:

1. *System design based on a constant profile of waste water*

The size of the system is performed following the same methodology of case 2 but for T_{net}=7ºC and Tgrey=25ºC. These temperatures correspond to the worst expected conditions along the year. The available m_{gw} is the mean value of the grey water produced along the day.

The tandem HP-ST_{DHW} is sized according to these conditions. In this conditions, it is necessary to include in the design the ST_{gw} in order to accumulate the produced grey water when the system is not on. This component is dimensioned as: $Volume_{STgw}=\gamma \cdot Volume_{STDHW}$. Two solutions are analysed for this case:

Case 3a: Solution with minimum heat pump size (scale factor).
Case 3b: Solution with minimum ST_{dhw}.

2. *System design based on a real profile of waste water*

The system has been optimized in order to satisfy the real profiles of the wastewater and of the net water temperature. This optimization is based mainly in:

- C_0 control: This parameter is optimized when using the highest available m_{wgrey} To maximize its use, the control is based on the maximum available m_{wgrey}.

- α control:The minimum α capable to satisfy the demand is the one that ensures the shortest water stored time (for a given size of the components).

Finally, and following the same procedure as before, the two cases were analyzed:

Case 3.2.a: Minimum heating capacity
Case 3.2.b: Minimum ST_{dhw} .

4. Results

This section shows the results obtained from the previous cases. First, the feasible set of combinations are detailed by case. Second, the most representative results are collected in Table 4 in order to compare them. Third, a detailed analysis of the obtained results from CASE 3 is presented.

Case 1: Infinite availability of grey water

Figure 4 depicts the possible sizes combinations for the optimal α that meet the discomfort standards described in the methodology section. Figure 4a refers to the operating hours, Figure 4b to the COP of the system and Figure 4c to the associated CO2 emissions.

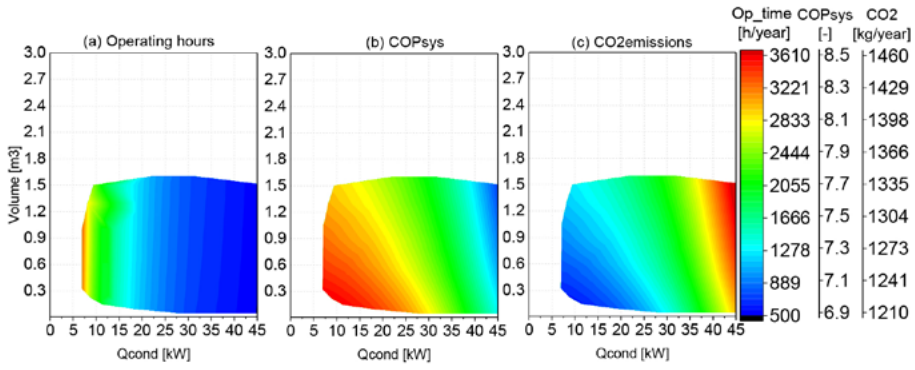

Figure 4: Annual operating hours, COP of the system and CO2 emissions associated to an infinite available grey water heat source and the optimal alpha.

According to Figure , low-temperature heat source recuperation has a great potential in DHW production applications. There is a wide range of combinations HP-ST_{DHW} that result in similar CO2 emissions (around 1230kg/year) and that are capable to operate under COPs up to 8.5 with operating hours around 2200 hours (6h/day). From all these combinations, the minimum CO2 emissions value is obtained for α=0.5, Scale=0.15 (heating capacity of 9.42Kw) and a ST_{DHW}=250litre.

To be able to compare directly results, that case has been taken as an example or base case out of all the possible best combinations. These results are presented in table 4.

Case 2: Finite availability of grey water

Figure 5 shows the possible ST-HP combinations for the optimal α that meet the discomfort standards described in the methodology section when limiting grey water to the considered availability. Figure 5a refers to the operating hours, Figure 5b to the COP of the system and Figure 5c to the associated CO2 emissions.

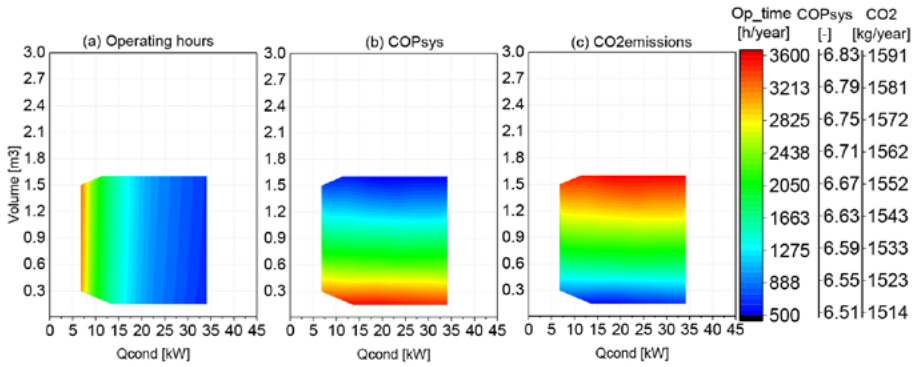

Figure 5: Annual operating hours, COP of the system and CO2 emissions associated to a finite available grey water heat source and the optimal alpha.

In this case, the reference combination obtained with optimal m_{wgrey} does not meet comfort standards. Hence, higher ST and/or heating capacities are required. Furthermore, the limitation of m_{wgrey}, lead to small COP variations with the increase of the heating capacity of the heat pump (for a given ST_{DHW} size). The ST_{DHW} size the most influent variable on the performance.

According to Figure and Figure 5, from the comparison of the optimal solutions in both systems (the combination with minimum CO2 strictly), the limitation of the available grey water results in a reduction in the COP of the system up to 20%.

In order to compare from a quantitative point of view the obtained results. Table 4 presents the numerical values for case 2a (solution with the minimum heat pump size) and case 2b (solution with the minimum ST size). In this table, it can be seen that for the case 2a the heating capacity is reduced due to a COP_{hp} loss and the solution results in higher ST_{DHW} as well as CO2 emissions. For the case 2b, the heating capacity required is significantly greater and 23% increase of CO2 emissions is obtained.

Case 3: Finite and variable availability of grey water

Similar results to the ones shown Figure 5 were obtained from the parametric studies performed in case 3 to design the components of the system. From all the possible combinations, two have been highlighted: the combination with minimum Scale (case 3. a) and the combination with minimums ST_{DHW} and ST_{gw} (case 3. b). The same situation is found once the system is adapted to the real profiles and results considering the adaptation to the profiles for the minimum HP size (case 3.c) and the minimum ST_{DHW} and ST_{gw} sizes (case 3.d) are highlighted Table 4 collects the most important results of each case.

Table 3: STgw-HP-STdhw optimal combinations for infinite availability of the heat source, finite availability but constant, and finite and variable availability.

		Scale [-]	Heating capacity [kW]	ST_{DHW} [l]	ST_{gw} [l]	α [-]	COPsys [-]	Annual Op.g hours [h]	Annual emissions [kgCO2]
1	Infinite grey	0.15	9.42	250	-	0.5	8.49	2310	1219.4
2a	Finite, $Scale_{min}$	0.15	6.9	300	-	0.9	6.85	3100	1510.9
2b	Finite, ST_{dhwmin}	0.2	9.08	250	-	0.9	6.8	2351	1522.6
3a	Design cond. $Scale_{min}$	0.15	6.06	500	1250	0.9	5.68	4261	1970.6
3b	Design cond. ST_{dhwmin}	0.25	10.09	350	875	0.9	5.73	2541	1959.6
3c	Real	0.15	6.81	500	1250	0.9	6.67	3175	1540.3

3d	cond. $Scale_{min}$ Real cond. ST_{dhwmin}	0.25	11.38	350	875	0.5	6.72	1890	1529.1

According to Table 3, the consideration of real profiles (demand, temperatures and grey water availability) with a design based on extreme constant conditions, cases 3.a-3.b leads to a solution with higher sizes of the main components and the performance of the system decreases in more than 30% compared to case 1 and 20 compared to case 2. However, once the design is dynamically adapted to the variable conditions (cases 3.c-3.d)., the loss of efficiency diminishes to 2% compared to Case 2. High values of optimal α allow the reduction of the ST_{gw} γ_{min} parameter, while low-medium values require the design condition of γ_{min}.

Figure 6 contains the main characteristics of the grey water heat source. Figure 6a represents the monthly grey water energy extracted by the HP (grey column) and by the HE (line-filled column), the grey energy available in light brown and the percentage of energy extracted from the total available. Figure 6b shows the temperature of the grey water at the outlet of the evaporator (grey water temperature to the sewage) through the year.

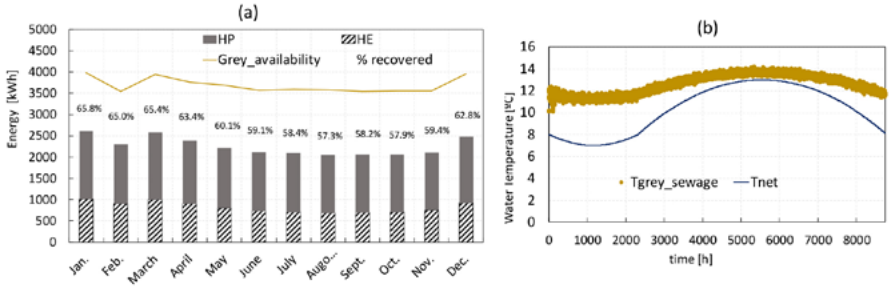

Figure 6: Monthly grey energy recovered and available and final annual grey water outlet temperature (to the sewage).

As it can be seen in Figure 6, a significant heat extraction is done by the HE with slightly seasonal fluctuations. From the available energy to extract (considering the minimum water temperature of the sewage as 2ºC), an average extraction of 60% has been enough for the DHW supply. In addition, figure 6b represents the net water temperature and the temperature of the grey water at the outlet of the SHP, it can be seen that always the Tgrey_sewage >Tnet, therefore the system is able to satisfy the DHW demand only with recovered energy from the dwellings, in addition figure 6b also shows that the energy recovery system is more effective during the colder months.

Results highlight the great potential of grey water heat recovery as a heat source for DHW production based on a HE (recuperator) and a HP.

5. Conclusions

In this work, the influence of having a limited (and variable) availability of heat source at a given temperature in order to satisfy the demand of DHW has been addressed. The obtained results have been systematically compared with the results obtained when this restriction is not present and an optimum system configuration (HE (recuperator)+SHP+STdhw+STgw) have been proposed.

This analysis has allowed estimating the variations in energy consumption that could be expected from different design criteria. Finally, a system in order to satisfy the DHW demand of 20 dwellings using their grey water production as a heat source has been analysed in detail.

Regarding to the obtained results, the main conclusions can be summarized as:

- A decrease of 20% in the efficiency could be derived when there is a limitation of the available grey water in terms of average quantity compared with a system in which that availability of heat source water is not limited.
- When there is a not constant availability of grey water, and the system is sized according to the most critical conditions, the energy efficiency of the system could be reduced up to 17%.
- In the previous situation, significantly larger sizes of the components are required in order to satisfy the user comfort levels (for instance, double ST_{DHW} capacities for the minimum HPsize).

- The systems with a variable grey water availability could increase significantly their efficiency if the design conditions are based on the real profiles instead of the most critical conditions. With that design criteria, the decrease on the performance is only 2% compared to the case with a constant availability of grey water (case 2).
- The system is can work only with energy recovered from the heat pump, and the advantage of this type of system is higher when the ambient temperatures are lower.

Finally, a great potential of grey water used as a heat source for DHW production based on SHP has been demonstrated. When the system is properly designed and adapted to real availability and demand profiles, it is able to supply the required energy for water heating purpose only using only the grey water produced by the dwelling with high efficiency. In fact, only with the extraction of 60% of the available energy all the production can be satisfied for the example analysed in this work and all the used energy is energy recovered from the grey water source. Comparing this case with the case in which this energy is extracted from a heat pump of the same characteristics but using the air as a heat source, the potential savings derived from using the grey water are higher than 40%.

Nomenclature

DHW: domestic hot water
ST: storage tank
HE: pre-heating heat exchanger (recuperator)
SHP: subcooled heat pump
Tei: water inlet temperature at the evaporator [ºC]
Teo: water outlet temperature at the evaporator [ºC]
Tci: water inlet temperature at the condenser [ºC]
Tco: water outlet temperature at the condenser [ºC]
Tnet: water mains/net temperature [ºC]
Tgrey: water heat recovery temperature [ºC]
Tsewage: grey water temperature after its recovery (to the sewage) [ºC]
T_{ST}: water stored temperature in the respective tank [ºC]
Thot= water temperature at the system conditions [ºC]
Tuser= water temperature supplied to the user [ºC]
Tdemanded=water demand temperature [ºC]
Tset= temperature control [ºC]
Tamb= ambient temperature [ºC]
Qcond=Heat pump heating capacity [kW]
Qevap=Heat Pump cooling capacity [kW]
COP_{hp}: Heat pump Coefficient of Performance, [-]
COP_{sys}: System Coefficient of Performance, [-]
COP_{Lorenz}: Lorenz Coefficient of Performance, [-]
m_{wgr}: grey water mass flow rate [kg/s]
mw_{user}= water mass flow rate to the user [kg/s]
m_{wc}:condenser water mass flow rate [kg/s]
m_{we}:evaporator water mass flow rate [kg/s]
Wc: Heat pump electric consumption [kW]
Scale: Relative size of the heat pump compared to the reference value
Volume: capacity of the respective tank [litre]
ρ: Water density [kg/m3]
α: Control level rate in the DHW tank[-]
β: Control level rate in the grey water tank[-]
λ: Ratio between the hot water mass flow and the grey water mass flow [-]
γ: proportion of the DHW storage tank capacity [-]
C_0: proportion of the condenser water mass flow rate [-]
Subscripts
ST: storage tank
HP: Heat pump
gw: grey water
DHW: domestic hot water
hot: hot water (at production temperature, 64ºC)

Abstract

In recent years, variable-speed heat pump systems for residential applications have gained significant attention in order to improve the part-load operations during heating and cooling seasons. A single-stage 5-ton (17.58 kW) heat pump unit with R-410A as a working fluid has been considered as a test case to assess the performance of a variable-speed rolling piston compressor. Moreover, the heat pump has been retrofitted with a prototype expansion work-recovery device to replace the conventional expansion valve for cooling mode. The heat pump performance has been tested extensively in a pair of psychrometric chambers. In order to facilitate future optimization of the system, a fully-mechanistic steady-state cycle model of the heat pump has been developed. In particular, the system model is based on a charge-sensitive approach with semi-empirical models for the compressor and the work-recovery device as well as detailed heat exchanger models. The cycle model has been validated and tuned with the experimental data collected. Future work is to utilize the validated mechanistic model for cycle optimization and charge sensitivity studies.

1. Introduction

Growing concerns over climate change are driving innovation in almost every industry. However, given that in 2017, 38% of US energy consumption was in buildings [1], much of which is attributable to heating, ventilation, air conditioning, and refrigeration (HVAC&R), innovation in this industry is particularly vital. To this end, both academia and industry have been investigating different ways to increase the efficiency of the vapor compression cycle (VCC). Most of the optimization efforts focused on three of the four primary components in a VCC, being the compressor, the condenser, and the evaporator. Within these efforts, the use of variable-speed compressors represents a significant performance benefit without any fundamental changes to the cycle. The fourth component of a VCC enables the expansion from condensing to evaporating pressure and is generally achieved with a thermostatic expansion valve (TXV) or an electronic expansion valve (EXV). When modeling these devices an isenthalpic assumption is generally made, meaning that any potentially recoverable work from the expansion process is wasted. In response to this, researchers have investigated

E-mail address: bartar@purdue.edu.

several ways to recover the expansion work. The two most common methods for expansion work recovery in VCCs are ejectors and expanders. The former has been proven to be more reliable and is by far the most common technique used in industry. Two of the most common techniques for controlling an ejector are actively-varying geometry of a single ejector [2-4] or the use of a multiple fixed-geometry ejectors in parallel [5-7]. While expanders have been theoretically shown to have greater potential for increased coefficient of performance (COP) benefits relative to ejectors, designing these devices for application in HVAC&R with a high enough isentropic efficiency to realize this gain has proven to be challenging, before even considering how to control them. To reduce overall development costs, high-fidelity VCC system models have been extensively researched as well. Both dynamic and steady-state models have been researched, but within those categories there is still a lack of charge-sensitive mechanistic models. Consideration of the charge inventory within a VCC and its optimization are essential to overall cycle performance. Experimentally-validated charge-sensitive mechanistic models utilizing charge tuning methods proposed by Shen et al. [8] have been developed by Bahman et al. for a 4-component VCC [9] as well as a VCC with economization and compressor vapor-injection [10].

This study focuses on the development of a detailed mechanistic model for an R-410A residential heat pump system that utilizes an expansion work recovery device with phase separation and an evaporator vapor bypass previously investigated by Czapla et al. [11] and Barta et al. [12]. Cycle performance was predicted with imposition of charge inventory with estimation using both one- and two-point tuning methods. Individual component efficiencies within the expander were modeled and experimentally-validated to isolate losses within the component.

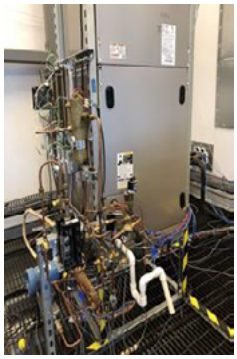

Fig. 2. View of the indoor unit showing the expander

Fig. 3. View of the variable-speed rolling piston compressor

2. Model Description

Fig. 1 shows the schematic of the variable-speed heat pump system to be modeled, with a photo of the indoor unit shown in Fig. 2. The primary difference between this cycle and a standard four-component VCC is the inclusion of the expander/separator, which simultaneously recovers expansion energy and separates vapor and liquid phases from the turbine outlet. The liquid exits the bottom of the expander housing to enter the evaporator, while the vapor exits the top before passing through a resistive heater to ensure superheat and mixing with the evaporator outlet upstream of the accumulator. The cycle components are simulated in an object-oriented fashion by using the programming language Python [13]. The thermo-physical properties of the working fluid (R-410A) were obtained from Bell et al. [14].

2.1. Compressor model

A variable speed reciprocating compressor model proposed by Mendoza-Miranda et al. [15] was used which is based on dimensionless volumetric, isentropic, and overall efficiencies. This model has also been shown to be applicable to scroll and rotary rolling piston compressors. The model characterized the compressor efficiencies in terms of certain groups of dimensionless parameters. Specific experimental data from a 5-ton (17.58 kW) Hitachi variable speed rotary rolling piston compressor (Fig. 3) were used to determine the values of the dimensionless parameters (*i.e.,* a_i coefficient values). Furthermore, the model was capable of accounting for different working fluids. In particular, Mendoza-Miranda et al. [15] employed the model to analyze the performance of a variable speed reciprocating compressor using R-1234yf, R-1234ze(E), and R-450A as alternatives to R-134a. Bahman et al. [9] validated the model for variable speed rolling-piston compressor using R-410A. The correlations for the dimensionless efficiencies were expressed as a power law function of the remaining π groups and given in Eqs. 1 to 3. The dimensionless groups for volumetric, isentropic, and overall efficiency can be found in Bahman et al. [9].

$$\eta_v = \pi_2^{0.1257}\pi_4^{0.0958}\pi_5^{0.4158} \quad (1)$$

$$\eta_s = \pi_2^{0.2166}\pi_3^{0.34781}\pi_4^{0.0773}\pi_6^{-0.03923} \quad (2)$$

$$\eta_{oa} = \pi_2^{-0.3632}\pi_3^{-0.30562}\pi_6^{0.02766}\pi_7^{0.76003} \quad (3)$$

The comparisons between measured and predicted values of the compressor mass flow rate, discharge temperature, and electric power input can be found in Bahman et al. [9].

2.2. Heat exchanger models

The heat exchanger models from Bell [16] were modified to be used in this work. The condenser model

was constructed using a moving boundary method, which divides the heat exchangers according to the phases of refrigerant flow. Each section of the heat exchanger models was simulated using the ε-NTU method as separate crossflow fin-and-tube heat exchangers with louvered fins [17], assuming constant refrigerant pressure equal to the saturation pressure.

To accurately estimate the behavior of the heat transfer from the air to the refrigerant side of the evaporator, the partially-wet and partially-dry method by Braun [18] is utilized in predicting the air side sensible and latent heat transfer when the surface temperature of the coil falls below the dew-point of air at the inlet of the evaporator. The evaporator model was solved by separating the heat exchanger into two sections. The section with surface temperatures higher than the dew-point was solved by a completely dry analysis, while the other section was solved assuming a completely wet analysis. Both heat exchanger models included Zivi slip flow model [19] to improve the refrigerant charge estimation in the two-phase region. The correlations used to estimate the heat transfer coefficients and friction factors in the condenser and evaporator models are summarized in Table 1, while the geometrical parameters used are listed in Table 2.

Both evaporator and condenser fans were modeled by using experimental data for steady-state operation conditions. The average airflow rate and power consumption for the evaporator fan were equal to 0.826 m^3/s and 0.4 kW, respectively, while the airflow across the condenser fan was equal to 1.91 m^3/s corresponding to an average measured power consumption of 0.25 kW.

Table 1. Heat transfer and pressure drop correlations in heat exchanger models

		Single-Phase	Two-Phase

Air-Side	Heat Transfer	Wang et al. [25]	
	Pressure Drop	Wang et al. [25]	
	Fin Efficiency	Schmidt [26] modified by Hong and Webb [27]	

Table 2. Geometrical parameters in heat exchanger models

Parameter	Condenser	Evaporator	Parameter	Condenser	Evaporator
Number of tubes per bank	24	60	Transverse distance of tubes [mm]	25.4	25.4
Number of banks	2	3	Fins per inch	20	14.5
Number of circuits	8	8	Fin waviness [mm]	1.0	1.0
Length of tubes [mm]	2252	452	Half-wavelength of fin wave [mm]	1.0	1.0
Outer diameter of tubes [mm]	9.13	9.13	Fin thickness [mm]	0.11	0.11
Inner diameter of tubes [mm]	8.49	8.49	Conductivity of fins [W/m-K]	237	117
Longitudinal distance of tubes [mm]	19.1	19.1			

2.3. Expander and separator model

The expander model consisted of a series of sub-models whose efficiencies were experimentally validated. A schematic showing the sub-models is provided in Fig. 4. The thermo-physical properties of the inlet state were measured, and the electrical power $\dot{W}_{elec}$ output was also measured. Generator efficiency η_{elec} was assumed to be 88% per manufacturer recommendation and mechanical efficiency η_{mech} was assumed to be 90%.

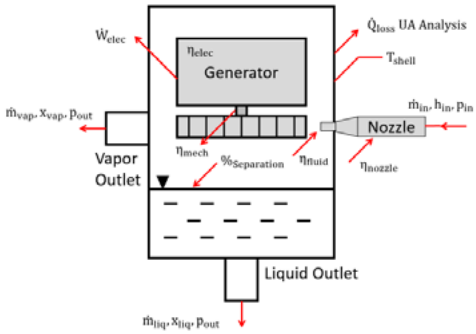

Fig. 4. Expander schematic with sub-model efficiencies

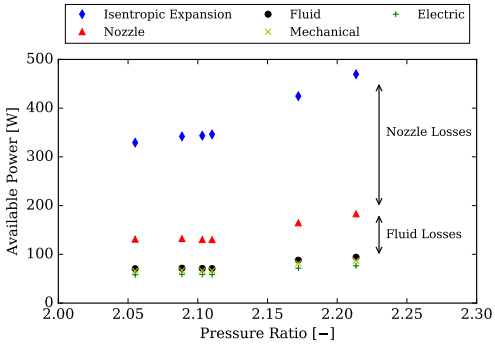

Fig. 5. Expander sub-model power availability visualization

An experimentally-validated nozzle model from Stania [28] was utilized to determine the nozzle isentropic efficiency η_{nozzle}. The nozzle model was developed for converging nozzles and includes modifications to Elliot and Weinberg [29] such as the inclusion of inter-phase drag within the vapor dome and the Smith [30] slip flow model, among others. These calculations left only the fluid efficiency, which represents losses between the outlet of the nozzle and turbine, as well as when the flow impacts the turbine. Using six experimental data points, a polynomial of this efficiency was developed as a function of expander pressure ratio. The assessed power extracted from each sub-model is shown in Fig. 5. Additionally, a natural convection heat transfer analysis was conducted to estimate the heat loss. The heat transfer rates were on the order of 2 to 5 W, but this transfer was important for completeness of the energy balance. Finally, ideal separation of phases was not achieved experimentally. As such, the liquid outlet quality was estimated as 0.025 from experimental data.

2.4. Linesets model

The pressure drop of refrigerant flow in the system linesets was calculated using ACHP model Bell [31] with the Churchill [23] correlation to estimate the pressure drop friction factor. The ε-NTU method from Bergman et al. [17] was used to estimate the amount of heat loss, if any, in all the linesets. Note that the volume of the linesets was considered for the purpose of refrigerant charge calculation. The geometry of the pipelines was measured from the experimental setup and is summarized in Table 3.

Table 3. Geometrical parameters of the system linesets

	Suction line	Discharge line	Liquid line	Accumulator line

Length [mm]	7600	300	7600	571
Outer diameter of tubes [mm]	28.58	28.58	9.53	22.23
Inner diameter of tubes [mm]	26.04	26.04	6.35	19.05
Insulation thickness [mm]	20	-	20	-
Conductivity of tubes [W/m-K]	0.19	0.19	0.19	0.19
Conductivity of insulation [W/m-K]	0.036	-	0.036	-

2.5. Accumulator model

A suction gas accumulator was modeled as a cylindrical vapor-only container. This implies that natural heat transfer occurred between the surfaces of the accumulator and the surroundings. The natural convection correlations from Bergman et al. [17] was used to account for the heat transfer across the circumference of the accumulator. The volume of the accumulator was considered for the purpose of refrigerant charge estimation. The accumulator has a height of 274 mm with inner and outer diameters of 115 mm and 123.6 mm, respectively.

2.6. Charge model

Due to the inaccurate estimation of the system volumes, ambiguous flow patterns under two-phase flow conditions, and amount of refrigerant dissolved in the compressor lubricant, both a single-point and a two-point charge tuning procedure were implemented based on the methodology proposed and validated by Shen et al. [8]. The total refrigerant charge of the system is given by the sum of the mass calculated by the cycle model and a contribution fitted onto the experimental data, which can be expressed as

$$m_{\text{charge}} = m_{\text{pred}} + \Delta m_{\text{liq}} \tag{4}$$

$$\Delta m_{\text{liq}} = C + K\left(w_{\text{liq,pred}} - w_{\text{ref}}\right) \tag{5}$$

where C, K, and w_{ref} are the coefficients to be determined through only two experimental data points to calibrate the model. The tuning coefficients are listed in Table 4. Note that for the one-point regression model, Eq. 5 results with the coefficient C only.

Table 4. Charge model tuning coefficients

C [kg]	0.987
K	-1.059
w_{ref}	0.0466

2.7. Pre-conditioner model

In order to obtain good initial guesses and reduce computational time for the main cycle solver, a pre-conditioner model from Bell [31] was modified to estimate values for refrigerant evaporation and condensation temperatures. The pre-conditioner model duplicates the main cycle to be solved with simplified models for condenser and evaporator, as shown in Fig. 6. The independent variables (*i.e.,* T_{evap} and T_{cond}) are iterated to minimize the residual vector (Eq. 6) by means of *fsolve* function [32] until convergence. Note that the superheat degree T_{sh} is deterministically evaluated in the main cycle. However, in the pre-conditioner model a targeted value was used as an input to ensure continuity.

$$\vec{\Delta} = \begin{bmatrix} \dot{W}_{\text{comp}} + \dot{Q}_{\text{evap}} - \dot{Q}_{\text{cond}} - \dot{W}_{\text{exp}} + \dot{Q}_{\text{heater}} \\ \dot{Q}_{\text{cond,a}} - \dot{Q}_{\text{cond,r}} \\ \dot{Q}_{\text{evap,a}} - \dot{Q}_{\text{econ,r}} \end{bmatrix} \tag{6}$$

2.8. Overall system model

The flow chart in Fig. 7 shows the algorithm used in the system-level solver. The components in the system-level model were simulated consecutively as shown in Fig. 7. The independent variables (*i.e.,* T_{evap}, T_{cond}, and T_{sh}) are iterated by means of the Broyden [33] method to drive the residual vector (Eq. 7) to zero.

$$\vec{\Delta} = \begin{bmatrix} m_{charge} - m_{charge,target} \\ h_{mix,out} - h_{accum.in} \\ \dot{Q}_{heater} - \dot{Q}_{target} \end{bmatrix} \tag{7}$$

The model checks for the pressure drop residual (Eq. 8) after the residual vector (Eq. 7) converges. The pressure drops in the high- and low-pressure linesets are considered after the cycle iteration completed to avoid numerical difficulties. Hence, new effective saturation temperatures (*i.e.,* T^*_{cond} and T^*_{evap}) are calculated and iterated in the cycle model until the updated effective pressure drops (*i.e.,* P^*_{high} and P^*_{low}) are equal to the pressure drop terms calculated from the converged cycle model (*i.e.,* P_{high} and P_{low}). The solver converges when the pressure drop residual (Eq. 8) is less than 1 Pa.

$$\vec{\Delta} = \begin{bmatrix} P^*_{high} - P_{high} \\ P^*_{low} - P_{low} \end{bmatrix} \tag{8}$$

3. Results and Discussion

3.1. Experimental methodologies

A 5-ton (17.58 kW) single-stage split-type heat pump with R-410A as the working fluid was installed inside a pair of psychrometric chambers at the Herrick Laboratories. A variable-speed rolling piston compressor was installed to replace the original scroll compressor, and the expander device was installed to replace the original TXV. The unit was tested at six points according to the test matrix in Table 5. All test conditions were performed according to AHRI Standard 210/240 [34] conditions using refrigerant-side data. The unit was charged with 4.81 kg (10.6 lb) to ensure consistent subcooling in the liquid line. Experimental cooling capacity, $\dot{Q}_{\text{evap}}$, and COP values for these test conditions are provided in Fig. 8. Cooling capacity and COP were defined based on AHRI Standard 210/240 [34] as shown in Eq. 9 and Eq. 10, respectively.

$$\dot{Q}_{\text{evap}} = \dot{m}_{\text{ref}}\left(h_{\text{evap,out}} - h_{\text{evap,in}}\right) \tag{9}$$

$$\text{COP} = \frac{\dot{Q}_{\text{evap}}}{\dot{W}_{\text{tot}}} \tag{10}$$

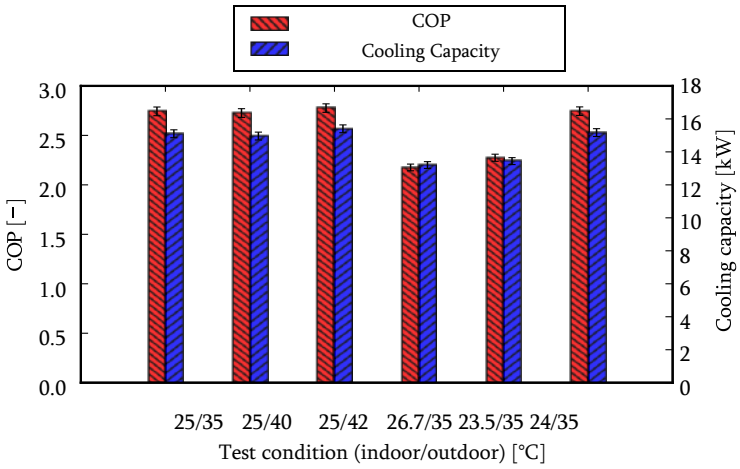

Fig. 8. Experimental COP and cooling capacities

Table 6. Tuning multipliers for expander heat pump cycle model

Compressor displacement scale factor	1.002
Condenser air-side convection heat transfer coefficient	1.289
Condenser refrigerant-side convection coefficient	0.973
Condenser refrigerant-side pressure drop correlation	1.077
Evaporator air-side convection heat transfer coefficient	1.302
Evaporator refrigerant-side convection coefficient	1.6
Evaporator refrigerant-side pressure drop correlation	0.998
Expander and separator vapor mass fraction	0.058

3.2. Model tuning

There was a systematic bias between the simulation and experimental results due to simplifications and imperfect information related to the heat pump system components. To minimize the bias, eight tuning multipliers were introduced to adjust mass flow rates, heat transfer coefficients and pressure drop on both air-side and refrigerant-side for the condenser and evaporator model as well as the separation fraction in the expander. The estimation of the multipliers was conducted by means of an iterative scheme to eliminate the discrepancy between the experimental results and the estimations of the mass flow rates, the condenser and evaporator heat transfer rates, the compressor power consumption, and the expander power generation. The optimization problem was solved with a bounded differential evolutionary (DE) method [35] and the resulting tuning factors are summarized in Table 6. It can be noticed from Table 6 that the air-side multipliers for the evaporator and the condenser are relatively high (approximately equal to 1.3) due to the influence of the air leakage around the heat exchangers in the experimental measurements.

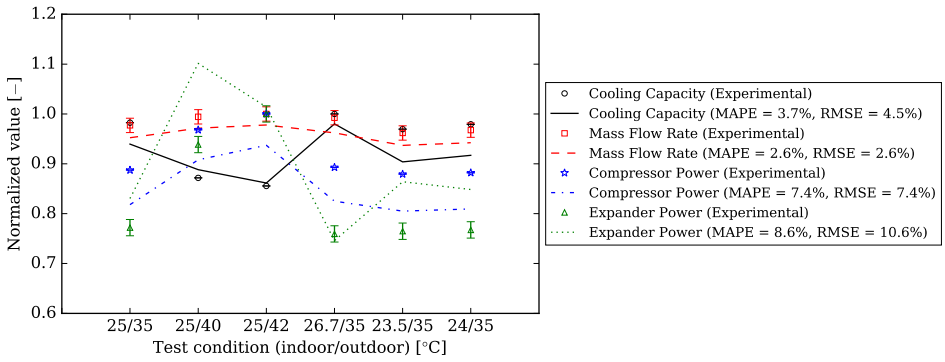

Fig. 9. Comparison of estimated model performance parameters with experimental data (normalized with maximum experimental value)

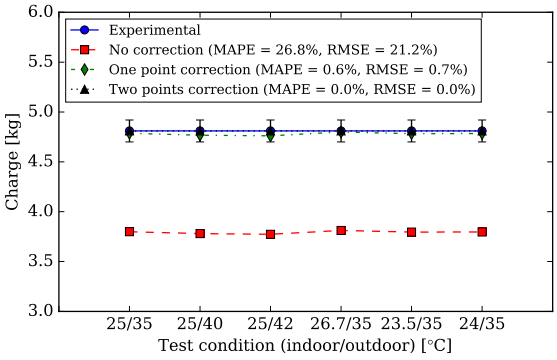

Fig. 10. Comparison of charge prediction with experimental data using one- and two-point regression charge model

3.3. Model validation

The validation was carried out with the six test conditions which were experimentally conducted on the retrofitted heat pump unit with expander device and variable-speed rolling piston compressor. The comparisons of the refrigerant mass flow rate, the condenser and evaporator capacities as well as the compressor power consumption and expander power generation between the model simulations and the experimental results are illustrated in Fig. 9. The error between the predicted and experimental values is calculated by the mean absolute percentage error (MAPE) and the root mean square deviation error (RMSE). Fig. 9 shows that the model, after tuning, captured the system and component performances within a reasonable margin of error. The minimum MAPE and RMSE of 2.6% and 2.6% corresponded to the total mass flow rate, while the maximum MAPE and RMSE of 8.6% and 10.6% were associated with the predictions of the expander power generation, respectively.

Using the charge model coefficients (Table 4) and the system tuning factors (Table 6), as well as by imposing the system charge inventory, the cycle was simulated at the same experimental test conditions to assess the charge estimation as shown in Fig. 10. Fig. 10 compares the charge predictions for the cases without any correction with one-point regression charge model, and with two-point model. It can be seen that the one-point charge model eliminates all the biases and predicts the charge inventory with MAPE and RMSE less than approximately 1%, while the two-point charge model [8] perfectly estimates the system charge with no errors.

4. Conclusions and Recommendations

This paper aimed to develop a detailed mechanistic and charge-sensitive model for an expander heat pump system to accurately estimate the system performance. The developed system model was tuned and validated with experimental data from a 5-ton (17.58 kW) single-stage split-type heat pump tested at different operating conditions in the Herrick Laboratories. The results yielded the following conclusions. First, the mechanistic expander heat pump system model predicted the performance parameters (*i.e.,* mass flow rates, compressor and expander power, and heat exchanger capacities) with a reasonable margin of MAPE and RMSE less than approximately 9% and 11%, respectively. Second, the charge imposed model with one- and two-point correction methods accounted for the discrepancy in refrigerant charge estimation with MAPE and RMSE less than approximately 1%. Finally, the detailed charge inventory model allows the analyses of drop-in working fluid replacements and their effects on the system sizing. Furthermore, the model also allows to optimize the charge level to take advantage of variable-speed compressors and power generation expanders. Future work entails the use of the system model for system, charge, drop-in fluid assessment, and multi-objective economic optimization. Additionally, the sub-models will be utilized to prioritize expander component re-design and further experimental analysis.

Abstract

In many studies, numerical analysis in adsorption chillers has focused on analyzing adsorption bed, which is the most important part, and evaporator and condenser are ideally assumed. It is doubtful whether this analysis properly evaluated the performance of the adsorption chillers. Although there have been some studies involving evaporators and condensers, it is questionable whether this is a quantitative result because the adsorption bed which has the greatest effect on performance, is analyzed by a lumped parameter model (LPM). In this study, an adsorption chiller including an evaporator and a condenser is analyzed and the results are compared with the result of a previous study that assumes an ideal evaporator and a condenser. As a result of analyzing in terms of coefficient of performance and specific cooling power, the analysis including the evaporator and condenser showed 16.12% and 24.64% overestimation compared. Also, LPM analysis including evaporator and condenser showed that COP and SCP were 22.82% and 11.28% larger than our model, respectively

1. introduction

Because of global warming and economic development, cooling demand has rapidly increased. There are many kinds of refrigerator types. The vapor compression refrigerator has been most commonly used, however, it suffers from a negative impact on the environment and an excessive electric power requirement. Therefore, many researchers have focused on developments of eco-friendly refrigeration systems, and heat driven refrigerators have been highly attracted such as absorption, desiccant, and adsorption cooling system.

The adsorption refrigerator operates reversible adsorption and desorption processes, in a cycle of preheating, heating, pre-cooling, and cooling. The size of adsorption chiller is large and cycle time is too long. For this reason, the experimental study is highly time-consuming and expensive, a numerical study has been widely used, to understand the process in adsorption refrigerator.

Niazmand et al [1] focused on the issue of bed geometry and found the difference in performance caused by heat and mass transfer ability. The performance of refrigerator was improved by changing fin height and fin space. Mahdavikhah et al. [2] investigated the pressure distribution of the bed in isosteric phase to understand the complex mechanism of heat and mass transfer in the square finned adsorption bed. They found the optimized shape which evenly distributed the heat energy.

From the literature survey, even though adsorption bed is one of the crucial components in adsorption refrigerator, the research target was mainly confined to the adsorption bed. The effect of its integration with evaporator and condenser has not been closely examined till now. A few works have focused on this issue. Khan et al. [3] numerically analyzed reheat-2stage adsorption refrigerator using LPM (lumped parameter model). They performed a case study with the parameters of silica gel mass and its surface area. Zhang et al. [4] analyzed an adsorption refrigerator driven by solar power with Simulink. They found the cooling capacity by assuming day-time solar radiation and showed that the COP was different depending on the initial temperature. Ng et al. [5] researched a desalination cycle driven by waste heat and suggested an optimal condition.

A few works have focused on the analysis including not only adsorption bed but also additionally including evaporator and condenser. Therefore, in this study, we focus on refined CFD simulation for adsorption bed with evaporator and condenser which is the more realistic model.

2. Numerical method

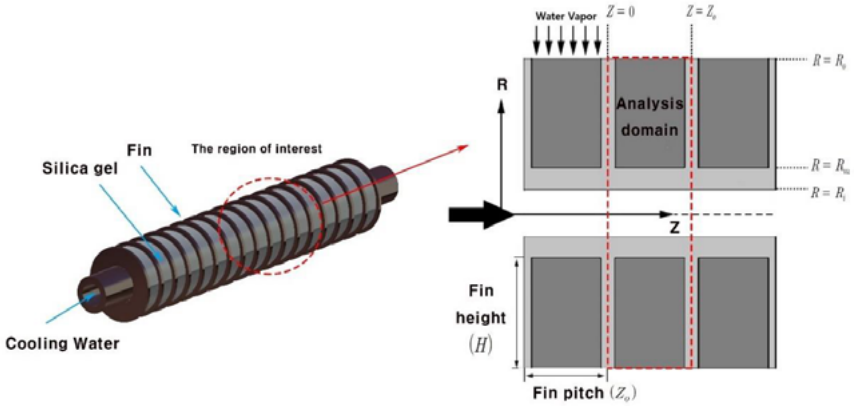

Fig. 1. numerical model of the circular fin – tube

Fig. 1 describe numerical model of fin-tube type adsorption chiller. The numerical model includes the following assumptions.

(1) 2-D axisymmetric model is assumed.
(2) No heat loss through the wall and effect of radiation is negligible.
(3) Vapor is an ideal gas and silica gel is liquid phase.
(4) Particle has uniform size and same porosity.

The detailed properties such as isotherm of adsorbent, bed analysis model, and numerical model verification were described in our recent studies (Hong et al. [6]), so it is not discussed further.

Another model, which contains evaporator and condenser, use same equation with previous model for analysis of adsorption bed. We use equations for evaporator and condenser which can be found in some existing paper (Khan et al. [3]).

3. Result

Fig. 2 describes the Clapyron diagram of an adsorption refrigerator that reaches quasi-equilibrium state. As indicated by the dotted line, the idealized model does not follow the actual pressure, but rather has constant saturation pressure corresponding 15℃ and 30℃, which are evaporator and condenser temperature. On the other hand, a realistic model indicated by the solid line follows the pressure corresponded with actual evaporation or condensation temperature. The existence of the pressure gradient finally affects the adsorption/desorption isotherm. Fig. 3 shows difference in water uptake amount.

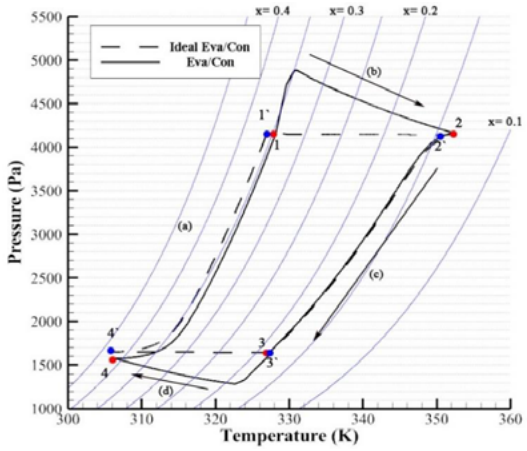

Fig. 2. P-T diagram in adsorption bed of two models

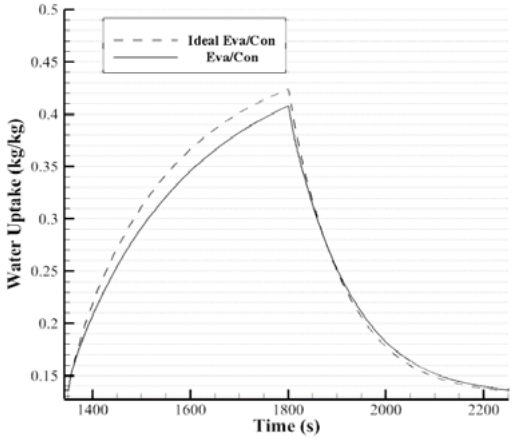

Fig. 3. Difference in water uptake between two model

For this reason, when evaporator and condenser was ideally designed, COP was overvalued up to 16.12%. Furthermore, SCP was overvalued up to 24.64%. So, it is better to use the analysis which cover evaporator and condenser to avoid distorting the result.

Frosting and Defrosting Behavior of Evaporators

Christoph Reichl[a,*], Mirza Popovac[a], Felix Hochwallner[a], Peter Wimberger[b], Felix Linhardt[a,b], Thomas Fleckl[a], Johann Emhofer[a]

Abstract

Air-to-water heat pumps - being essential to reach the ambitious climate goals – don't come without challenges: Evaporators of air-to-water heat pumps are prone to severe frosting in humid climatic during late fall, winter and spring. To sustain a reasonable CoP, de-frosting strategies are employed to remove the frost layer and restore normal operation. De-frosting, however, also reduces efficiency due to downtimes and heat loss due to reverse operation. Frosting and de-frosting of evaporators is characterized using overview and detailed image capturing. The frost growth is additionally quantitatively assessed using a digital high-resolution scale. Together with the thermodynamic data of the heat pump and the control parameters of the climatic chamber a full transient data set is available and analysed deriving frosting and de-frosting correlations. The extensive data set is an important base for numerical simulation: Frost growth and weight increase can be used to validate three-dimensional frosting models necessary to simulate and - in a second stage - optimize evaporator designs. Furthermore, the thermodynamic behaviour during frosting and de-frosting is an important input to one-dimensional system models of heat pumps.

1. Introduction

The frosting of heat exchangers is typically undesired in heat pump operation, given that in most of the cases it implies a deterioration of the equipment performance or even critical safety problems. In that view, the understanding of the factors affecting the frosting process is of high practical relevance, and a large research community is involved in the investigation of the frosting behaviour.

Empirical correlations for the relevant frost characteristics (respectively, frost density and conductivity, mass diffusivity and latent heat of sublimation) have been presented by [1], [2] and [3], among others. This is accompanied by comprehensive numerical work to provide the theoretical background: In a series of studies, Na and Webb [4], [5] presented their work on the frost formation over simple geometrical configurations, successfully reproducing the experimental frosting results. Focusing on the reduction of the computational cost, [6] proposed an algebraic approach for the frost growth and densification. [7] advanced the psychometric and surface conditions under which the frost formation occurs.

Comprehensive reviews are available on frosting of air-to-air heat exchangers (see [8], [9]) and the frost deposition on flat surfaces [10]. Different surface structures have been investigated [11], [12]. Heat transfer characteristics under frosting and defrosting are discussed in [13] and have been put in the general context of building applications by [14].

In this paper time dependent frosting of the heat exchanger has been observed in the SilentAirHP heat pump assembly by measuring the mass increase and using postprocessing of captured images of the heat exchanger during frosting for different environmental conditions. In section 2 we will describe the experimental heat pump setup. This is followed by a discussion of the experimental methods used to characterize frosting on the evaporator in section 3. In section 4 we are going to present and discuss the experimental results. We will conclude this work by summarizing our experimental approaches and presenting an overview of planned future work.

2. Experimental Heat Pump and Evaporator Component

For our measurements we used an experimental air-source heat pump (see Figure 1) which was designed to provide a heating power of 5 kW at a heating water temperature of 35°C and at an ambient air temperature of 2°C. The refrigerant R410A was used and the entire heat pump was located inside the AIT climatic chambers during the measurements. Inside the chamber, the air temperature and humidity could be controlled. The heating water was cooled with an in-house chilled water reservoir with the back flow of the heating water regulated to 30°C. The compressor was operated at a fixed rotational speed of 98Hz. The superheating was always set to 7°C during the experiments. The fan operated at a constant rotational speed what corresponds to an average velocity of 2 m/s at the fin and tube evaporator. The dimensions of the evaporator are 630 mm x 560 mm with a depth of 120 mm. The fins are made of corrugated aluminium and placed in a distance of 4 mm. 78 horizontal tubes made of smooth copper are organized in 4 columns in air flow direction. The overall pressure drop of the evaporator is about 54 Pa, if dry. The condenser has been realized as a plate condenser designed for a heating capacity of 5 kW at an outside air temperature of 2°C and a supply temperature of 35°C and a condensation temperature of 40°C.

3. Measurement methods

Alongside the acquisition of thermodynamic data of both the heat pump and climatic chamber, transient weight measurements and image capturing techniques have been used.

3.1. Heat Pump and Climatic Chamber Thermodynamics

The temperatures at the refrigerant inlet and outlet of the evaporator were measured with calibrated PT100-class A temperature sensors. The sensors were mounted with heat-conductive paste on the outside of the copper pipes as close to the inlet as possible. Furthermore, the sensors were insulated to reduce heat exchange with the ambient air. The climatic conditions in the chamber are measured with several combined temperature and humidity sensors placed at the suction side of the heat exchanger according to the standards normally used for heat pump certification tests (EN14511-3:2018) [15]. An additional temperature and humidity sensor is placed at the suction side for climate chamber control.

3.2. Transient Weight Measurements

The heat pump assembly has been placed on a scale capable of measuring the weight as a function of time. By calculating the difference between the increasing weight and the initial weight, the amount of frost on the heat exchanger can be extracted. As the weight of the heat pump assembly was by a factor of 1.5 higher than the maximum detectable load of the scales, a balance construction was put in place and the system was calibrated by subsequently placing known weights on the dry heat exchanger and recording a calibration curve before starting the frosting experiments.

We selected a setup with an air inflow temperature of 2°C with quite small defrosting cycle times for better visualization of the procedure. Figure 3 shows the measured mass signal on the left side. As a next step each frosting cycle is identified (shown in Figure 3 right side marked with a unique colour). As the final step, the mass signals of the different frosting cycles are superimposed (see Figure 4) and a mean mass signal is derived which can then be used for comparison to numerical data (see also Figure 11).

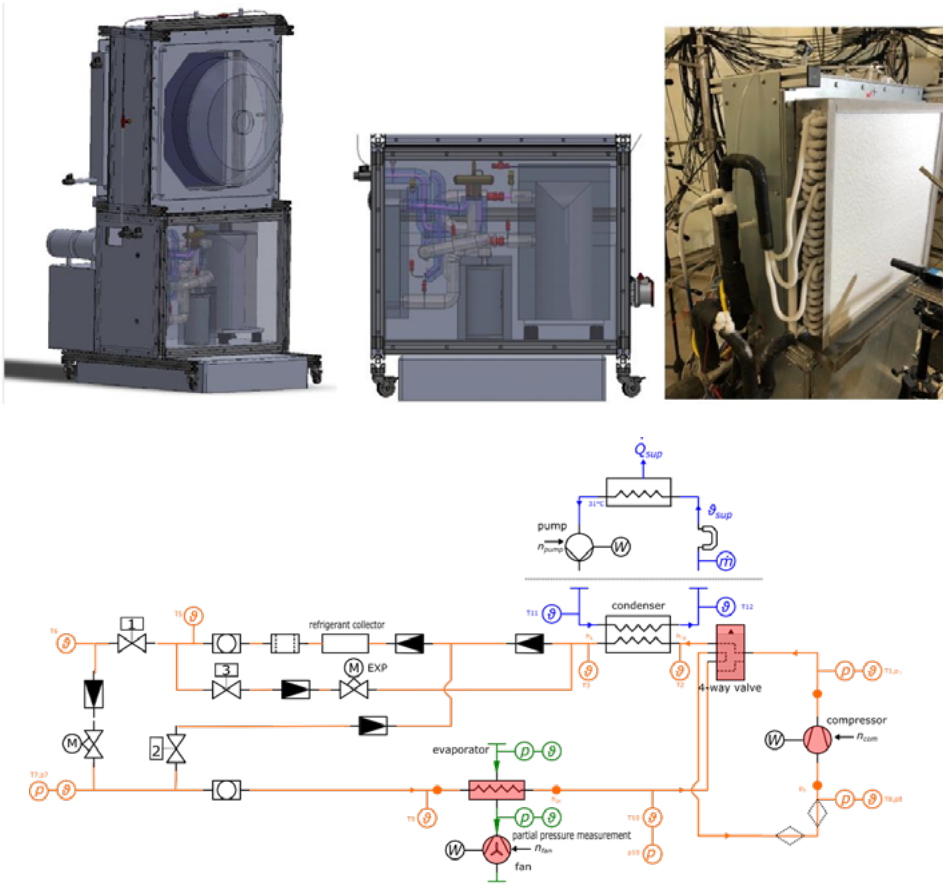

Fig. 1. (top left) Sketch of the experimental SilentAirHP heat pump showing the major components; (top middle) lower part of the SilentAirHP with compressor, condenser, expansion valve and duct network; (top right) SilentAirHP evaporator fully covered with ice in the climatic chamber of AIT. (bottom): sketch of the heat pump design with sensor positions.

3.3. Image Capturing and Highlight Event Extraction

Two cameras have been used to capture the frosting of the heat exchanger. A thermal-camera capable of recording thermographic stills and standard image stills at the same time and a macro camera recording a detailed view of a part of the heat exchanger used for highlight event extraction. For the standard images both, a normal view and a differential view between the actual image and an image recorded in the initial state (without frost) is shown: an example of the detailed view is given in Figure 2 on the right side; the total view is given on the left side. The setup of the cameras can also be seen in Figure 5.

In order to quantify the frost accumulation, the scale signal and the amount of pixel exceeding a certain brightness threshold in the pictures may be used. A pixel exceeds the brightness threshold if the mean of the red, green and blue value is higher than 200. At the beginning only the pixels displaying the metallic surface of the fins will exceed this brightness threshold. But as soon as frost is accumulating, additional pixel will exceed this threshold. Pixels exceeding the stated threshold (“white” pixels) are from now flagged as highlight events for additional processing.

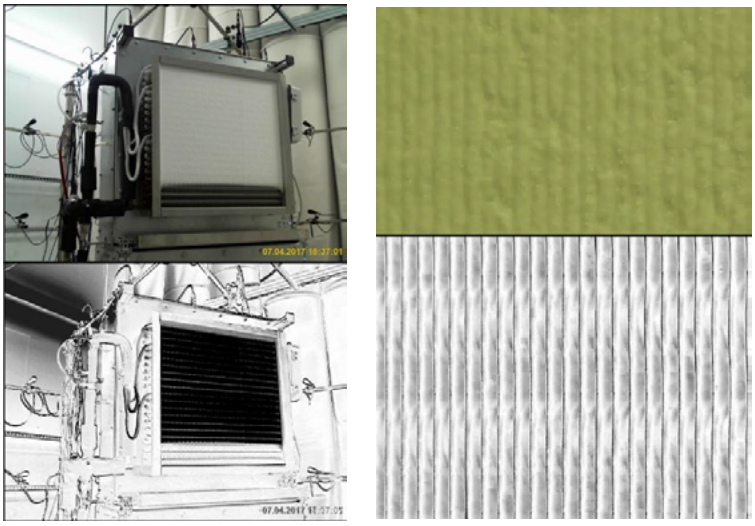

Fig. 2. Measurement overview with full frosting. The humidity in the climatic chamber has been increased to its maximum reachable value to reach full frost state. Left side: full image of the heat pump showing severe frosting on the top and a differential image of the heat exchanger showing frost only on the bottom; Right side: detailed view on the heat exchanger fins with full frosting on top and differential image of detailed view on the frosting heat exchanger showing frost only on the bottom.

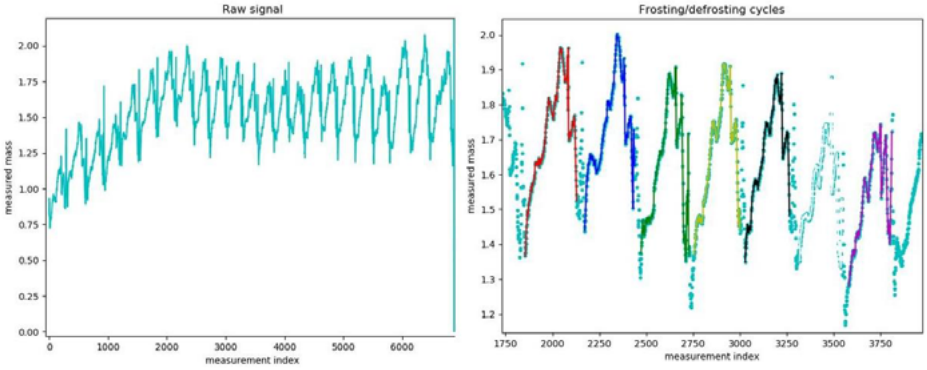

Fig. 3. (left) Measured mass given in kg shown as function of the measurement index for an inflow air temperature of 2°C; (right) Frost mass versus measurement index for a section of the whole measurement period (shown on left side). Each frosting cycle is identified by visual inspection and marked with a unique colour for visualization.

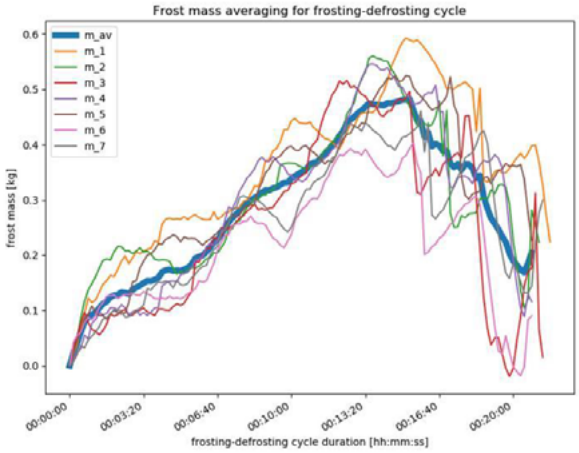

Fig. 4. Frost mass given in kg as a function of frosting-defrosting duration. The single repetitive events shown in Fig. 3 right are now superimposed to allow for the generation of a mean average frosting cycle and presented via the time duration.

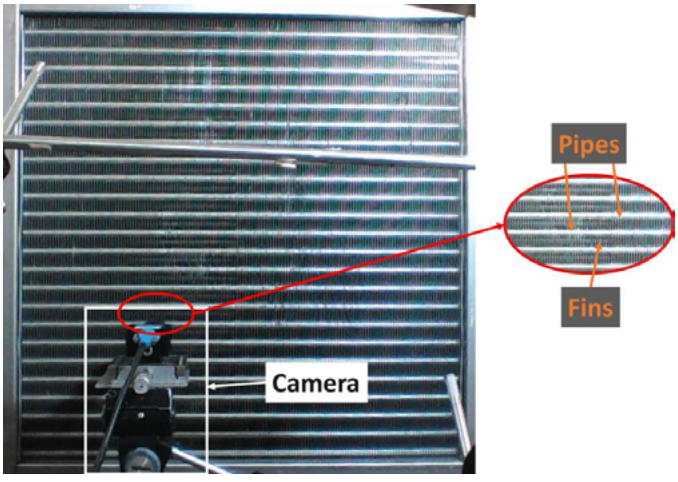

Fig. 5. Surface of the SilentAirHP heat exchanger and macro camera used to visualize the frost accumulation on the heat exchanger fins.

4. Experimental Results and Discussion

A common webcam can also be used to visualize the nonuniform frost accumulation on the heat exchanger surface (see Figure 6). It can be seen, that the frost is not forming uniformly on the whole heat exchanger surface, but rather patchy. The camera with the macro lenses used to visualize the frost growth between two fins is located at a representative area, where the frost growth is clearly visible. The rod looming over the pictures is a humidity sensor.

The macro camera was used to give a detailed view of the frost accumulation and dissipation on one or two fins of the heat exchanger. In Figure 5 the surface of the SilentAirHP heat exchanger and the macro camera used to visualize the frost accumulation on the heat exchanger fins is shown. The boundary conditions for the frosting behaviour analysis of the SilentAirHP are listed in Table 1. The pictures of the frost accumulation

between two fins can be seen in Figure 7. In Figure 8 the scale measurements and the amount of highlight events is shown over time.

Table 1. Operation and ambient conditions for the analysis of the frosting behaviour of the SilentAirHP.

θ_{amb}	RH_{amb}	η_{comp}	η_{fan}	Refrigerant	Fin type	Coating	Fin area
6.3°C	71.8%	94 Hz	99 Hz	R410A	Straight flat fins	Clearcoat U-Sil 120 GL	11.44 m^2

Legend:
θ_{amb} … Ambient temperature // RH_{amb} … Relative Humidty // η_{comp} … Rotational frequency of the compressor
η_{fan} … Rotational frequency of the fan // Refrigerant … Used refrigerant // Fin type … Fin type used for the reported measurement
Coating … Coating used for surface treatment of the fins // Fin area … Total area of the fins

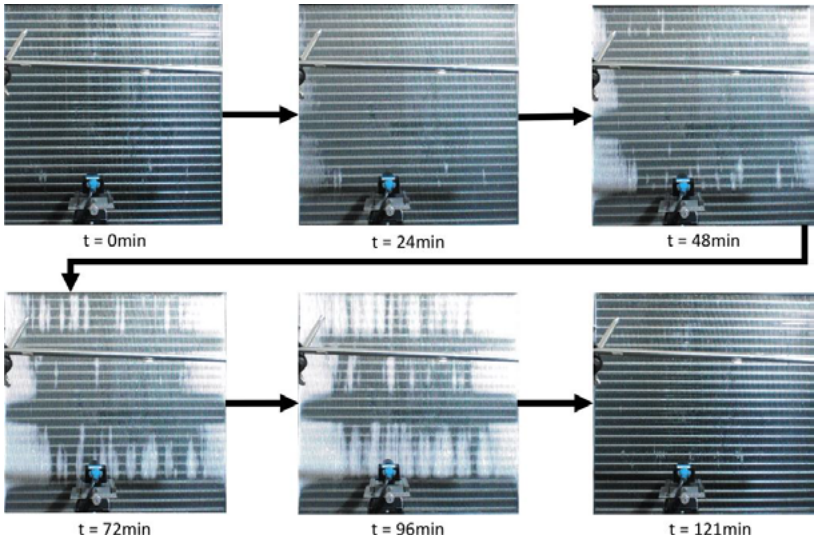

Fig. 6. Nonuniform frost formation on the heat exchanger surface of the SilentAirHP.

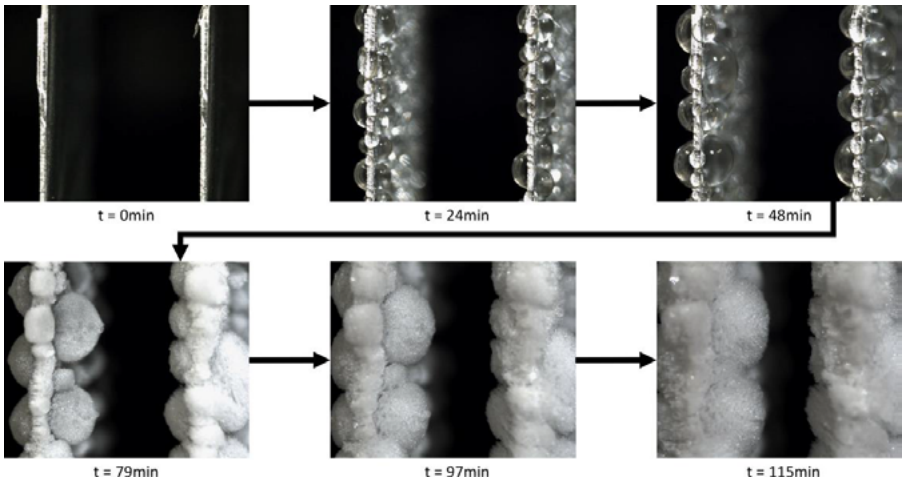

Fig. 7. Frost accumulation on two fins of the coated evaporator of the SilentAirHP for operation and ambient conditions as defined in Table 1.

Frosting of the SilentAirHP starts with small water drops condensing on the surface of the vertical fins. The water drops start fusing together forming bigger water drops. These bigger water drops start to freeze, building frost globes on the fins of the heat exchanger. Advancing in time, the frost globes start fusing together and the frost continues to densify. When the frost layer is too thick, the SilentAirHP starts to defrost, in order to assure continues stable operation. This defrosting is done by reversing the cycle via a four-way valve.

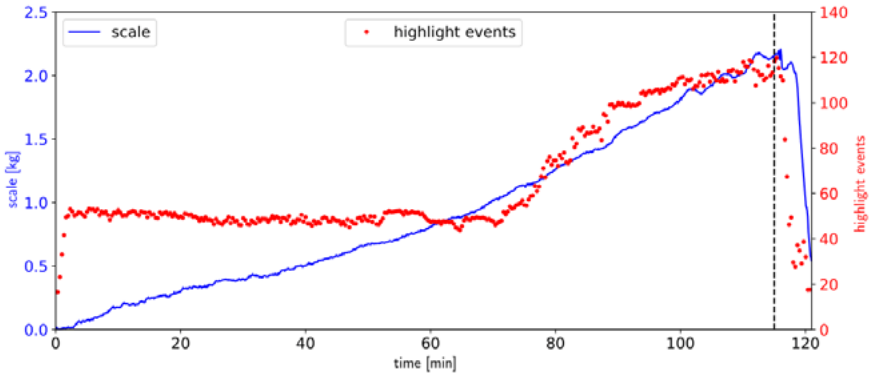

Fig. 8. Scale measurement and amount of highlight events in pictures of the SilentAirHP during frosting conditions and defrosting operation. The time when defrosting is initiated is marked with a dotted line.

After reversing the cycle, the frosted heat exchanger, which acted as the evaporator for the refrigerant, afterwards works as the condenser for the refrigerant, transferring heat to the outlet air and to the frost on its fins. Defrosting of the heat exchanger is done in a very short period of time. The defrosting of the SilentAirHP can be seen in Figure 9.

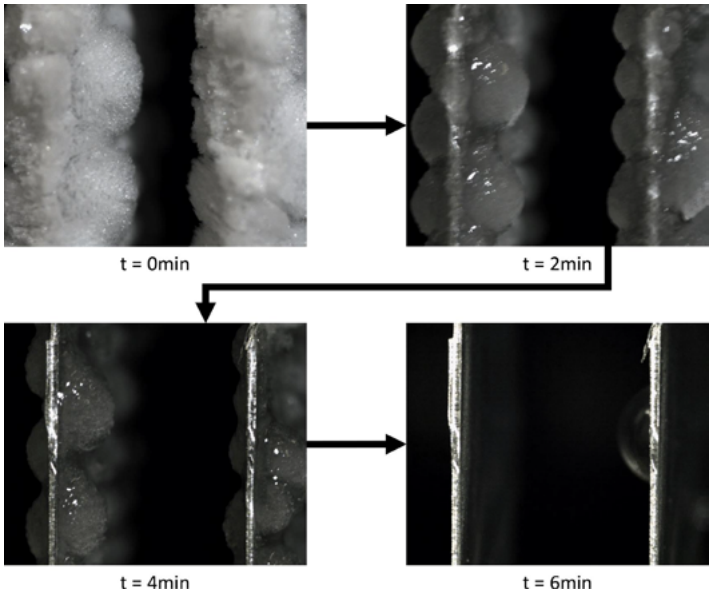

Fig. 9. Defrosting of the coated evaporator of the SilentAirHP for operation and ambient conditions as defined in Table 1.

Defrosting of the SilentAirHP takes only 6 min, while the operation at frosting conditions was able to be operated in an almost stable manner for 115 minutes for the settings given in Table 1. Therefore, the heat pump can be operated in regular heating mode for approximately 95% of the time at these conditions. When the ice layer is formed on the evaporator surface, however, the heat pump performance begins to decrease slightly. This can also be seen in the temperature sensors placed inside the heat pump (see Fig. 12). When the frost layer grows starting around 70 minutes (see Fig. 8), the valve, compressor and condenser temperatures both on the discharge and suction side begin to fall slightly indicating this decrease in performance.

During the remaining 5% of the time the heat exchanger has to be defrosted. When defrosting is started, the fins rapidly take the hot temperature of the refrigerant. Therefore, the frost is melted from its surface, forming liquid water which flows down the vertical fins. This water flows down the heat exchanger until it reaches the ground it stands on. In Figure 8 the scale measurements and the amount of highlight events in the pictures during frosting and defrosting operation of the SilentAirHP is shown. The mass on the heat exchanger is constantly rising, due to condensing water on the heat exchanger fins and afterwards frosting of the water drops and densifying of the frost. During the first 70 minutes nearly no change in highlight events is visible, as the condensed water drops do not count as highlight events, but only frost does. After 70 minutes the amount of highlight events is increasing. Just after beginning of defrost operation, which is marked with a dotted line in the plot, the amount of highlight events and the mass of the scale is decreasing rapidly, as the frost is melting, and the water drains off. It is interesting to compare the close-up view (Figure 7) with the global view (Figure 6): On the first and last picture in the global view, where the close up camera suggests complete termination of the defrosting operation, falling water drops are still visible on the webcam pictures.

Frosting cycles have been measured for several environmental conditions defined by the evaporator air inflow temperature. The climate chamber was set to a sustain a defined relative humidity. This can only be achieved with some fluctuations especially in the vicinity of defrosting. For and outdoor air temperature of 2°C, 4.5°C and 7°C, a relative humidity of 87.3%, 86.4% and 78%, respectively was measured. During defrosting, however, the relative humidity in the chamber cannot be sustained by the climate chamber control and deviates from this number. After defrosting the humidity control of the climate chamber is able to bring the conditions back. The relative mass signals are shown in Figure 10 for air inflow temperatures of 2.0°C, 4.5°C and 7.0°C. The average frost mass for these different air inflow temperatures is shown in Figure 11. It can clearly be seen, that the implemented control algorithm acts differently for the different situations. Cycle times for the 7°C air inflow temperature are - with around 120 min - longer than those for an air inflow temperature of 4.5°C which lie around 80 minutes. Not only the amount of accumulated frost is different – also the shape of the weight increase curves shows a different behaviour – not only in curvature but also in their repetitiveness. The employed control algorithm leads to very frequent defrosting for the 2°C air inflow temperature setting.

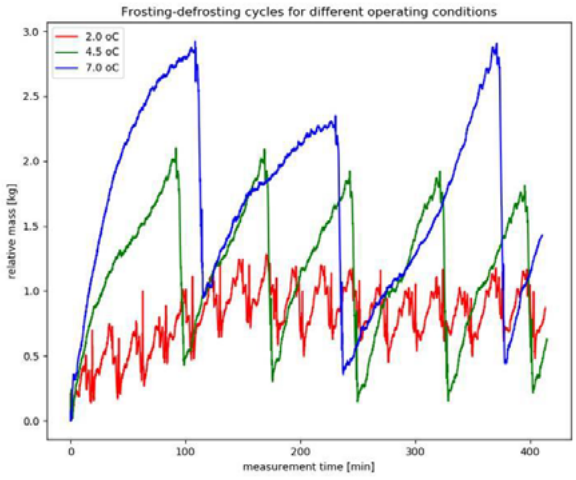

Fig. 10. Frost mass given as a function of the measurement time for three different temperatures (given in °C) of the inflow air. In all cases, several frosting/defrosting cycles are shown.

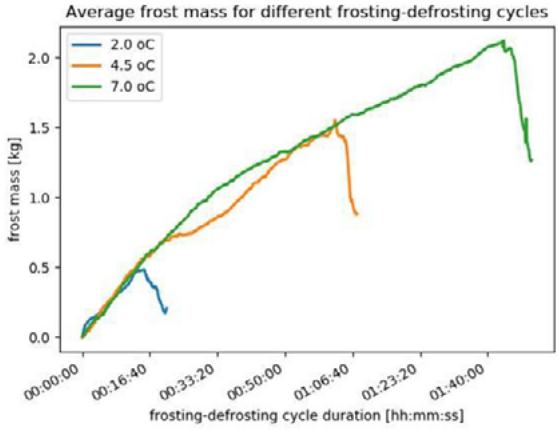

Fig. 11. Average frost mass given as a function of the measurement time for three different temperatures (given in °C) of the inflow air.

Defrosting of the heat pump was triggered once the evaporator pressure (which is equivalent to an evaporation temperature) has fallen below a certain lower limit. This is an indication for a decreased heat transfer through the evaporator what goes hand in hand with an increased frost thickness and a lower COP. Since, the defrost condition was not corelated to the outdoor temperature condition in our experiments, the time before defrosting increases for higher outdoor temperatures. This fact is also reflected in the differences in frost aggregation (mass uptake, see Figure 11).

The refrigerant temperatures during operation are shown in Figure 12 for the settings given in Table 1. During operation of the heat pump at frosting conditions most refrigerant temperatures fluctuate but the mean of most temperatures stay approximately constant. However, about thirty minutes before defrosting the mean of some refrigerant temperatures, as well as the compressor suction and discharge temperatures, decrease slightly. When defrosting is initiated the compressor discharge temperature, the valve suction temperature, the condenser suction temperature and the condenser discharge temperature fall significantly. Meanwhile, the compressor suction and the valve discharge temperature rise. This operation mode is maintained only for a very short time and the temperatures are fluctuating heavily during this mode.

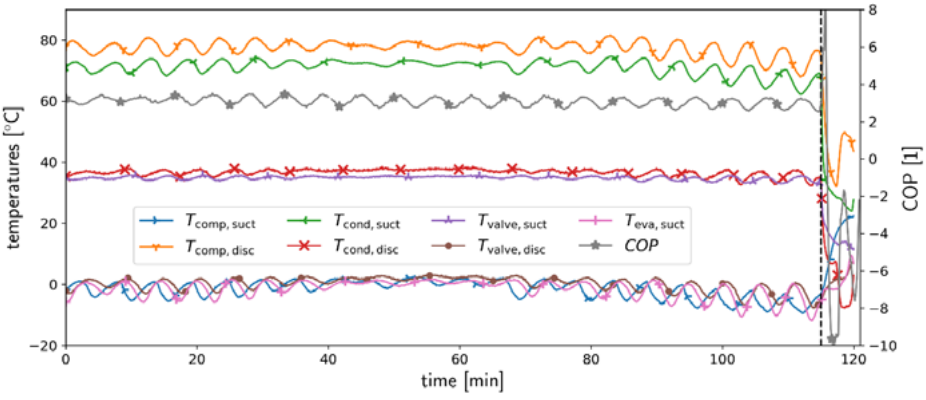

Fig. 12. Development of the refrigerant temperatures over time during operation of the SilentAirHP at frosting conditions. The time when defrosting is initiated is marked with a black dotted line. The CoP is added as a grey curve.

5. Conclusions and Outlook

Frosting of evaporators is commonly observed especially in mild climates and a defrosting procedure has to be put in place allow for a continuous operation of the heat pump. The evaporator, however, is only one part of the complete setup: Frosting of the fins and tubes and hence subsequent blocking of the evaporator leads to an increased pressure drop over the evaporator which could force the fan to run in a different operating point. Furthermore, the frost layer changes the heat transfer characteristics of the evaporator.

In this paper we introduced methods for measuring the weight increase using scales and visualizing ice accretion using postprocessing of images captured from the evaporator surface during heat pump operation. We could show, that there is a good correlation between the weight increase and the number of highlight events present in the images captured. Furthermore, the formation of droplets on the fin structures and subsequently freezing eventually building up an ice layer between the fins could be shown with a macro camera providing very detailed images. It should be noted, that selecting the right spot for the macro camera is important to achieve representative ice accretion data.

The experimental characterization methodologies built around the experimental heat pump "SilentAirHP" proved to be a robust testbed for identification of efficient ways to detect frosting states, which will be used to derive soft sensors in the framework of the IoT (Internet of Things) heat pump initiative. The test-rig using full control capabilities of the self-made heat pump is further capable of comparing different evaporators and/or evaporators with different coatings.

Finally, the data base available through the frosting and defrosting experiments is key to validate numerical simulations performed to simulate the frosting process either on full evaporator geometries or smaller symmetric elements used to reconstruct the behaviour of the full evaporator setups. The images from the macro camera visualize the frosting process and can be used to compare to very high detailed simulation results. The numerical approaches allow for assisting in evaporator design and development.

Theoretical Analysis of Mass Transfer in a Vacuum Membrane Dehumidification System

Hye-Jin Cho[a], Seong-Yong Cheon[a], Su Liu[a], Jae-Weon Jeong[a*]

[a]Department of Architectural Engineering, College of Engineering, Hanyang University, Seoul, 04763, Republic of Seoul

Abstract

This paper theoretically investigated the dehumidification performance of a vacuum membrane dehumidification system. Dehumidification effectiveness and the coefficient of performance (COP) were adopted as measures of performance. A one-dimensional numerical model was developed to analyze the mass transfer in a membrane dehumidifier module as a function of variation of four operating parameters: the inlet air temperature, humidity ratio, velocity, and the pressure in the vacuum side. Parametric analysis of the proposed model demonstrated that the inlet air velocity and the pressure in the vacuum side significantly affected dehumidification performance. When the pressure in the vacuum side decreased from 101.3 to 1.0 kPa, the dehumidification effectiveness increased from 2.1 to 54.1 %, while the COP decreased from 23.9 to 1.7. Similarly, the dehumidification effectiveness decreased from 73.9 to 15.8 % and the COP increased from 1.9 to 2.5 with an increase in air velocity from 0.1 to 2.0 m/s. In addition, the energy performance of the proposed vacuum membrane dehumidification system in building application was evaluated by comparing with a conventional cooling coil system.

1. Introduction

To provide a suitable indoor environment to building occupants, the temperature and humidity of air inducted from the outside into buildings should be controlled. For decades, vapor compression-based air conditioning systems have been widely adopted in air conditioning systems since they are highly effective and convenient in operation. However, vapor compression air conditioning systems may have energy penalty because of the overcooling and reheating of the process air [1]. Desiccant-assisted systems have been suggested as an alternative option for dehumidification in air conditioning applications [2]. A desiccant absorbs moisture when a water vapor pressure difference exists between the process air and desiccant. Consequently, the desiccant system does not require the supply of overcooling and reheating energy. However, regeneration of the desiccant material results in considerable energy consumption if there are no free-heat sources.

Vacuum membrane-based dehumidification systems have been suggested in recent years as an alternative to vapor compression and desiccant-based dehumidification systems [3,4]. The membrane is made of hydrophilic and polymeric materials for transferring water vapor across the membrane. In a vacuum membrane dehumidification system, the main driving force for the transfer of moisture is the pressure difference across the membrane. Water vapor in the humid process air is absorbed and diffuses through the membrane owing to the pressure difference, which is generated by a vacuum pump depressurizing the permeate side. Water vapor that has penetrated to the permeate side is exhausted externally. Accordingly, the vacuum membrane dehumidification system can isothermally remove the latent load in the process air, and does not require heating or cooling during dehumidification.

Several studies have investigated the potential of vacuum membrane dehumidification systems as a function of the membrane's material and configuration under various operating conditions [5–7]. However, research that addresses the operating conditions and workable design of a vacuum membrane dehumidifier remain very rare.

This study suggested the operating conditions and configuration of a vacuum membrane dehumidifier based on the results of a theoretical analysis. A one-dimensional numerical model for a vacuum membrane dehumidifier is derived, and the sensitivity of dehumidification performance to each operating parameter was analyzed by using the proposed model. The dehumidification and energy performance of the proposed system were evaluated by comparing it with a conventional vapor compression-based dehumidification system.

2. Vacuum membrane dehumidification system

2.1. System overview

In a vacuum membrane-based dehumidification system, dehumidification occurs by the vapor pressure difference between the feed side (or primary air side) and the permeate side (or secondary air side), which is separated by a dense hydrophilic membrane (Fig. 1). During dehumidification, water vapor in the feed side diffuses on the membrane and is transferred to the permeate side, and is then exhausted to the outside by a vacuum pump. The key function of the membrane is selective gas separation. In membrane-based gas separation, a membrane is characterized by its permeance, that is, the amount of a species passing through the membrane per unit area and unit pressure difference, and by its selectivity, the ratio of the amount of a species passing through membrane to that of other species [7]. Therefore, the permeability and the selectivity of the membrane to water vapor have significant impacts on the performance of the vacuum membrane dehumidification system.

In this study, a hollow fiber polyamide membrane coated with carboxylated titanium dioxide (C-TiO_2) nanoparticles dehumidifier was adopted. This membrane has a water vapour permeance of 4.68×10^{-7} mol/s m^2Pa and a selectivity of 510 for water vapor/dry air [3]. The thickness of membrane was 150 μm, and the inner and outer diameters of the hollow fiber were 480 μm and 685 μm, respectively. The outer diameter of the membrane module was 0.2 m. The number of hollow fibers in the membrane modules was set at 30,000.

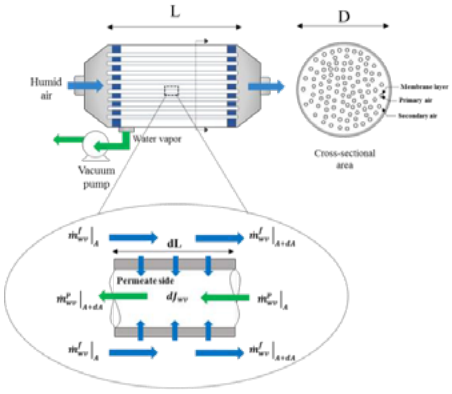

Fig. 1. Schematic of a vacuum membrane dehumidification system.

2.2. Numerical model derivation

In this study, it was assumed that mass transfer occurred along the direction of air flow (i.e. x-axis), from *x=0 to x=L*, and the water vapor transferred to the permeate side was exhausted in the opposite direction, from *x=L to x=0*, by the vacuum pump (Fig. 1). Other assumptions are as follow:

1. Dehumidification occurs under ideal gas conditions.
2. Dehumidification occurs in a steady state.
3. The permeability and selectivity are constant.
4. The process air only consists of water vapor and dry air.
5. The total air pressure from feed and permeate sides remain constant.
6. The initial water vapor pressure in permeate side is zero, the initial dry air pressure in permeate side is equal to the total vacuum side pressure.

2.3. Overall mass transfer coefficient

The simulation model in this work mainly consists of an overall mass transfer coefficient model and the mass balance equations between the air in feed side and permeate sides. In the overall mass transfer coefficient model, the convection-based mass transfer of the boundary layer of feed/permeate sides, and the permeance of the membrane to water vapor was considered. In addition, the overall mass resistance of the dry air should be considered in the performance of a vacuum membrane dehumidification system. Therefore, the overall mass transfer resistance of water vapor ($R_{t,wv}$) and dry air ($R_{t,da}$) can be estimated by the mass transfer resistance of water vapor ($R_{diff,wv}$) and dry air ($R_{diff,da}$), the mass resistance of the boundary layer in the feed side (R_{bl}^{f}) and permeate sides (R_{bl}^{p}) (Eqs. 1 and 2):

$$R_{t,wv} = R_{diff,wv} + R_{bl}^{f} + R_{bl}^{p} \tag{1}$$

$$R_{t,da} = R_{diff,da} + R_{bl}^{f} + R_{bl}^{p} \tag{2}$$

The overall mass resistance of the boundary layer can be estimated by Eq.3 with the molar density (ρ), and the mass transfer coefficient at the boundary layer (k_{bl}), which is defined by Eq. 4:

$$R_{bl} = \frac{1}{\rho k_{bl}} \tag{3}$$

$$k_{bl} = \frac{D_w \cdot Sh}{D_h} \tag{4}$$

where D_w is the diffusivity of water vapor in air, *Sh* is the Sherwood dimensionless number, and D_h is the hydraulic diameter of the fiber module. In this study, the *Sh* is defined by an empirical model, including the Reynolds (*Re*) and Schmidt (*Sc*) numbers (Eq.5), as suggested by Wang et al. [8]:

$$Sh = 0.3 + (0.62 Re_a^{0.5} \frac{Sc_a^{\frac{1}{3}}}{(1+(\frac{0.4}{Sc_a})^{\frac{2}{3}})^{\frac{1}{4}}} \cdot (1 + \frac{(\frac{Re_a}{282000})^5}{8})^{4/5} \tag{5}$$

In terms of the mass transfer coefficient of the dense membrane, the overall mass transfer resistance can be calculated from the membrane's thickness (δ_m) and water vapor permeance (Per_{wv}) (Eq. 6):

$$R_{diff,wv} = \frac{1}{Per_{wv}} \tag{6}$$

In addition, the overall mass transfer resistance of the dry air can be obtained if the water vapor permeance and the water vapor/dry air selectivity are known (Eq. 7):

$$Per_{da} = \frac{Per_{wv}}{Sel} \tag{7}$$

2.4. Mass balance equations

The mass balance of the water vapor in the feed/permeate sides can be written by the governing equations for the mass flux of water vapor (Eqs. 8 and 9):

$$\frac{dJ_{wv}}{dA} = \frac{(P^f_{wv} - P^p_{wv})}{R_{t,wv}} \tag{8}$$

$$dA = n_{fiber} \cdot \pi \cdot d_{i,f} \cdot dx \tag{9}$$

Where dJ_{wv}/dA indicate the mass flux of water vapor for the superficial surface area of each fiber module (dA), which can be obtained from the number of hollow fibers, the inner fiber diameter and fiber length. The total water vapor mass flow rate in feed/permeate sides after passing through the membrane can be estimated from the calculated mass flux for water vapor for each module (Eqs. 10 and 11):

$$\dot{m}^f_{wv}\big|_{A+dA} = \dot{m}^f_{wv}\big|_A - dJ_{wv} \tag{10}$$

$$\dot{m}^p_{wv}\big|_{A+dA} = \dot{m}^p_{wv}\big|_A + dJ_{wv} \tag{11}$$

Where $\dot{m}^f_{wv}$ and $\dot{m}^p_{wv}$ is the mass flow rate of water vapor of the feed/permeate sides and the pressure of the water vapor in feed/permeate sides can be obtained from Dalton's law of partial pressures for an ideal gas. The total dry air vapor mas flow rate in feed/permeate sides can also be obtained with the same method (Eqs. 12 and 13):

$$\dot{m}^f_{da}\big|_{A+dA} = \dot{m}^f_{da}\big|_A - dJ_{da} \tag{12}$$

$$\dot{m}^p_{da}\big|_{A+dA} = \dot{m}^p_{da}\big|_A + dJ_{da} \tag{13}$$

Then, the outlet air humidity ratio can be obtained from the pressure of the water vapor and dry air of the feed side (Eq. 14).

$$\omega_{a,out} = 0.622 \frac{P^f_{wv,out}}{P^f_{da,out}} \tag{14}$$

The differential elements of the computational domain can be expressed as *dx=L/N* when the domain is discretized by dividing the module length *L* (*x-axis*) into N segments. In this work, the domain was divided into 20 along the *x-axis*. Therefore, the governing equations for calculating the mass flux of the water vapor can be expressed the following discretized form (Eqs. 15–18):

$$J_{wv}[i+1] - J_{wv}[i] = \frac{\left(P^f_{wv}[i] - P^p_{wv}[i]\right)}{R_{t,wv}} \left(n_{fiber} \cdot \pi \cdot D_{i,f} \cdot \frac{L}{N}\right) \tag{15}$$

$$\dot{m}^f_{wv}[i+1] = \dot{m}^f_{wv}[i] - (J_{wv}[i+1] - J_{wv}[i]) \tag{16}$$

$$\dot{m}^p_{wv}[i+1] = \dot{m}^p_{wv}[i] + (J_{wv}[i+1] - J_{wv}[i]) \tag{17}$$

$$\omega_a[i+1] = 0.622 \frac{P^f_{wv}[i+1]}{P^f_{da}[i+1]} \tag{18}$$

The mass flux of dry air also can be calculated the same way. The gradients of humidity ratio in feed side in each segment can be estimated when the following boundary conditions are given: the initial water vapor/dry air pressure in the feed side, calculated from the inlet air temperature and humidity ratio, the mass resistance in the feed side boundary layer, calculated from the inlet velocity, and the vacuum side total pressure.

3. Simulation results

Dehumidification effectiveness (ε_{deh}), defined as the ratio of the humidity ratio difference between the inlet and outlet air to the inlet air humidity ratio (Eq. 19), was used as a measure of performance:

$$\varepsilon_{deh} = \frac{\omega_{a,in} - \omega_{a,out}}{\omega_{a,in}} \tag{19}$$

In gas separation-based dehumidification the vacuum pump is used to compress the water vapor pressure of the feed side to equal that of the permeate side. The dehumidification COP was calculated as Eq. 20.

$$COP = \frac{\dot{Q}_{lat}}{W_{pump}} \tag{20}$$

Where $\dot{Q}_{lat}$ is the latent load removed by the vacuum membrane dehumidification system (Eq. 21), and W_{pump} is the vacuum pump's workload, obtained by Eq. 22.

$$\dot{Q}_{lat} = \dot{m}_a h_{fg} (\omega_{a,in} - \omega_{a,out}) \tag{21}$$

$$W_{pump} = \frac{\left(\frac{\dot{dm}_{mv}}{MW_{wv}} + \frac{\dot{dm}_{da}}{MW_{da}}\right) RT_k}{\varepsilon_{pump}} ln \frac{P_{atm}}{P_{vac}} \tag{22}$$

Where $\dot{dm}_{mv}$ and $\dot{dm}_{da}$ indicate the total mass flux of water vapor and dry air pumped by the vacuum pump, and the MW_{wv} and MW_{da} are the molar mass of water vapor and dry air, respectively. R is the ideal gas constant, and T_k is the absolute temperature of the inlet air. P_{atm} and P_{vac} indicate atmospheric and vacuum pressures, respectively and ε_{pump} is the vacuum pump's efficiency. In this study, vacuum pump efficiency was assumed to be 0.6.

3.1. Model validation

To validate the reliability of the proposed model, simulation results from the numerical model were compared with the experimental data from a previous study [7]. The operating ranges of the simulation conditions were set based on the valid range of each operating parameter: the inlet air temperature was varied from 25 to 33 ºC, the inlet air humidity ratio ranged from 0.012 to 0.026 kg/kg. The air flow rate was 0.067 kg/s. The permeability, selectivity, and the physical configuration of membrane dehumidifier were identical to those of the simulation model.

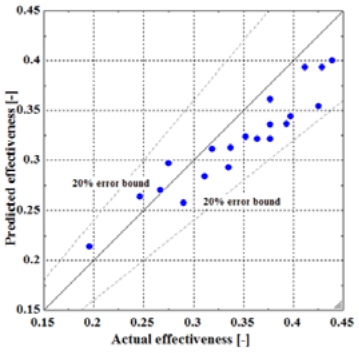

Fig. 2. Comparison of dehumidification effectiveness value with measurement data.

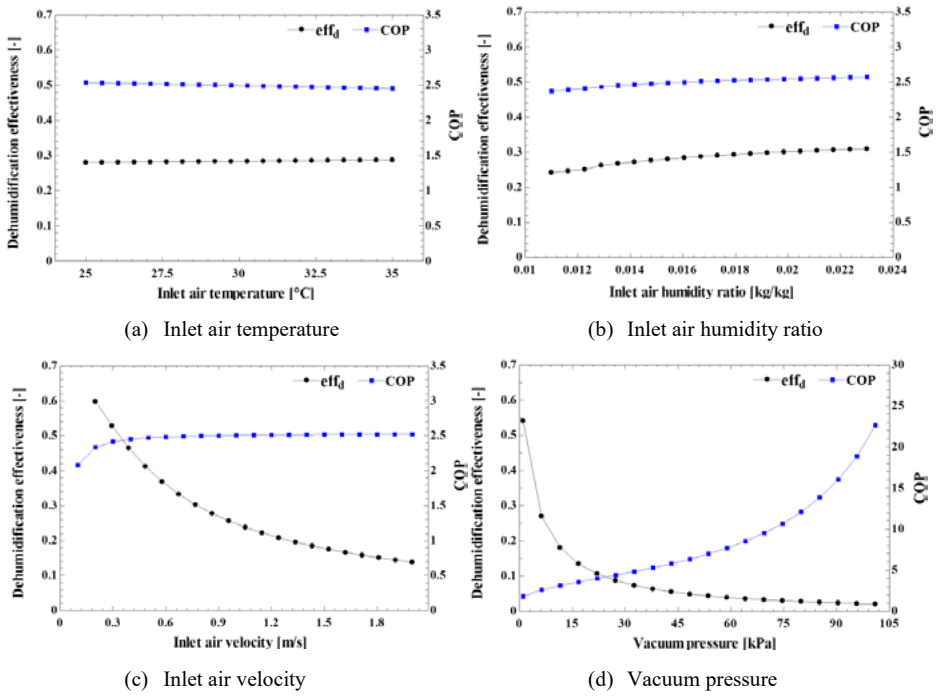
Figure 2 compares the dehumidification effectiveness values predicted by the proposed simulation model with the measurement data, which shows that the predicted values generally agreed well with the measurement data within 20 % error bounds. Therefore, the proposed model can be used to predict the dehumidification performance of a vacuum membrane dehumidification system.



3.2. Parametric analysis

In this section, parametric analysis was conducted to analyze the effects of variation in operating parameters on dehumidification performance of a vacuum membrane dehumidification system. The initial conditions of the four operating parameters were set as the average value in the valid range. Simulations were performed by sequentially varying each of operating parameters within the valid range, while the remaining parameters were fixed to their initial conditions. Table 1 shows the simulation conditions of each operating parameter.

Table 1. Simulation conditions of operating parameters.

Operating parameter	Range		
	Min.	Ave.	Max.
Inlet air temperature ($T_{a,in}$) [ºC]	25	30	35
Inlet air humidity ratio ($\omega_{a,in}$) [kg/kg]	0.011	0.017	0.023
Air velocity (V_a) [m/s]	0.1	1.0	2.0
Vacuum pressure (P_{vac}) [kPa]	1	5	100

Figure 3 shows the effect of each operating parameter on the dehumidification performance of a vacuum membrane dehumidification system. Air velocity (Fig. 3c) and the vacuum side pressure (Fig. 3d) significantly affected the dehumidification effectiveness and dehumidification COP, while the inlet air temperature and inlet air humidity ratio exerted minimal effect. When the vacuum side pressure increased from 1–100 kPa, the dehumidification effectiveness decreased from 55.5–2.1 % while the dehumidification COP increased from 2.15 to 23. This is because decreasing the permeate side pressure from atmospheric pressure to almost a complete vacuum can increase the water vapor difference between the feed and permeate sides, thereby increasing the driving force to remove water vapor in feed side. In terms of dehumidification COP, decreasing the vacuum side pressure had a negative effect because decreasing permeate side pressure to an almost complete vacuum imposes a large workload on the pump. Similarly, an increase in air velocity decreased the dehumidification effectiveness from 73.9 % to 15.8 %, and increased the dehumidification COP from 2.1 to 2.5. This is because the higher air velocity results in a shorter air-membrane contact time. Nevertheless, the higher air velocity increased the latent load removed by the membrane dehumidification system, which resulted in an increase of the dehumidification COP. Consequently, both dehumidification performance and COP of the vacuum membrane dehumidification system was highly affected by vacuum side pressure and inlet air velocity.

(c) Inlet air velocity (d) Vacuum pressure

Fig. 3. Effect of changes in operating parameters on dehumidification performance.

4. Application and discussion

In this section, energy and dehumidification performances were simulated to evaluate the operating performance of the vacuum membrane dehumidification system in HVAC applications. The design supply air flow rate was set at 200 m^3/h, which is a minimum ventilation rate for a single-story office building, located in Seoul, with 150 m^2 of floor area and eight occupants [9]. International weather for energy calculation (IWEC) data was adopted to perform the simulation for the cooling seasons in Seoul. The latent load in a model space was calculated using the TRNSYS 18 program, using the physical information of the model building (Table 2) and an office occupant and HVAC schedule addressed in ASHRAE 90.1 [10]. To maintain the supply air humidity ratio at a target point (i.e. 0.0085 kg/kg) during cooling seasons, the vacuum pump was operated to maintain the vacuum side pressure to a water vapor pressure of a target supply air (i.e. 1.19 kPa). A membrane dehumidifier with a module diameter in 0.6 m and a module length in 0.8 m was selected in order to accommodate the peak latent load during simulations.

Table 2. Physical information of the simulated building model.

Location	Seoul, Republic of Korea	
Building	15 × 10 × 3 m^3	
Heat gain	Occupants	5 persons /100 m^2
	Lights	13 W/m^2
	Computers	230 W/persons
U-value (insulation)	Exterior wall	0.524 W/m^2K

	Window	5.68 W/m^{2}K
	Roof	0.152 W/m^{2}K

4.1. Dehumidification performance

Figure 6 shows the supply air humidity ratio of the vacuum membrane dehumidification system. The performance of the dehumidifier was highly affected by the outdoor air humidity ratio. As shown in Figure 4, the supply air humidity ratio varied from 0.004 kg/kg to 0.0086 kg/kg, which demonstrated that the vacuum membrane dehumidification system can sufficiently dehumidify the outdoor air to meet the target point throughout most of the cooling seasons.

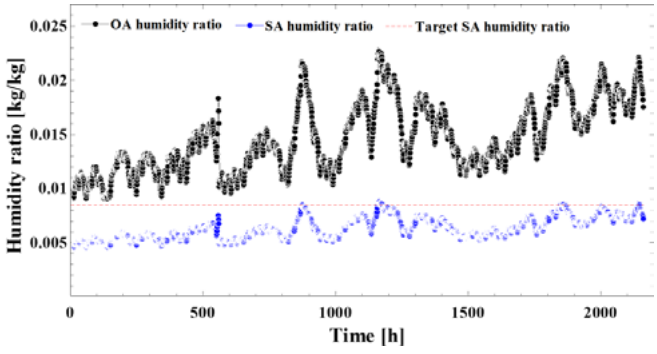

Fig. 4. Hourly supply air humidity ratio in a vacuum membrane dehumidification system.

A cooling coil was chosen as a reference system to evaluate the energy performance of the vacuum membrane dehumidification system in HVAC applications. It was assumed that the cooling coil removed the latent load to meet the supply air humidity ratio, which was the same as that of the vacuum membrane dehumidification system. Figure 5 shows the dehumidification process of a vacuum membrane dehumidification system and a conventional condensation-based dehumidification system. The vacuum membrane dehumidification system can isothermally dehumidify the outdoor air (Eq. 23), while the vapor compression system cools the outdoor air to the dew point temperature, which causes unnecessary sensible cooling (Eq. 24). Therefore, the latent cooling load for a vacuum membrane dehumidification system requires about 47 % less thermal load than that in a reference system (Fig. 6).

$$\dot{Q}_{VMD} = \dot{m}_{oa} h_{fg} (\omega_{oa} - \omega_{sa}) \tag{23}$$

$$\dot{Q}_{CC} = \dot{m}_{oa} (h_{oa} - h_{sa,dp}) \tag{24}$$

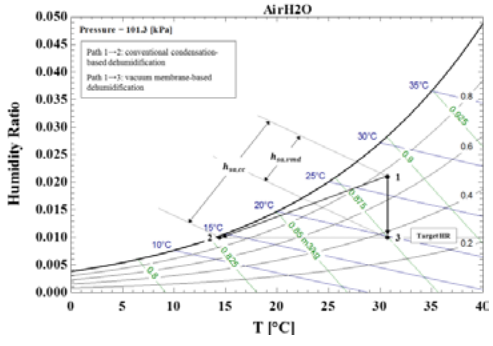

Fig. 5. Dehumidification of the proposed and reference case, presented in a psychrometric chart.

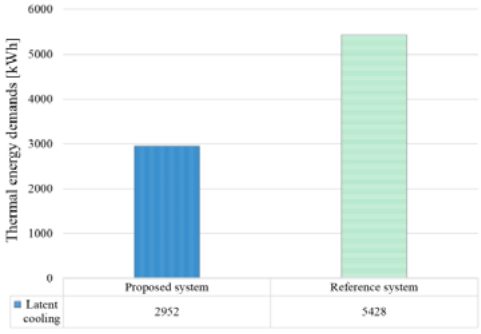

Fig. 6. Comparison of dehumidification loads.

4.2. Energy performance

Figure 8 shows that the vacuum membrane dehumidification system can reduce 47 % of the latent cooling load compared with a reference system. To evaluate the energy performance of the vacuum membrane dehumidification system, the primary energy consumption of both cases was calculated. The primary energy consumption of a vacuum membrane dehumidification system was estimated by calculating the vacuum pump operating energy with Eq. 22. The primary energy consumption of a reference system was obtained by using a chiller energy prediction model [11].

Figure 7 shows the primary energy consumption of the proposed system and reference case in cooling seasons. In contrast to the latent cooling load, the vacuum membrane dehumidification system could save only 5 % of primary energy compared to that of the reference system. This is because the dehumidification COP of a vacuum membrane dehumidifier is lower than that of the chiller. The COP of the vacuum membrane dehumidification system was maintained between 2.1 and 2.3, while that of the chiller ranged from 4.1 to 5.4. The vacuum pump should maintain the permeate side pressure to almost a complete vacuum to achieve satisfactory dehumidification, which leads to the high energy requirements of the vacuum pump. Therefore, one can conclude that the COP of the vacuum membrane dehumidification system should be improved by enhancing the dehumidification performance through a lower vacuum pump operating load.

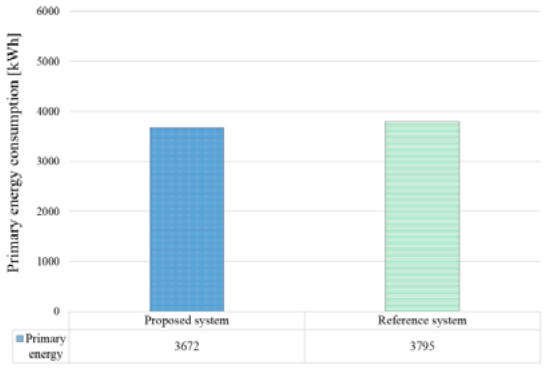

Fig. 7. Comparison of the primary energy consumption in VMD and CC

5. Conclusions

This study theoretically analyzed the dehumidification performance of a vacuum membrane dehumidification system. The governing equations for the mass flux of water vapor and dry air were derived based on the mass balance between the water vapor and dry air in the feed/permeate sides. The sensitivity of dehumidification performance on changes in operating parameters was analyzed using the proposed model. The vacuum side pressure and inlet air velocity were the most critical factors determining both dehumidification and energy performance. In particular, the dehumidification performance of a vacuum membrane dehumidification system significantly increased when the vacuum pump compressed the vacuum side pressure to equal the water vapor pressure in the inlet air.

The energy and operating performance of a vacuum membrane dehumidification system was also evaluated by comparing it with a conventional vapor compression system. The vacuum membrane dehumidification system decreased the latent cooling load by 47 % compared with a conventional cooling coil system. However, there was little energy saving potential because of the lower dehumidification COP compared to that of a reference system. Consequently, further study should consider the optimization of the vacuum pump operation strategy so that satisfactory dehumidification performance can be achieved with lower vacuum pump working loads.

Abstract

Membrane dehumidifiers dry air via an isothermal process, which is why they can potentially yield a better dehumidification performance than conventional dehumidification systems. In this research, the dehumidification performance of a hollow-fiber-membrane dehumidifier was estimated by means of a series of experiments. The membrane dehumidifier consists of a hollow-fiber-membrane unit and an air pump. As the prototype unit used a sweep-gas, the use of dehumidified air was a drawback on the permeate side. Five operating parameters were considered as effective dehumidification variables: inlet air temperature, inlet air relative humidity, intake air flow rate, sweep gas ratio, and inlet air pressure. The dehumidification performance of the membrane dehumidifier was quantified as the difference in the humidity ratio and amount of dehumidification. The experimental data were analyzed by means of a parametric study involving the five independent operating parameters. Consequently, we found that the dehumidification performance was significantly impacted by the inlet air pressure that formed the driving force, and the inlet air conditions also exhibited a positive correlation with performance. When the sweep-gas ratio ranged from 0.4 to 0.6, a high value of dehumidification was achieved under balanced flow conditions.

1. Introduction

Desiccant-based air-conditioning technologies have recently been proposed for decoupling dehumidification and sensible cooling as an alternative to conventional cooling and dehumidification systems [1,2]. Desiccant-material-based systems pre-condition the intake outdoor air, and subsequently, the dehumidified air is controlled by a mechanical and evaporative cooling system to achieve the target temperature. Decoupled air-conditioning systems can afford high energy savings when the significant amount of heat consumed for regenerating the desiccant material is supplied by free energy [3–5].

Recently, membrane-based dehumidification systems have been suggested as an alternative system of vapor compression and desiccant-based dehumidification [6,7]. There is no requirement for a cooling and heating source as isothermal processes in such systems, compared with conventional dehumidification systems. In a membrane dehumidification system, the intake air is dehumidified via transferring water vapor between hydrophilic membrane layers by the application of a partial vapor gradient [6]. When a vapor pressure gradient is generated between membrane layers, the water vapor in the process air soaks and diffuses to the membrane layer, and subsequently, the layer is desorbed by another air stream. In this regard, several studies have investigated the dehumidification performance of membrane driers made of various materials under several design conditions [8,9]. Bui et al. [8] theoretically investigated a membrane dehumidification system with a flat plate. The membrane materials were assumed to consist of ceramic and polymeric layers with high

E-mail address: jjwarc@hanyang.ac.kr (J.-W. Jeong).

permeability and selectivity of water vapor. The study results showed that the factors affecting the dehumidification performance included air velocity, permeability and selectivity of the membrane, pressure, and humidity of the processed air. Here, we note that membrane selectivity and pressure significantly affect a membrane drier's performance. Moreover, some studies have considered the use of membrane dehumidification systems for the air-conditioning of buildings; El-Dessouky et al. [10] proposed a membrane-dehumidifier-integrated air-cooling system, which has a vacuum-based membrane drier for dehumidification and evaporative coolers for sensible cooling. The authors showed that membrane-dehumidification-based air-conditioning systems can reduce the energy consumption by up to 86% when compared with conventional air-conditioning systems.

In this context, several studies have focused on membrane dehumidification systems to evaluate their energy and dehumidification performance for various membrane materials and system configurations. However, very few studies have experimentally evaluated the dehumidification performance of membrane dehumidification systems as applied to building heating, ventilation, and air-conditioning (HVAC). In this study, we developed a hollow-fiber-type membrane dehumidifier and evaluated its dehumidification performance under various operating conditions.

2. Hollow-fiber-membrane dehumidifier

In this section, we describe the general principle underlying membrane dehumidification along with the theoretical dehumidification process. Furthermore, we present our prototype hollow-fiber-membrane dehumidifier.

2.1 Hollow-fiber-membrane dehumidifier

The membrane dehumidifier dries the intake air via an isothermal process, which is hard to realize in conventional dehumidifiers. The membrane dehumidifier has two main parts: membrane modules and air compressor, as shown in Figure 1. The membrane module for dehumidification uses permeated water vapor, and the air compressor generates a partial vapor pressure gradient between the membrane layers. When the partial vapor pressure gradient between the membrane layers is created by the air compressor, the water vapor permeates from the feed side to the permeate side. The dehumidification performance is dependent on the membrane material, particularly its permeability and selectivity to water vapor. When the membrane affords a high level of permeability and selectivity, the dehumidification performance and energy efficiency of the membrane unit is correspondingly higher. In this study, the type of membrane used is a hollow-fiber membrane, which is easy to manufacture structurally, and the air compressor is used to pressurize the inlet air for creating the vapor pressure gradient between membrane layers. To maintain the dehumidification performance, a part of the intake air is "swept" out to the permeate side, thereby removing the water vapor.

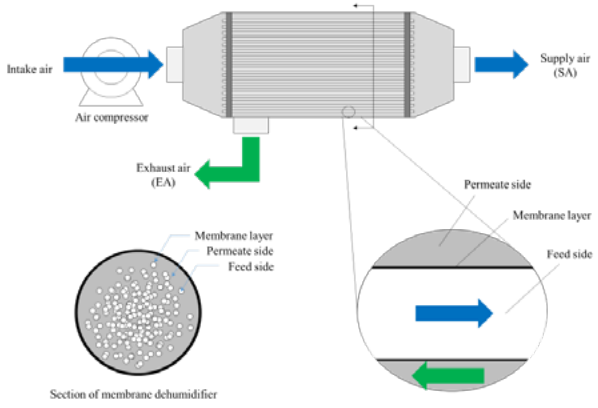

Fig. 1. Configuration of hollow-fiber-membrane dehumidifier

When the intake gas is assumed to be an ideal mixture of two gases, dry air and water vapor, the dehumidification process of the membrane dehumidifier can be represented by a solution–diffusion process between the feed side and the permeate side with a partial pressure gradient, as shown in Figure 2. When the feed-side air of the unit is pressurized for dehumidification, water vapor and dry air permeate through the membrane layer. The molar mass flow rates of water vapor and dry air (i.e., $\dot{M}'_w$ and $\dot{M}'_d$) through the membrane layer are estimated by means of the classical solution–diffusion model as represented by Equations (1) and (2), respectively. To estimate the partial pressure gradient, which acts as the force driving the dehumidification, we represent the partial pressure of each gas on the permeate side as the ratio of the molar mass flow rate through the membrane layer (i.e., y_1 and y_2) in Equations (3) and (4). The values of permeability (Per), selectivity (S), membrane area (A_{mem}), and membrane thickness (z) are determined according to the performance of the membrane materials, and these values affect the dehumidification performance along with energy consumption of the air compressor. Each molar mass flow rate is dependent on the membrane material and sweep gas used to remove the water vapor on the permeate side.

$$\dot{M}'_w = \frac{\mathrm{Per}_v A_{mem}}{z}\left(P_{f,v} - y_1 P_{p,tot}\right) \tag{1}$$

$$\dot{M}'_d = \frac{\mathrm{Per}_d A_{mem}}{z}\left(P_{f,d} - y_2 P_{p,tot}\right) = \frac{\mathrm{Per}_v}{S}\frac{A_{mem}}{z}\left(P_{f,v} - y_2 P_{p,tot}\right) \tag{2}$$

$$y_1 = \frac{\dot{M}'_v + \dot{M}'_{sweep,v}}{\dot{M}'_d + \dot{M}'_v + \dot{M}'_{sweep,d} + \dot{M}'_{sweep,v}} \tag{3}$$

$$y_2 = \frac{\dot{M}'_d + \dot{M}'_{sweep,d}}{\dot{M}'_d + \dot{M}'_v + \dot{M}'_{sweep,d} + \dot{M}'_{sweep,v}} \tag{4}$$

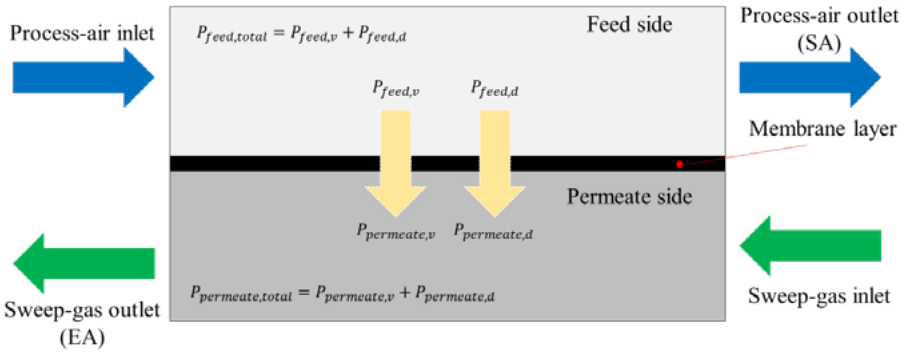

Fig. 2. Schematic of dehumidification process in membrane dehumidifier

2.2 Prototype of hollow-fiber-membrane dehumidifier

When the basic theoretical model does not consider the membrane type and configuration, it is not easy to estimate the dehumidification performance of the membrane dehumidifier under various operating conditions. Therefore, we developed a prototype hollow-fiber-membrane dehumidifier and estimated its dehumidification performance under various conditions. The configuration of the prototype unit is shown in Figure 3. The prototype unit has an inlet air channel on the feed side and sweep-gas air channel on the permeate side. In the study, the membrane module of our proposed dehumidifier was of the cylinder type, and the length of the module was 0.3 m, with the module diameter being 0.08 m. The module contained 170 hollow-fiber membranes each with a fiber inlet diameter of 1.6 mm, corresponding to a packing fraction ratio of 0.11. The hollow-fiber length was 0.23 m, and its total effective contacting area was 0.282 m^2. The specifications of our prototype module are listed in Table 1.

Table 1: Specifications of prototype unit

Design parameters	Values	Design parameters	Values
Module diameter [mm]	80	Fiber thickness [mm]	0.35
Module length [mm]	300	Contacting area of membrane [m^2]	0.282
Fiber inlet diameter [mm]	1.6	Number of fibers [-]	170
Fiber outlet diameter [mm]	2.3	Packing fraction [-]	0.11
Fiber length [mm]	230		

Fig. 3. Prototype configuration of hollow-fiber-membrane dehumidifier

3. Test setup and dehumidification performance

3.1 Experimental setup of prototype

To analyze the dehumidification performance of our prototype unit, we varied five independent parameters: air temperature, relative humidity, airflow rate, inlet air pressure, and sweep-gas ratio. The experimental setup for controlling these five independent parameters is shown in Figure 4. In the setup, the environmental chamber is used to maintain the experimental air conditions, and the air compressor maintains the airflow ratio of the conditioned air to the prototype unit. The rotation speed of the air compressor is controlled by means of a switched-mode power supply (SMPS) that controls the electric current and voltage. The pressure of the feed side is controlled by open-to-close ratio of the inlet valves to generate the partial pressure gradient. Moreover, the sweep-gas ratio, which corresponds to the ratio of the intake supply airflow rate to the sweep-gas flow rate, is controlled by the outlet valve as an adjustable open-to-close ratio. The measured data to estimate the dehumidification performance of the prototype unit are collected and saved in the data logger.

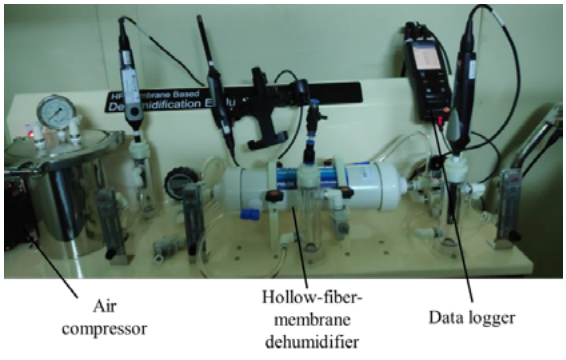

Fig. 4. Schematic of experimental setup of hollow-fiber-membrane dehumidifier

3.2 Operation conditions

In this study, we conducted 24 sets of experiments for analyzing the dehumidification performance of the hollow-fiber-membrane dehumidifier unit. The dehumidification performance of the prototype unit was estimated as the differential of the humidity ratio and amount of dehumidification, as expressed by Equations (5) and (6), respectively. The humidity ratio differential is representative of the driving force of the vapor pressure gradient, and the amount of dehumidification represents the dehumidification per unit time as a function of the latent cooling capacity.

$$\Delta w = w_{in} - w_{out} \quad (5)$$

$$\dot{m}_d = \dot{m}_{sa}\Delta w = (\dot{m}_{intake} - \dot{m}_{sweep})\Delta w \quad (6)$$

To analyze the dehumidification performance under various conditions, we acquired the performance data for various values of the five operating parameters: air temperature, relative humidity, airflow rate, sweep-gas ratio, and inlet air pressure. As the sweep-gas ratio is the airflow ratio of the intake air to the sweep-out air, a high level of sweep gas implies that the supply airflow rate is reduced for a given intake air flow rate. To estimate the differential of the humidity ratio and amount of dehumidification, each parameter was suitably varied. As the air temperature and humidity ratio were set to reflect humid and mild air conditions, these were maintained in the range of 15 to 30 ℃ and 40 to 80%, respectively. The detailed operational range is listed in Table 2. To estimate the dehumidification performance of the prototype unit, we did parametric study from the experimental results, which were based on the base case, and subsequently, only a single parameter was modulated in the operation range when all other parameters were fixed.

Table 2: Operating ranges of experimental conditions

Parameter	Symbol	Input values		
		Low	Base	High
Inlet air temperature [℃]	$T_{a,in}$	15	27	30
Inlet relative humidity [%]	$RH_{a,in}$	40	60	80
Inlet air flow rate [l/min]	$\dot{V}_{a,in}$	20	25	30
Sweep-gas ratio [−]	x	0.18	0.5	0.82
Inlet pressure [kPa]	p_{air}	101.3	101.3	260

The measurement sensors in our setup included high-precision humidity/temperature, differential pressure, and absolute pressure sensors. The high-precision humidity/temperature sensor measures the inlet and outlet temperatures and relative humidity. The airflow rate is measured by the differential pressure sensor in conjunction with a digital flow meter. The measurement points corresponding to airflow rate measurements include the inlet, outlet, and exhaust sides. The inlet air pressure is measured by the absolute pressure sensor, where the inlet air pressure is controlled by the air compressor by means of valves. To quantify the dehumidification performance, the measurement data were converted into the humidity ratio, which is affected by the air temperature, relative humidity, and pressure.

Table 3: Specifications of measuring instruments

Variable	Device	Characteristics		
Dry-bulb temperature and relative humidity of air	High-precision humidity/temperature probe	Range	Temperature	−20 ℃ to +55 ℃
			Relative humidity	0%–100%
		Accuracy	Temperature	±0.4 ℃
			Relative humidity	±2%RH
Air flow rate	Differential pressure sensor	Range	Pressure	0–1250 Pa
		Accuracy		±0.30%
Inlet air pressure	Absolute pressure sensor	Range	Pressure	0–1250 Pa
		Accuracy		±0.30%

4. Experimental results and discussion

We experimentally investigated the performance of the prototype unit considering the influences of the five air inlet parameters: inlet air temperature, relative humidity, air pressure, inlet air flow rate, and sweep-gas ratio. The influence of each of the five parameters considered was analyzed via the differential of the humidity ratio and amount of dehumidification; the results are shown in Figure 5.

We note from the figure that the air temperature and relative humidity exhibit a positive correlation with the differential of the humidity ratio and amount of dehumidification. We note that higher levels of inlet temperature and relative humidity correspond to a higher partial vapor gradient between the membrane layers. In addition, as the inlet air pressure increases, the partial vapor pressure gradient between membrane layer was increased , and the dehumidification performance improves. The sweep-gas ratio and intake airflow rate exhibit no positive correspondence with the dehumidification performance. When the sweep-gas ratio ranges from 0.4 to 0.6, the differential of the humidity ratio and the amount of dehumidification are maximal because the mass transfer between the feed and permeate sides increases as a balanced flow. When the intake air flow rate decreases, the face velocity on the feed side also decreases with increase in the contact time of the unit. The differential of the humidity ratio is strongly affected, but the amount of dehumidification is only relatively impacted by the airflow rate.

The main parameters that significantly affect the dehumidification performance of the prototype unit are the inlet air pressure and sweep-gas ratio. To increase the dehumidification performance, the inlet air pressure should be sufficiently high, and the sweep-gas ratio must be maintained around 0.5 for balanced flow. Here, we note that to control the outlet humidity ratio, a suitable rotation speed modulation strategy of the air compressor or sweep-gas ratio should be estimated.

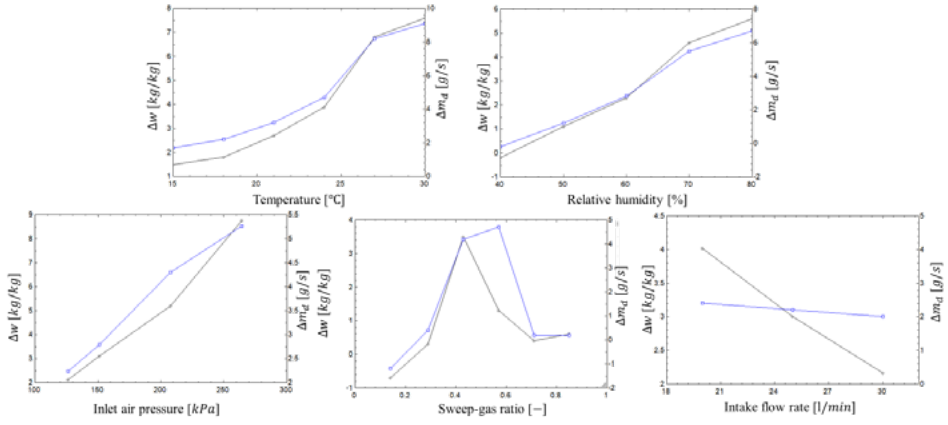

Fig. 5. Parametric analysis of hollow-fiber-membrane dehumidifier

5. Conclusions

In this study, we experimentally investigated the dehumidification performance of a hollow-fiber-membrane dehumidification unit. Our prototype unit was composed of a membrane module containing a bundle of hollow membranes and an air compressor to pressurize the inlet pressure, which forms the driving force underlying the process. Experiments were conducted using the prototype unit to estimate the differential of the humidity ratio and amount of dehumidification, and the relevant performance data were collected. The input parameters that influence the dehumidification performance are the air temperature, relative humidity, inlet air pressure, sweep-gas ratio, and intake air flow rate. The air temperature and relative humidity exhibited a positive correlation with the performance, which indicates that a larger amount of air with water vapor affords increased dehumidification performance. The inlet air pressure also positively affects the performance via increasing the driving force of the vapor pressure drop. The dehumidification performance was maximal when the sweep-gas ratio was in the range of 0.4 to 0.6 under balanced flow conditions. When the intake air flow rate was decreased, the dehumidification performance increased because of the increased contacting time of air with the prototype unit.

In future study, we plan to analyze the dehumidification efficiency under various operation conditions. In addition, the data collected in the study can be applied to extend the utilization of the control logic of the hollow-fiber-membrane dehumidifier.

Abstract

Membrane dehumidifiers dry air via an isothermal process, which is why they can potentially yield a better dehumidification performance than conventional dehumidification systems. In this research, the dehumidification performance of a hollow-fiber-membrane dehumidifier was estimated by means of a series of experiments. The membrane dehumidifier consists of a hollow-fiber-membrane unit and an air pump. As the prototype unit used a sweep-gas, the use of dehumidified air was a drawback on the permeate side. Five operating parameters were considered as effective dehumidification variables: inlet air temperature, inlet air relative humidity, intake air flow rate, sweep gas ratio, and inlet air pressure. The dehumidification performance of the membrane dehumidifier was quantified as the difference in the humidity ratio and amount of dehumidification. The experimental data were analyzed by means of a parametric study involving the five independent operating parameters. Consequently, we found that the dehumidification performance was significantly impacted by the inlet air pressure that formed the driving force, and the inlet air conditions also exhibited a positive correlation with performance. When the sweep-gas ratio ranged from 0.4 to 0.6, a high value of dehumidification was achieved under balanced flow conditions.

1. Introduction

Desiccant-based air-conditioning technologies have recently been proposed for decoupling dehumidification and sensible cooling as an alternative to conventional cooling and dehumidification systems [1,2]. Desiccant-material-based systems pre-condition the intake outdoor air, and subsequently, the dehumidified air is controlled by a mechanical and evaporative cooling system to achieve the target temperature. Decoupled air-conditioning systems can afford high energy savings when the significant amount of heat consumed for regenerating the desiccant material is supplied by free energy [3–5].

Recently, membrane-based dehumidification systems have been suggested as an alternative system of vapor compression and desiccant-based dehumidification [6,7]. There is no requirement for a cooling and heating source as isothermal processes in such systems, compared with conventional dehumidification systems. In a membrane dehumidification system, the intake air is dehumidified via transferring water vapor between hydrophilic membrane layers by the application of a partial vapor gradient [6]. When a vapor pressure gradient is generated between membrane layers, the water vapor in the process air soaks and diffuses to the membrane layer, and subsequently, the layer is desorbed by another air stream. In this regard, several studies have investigated the dehumidification performance of membrane driers made of various materials under several design conditions [8,9]. Bui et al. [8] theoretically investigated a membrane dehumidification system with a flat plate. The membrane materials were assumed to consist of ceramic and polymeric layers with high

E-mail address: jjwarc@hanyang.ac.kr (J.-W. Jeong).

permeability and selectivity of water vapor. The study results showed that the factors affecting the dehumidification performance included air velocity, permeability and selectivity of the membrane, pressure, and humidity of the processed air. Here, we note that membrane selectivity and pressure significantly affect a membrane drier's performance. Moreover, some studies have considered the use of membrane dehumidification systems for the air-conditioning of buildings; El-Dessouky et al. [10] proposed a membrane-dehumidifier-integrated air-cooling system, which has a vacuum-based membrane drier for dehumidification and evaporative coolers for sensible cooling. The authors showed that membrane-dehumidification-based air-conditioning systems can reduce the energy consumption by up to 86% when compared with conventional air-conditioning systems.

In this context, several studies have focused on membrane dehumidification systems to evaluate their energy and dehumidification performance for various membrane materials and system configurations. However, very few studies have experimentally evaluated the dehumidification performance of membrane dehumidification systems as applied to building heating, ventilation, and air-conditioning (HVAC). In this study, we developed a hollow-fiber-type membrane dehumidifier and evaluated its dehumidification performance under various operating conditions.

2. Hollow-fiber-membrane dehumidifier

In this section, we describe the general principle underlying membrane dehumidification along with the theoretical dehumidification process. Furthermore, we present our prototype hollow-fiber-membrane dehumidifier.

2.1 Hollow-fiber-membrane dehumidifier

The membrane dehumidifier dries the intake air via an isothermal process, which is hard to realize in conventional dehumidifiers. The membrane dehumidifier has two main parts: membrane modules and air compressor, as shown in Figure 1. The membrane module for dehumidification uses permeated water vapor, and the air compressor generates a partial vapor pressure gradient between the membrane layers. When the partial vapor pressure gradient between the membrane layers is created by the air compressor, the water vapor permeates from the feed side to the permeate side. The dehumidification performance is dependent on the membrane material, particularly its permeability and selectivity to water vapor. When the membrane affords a high level of permeability and selectivity, the dehumidification performance and energy efficiency of the membrane unit is correspondingly higher. In this study, the type of membrane used is a hollow-fiber membrane, which is easy to manufacture structurally, and the air compressor is used to pressurize the inlet air for creating the vapor pressure gradient between membrane layers. To maintain the dehumidification performance, a part of the intake air is "swept" out to the permeate side, thereby removing the water vapor.

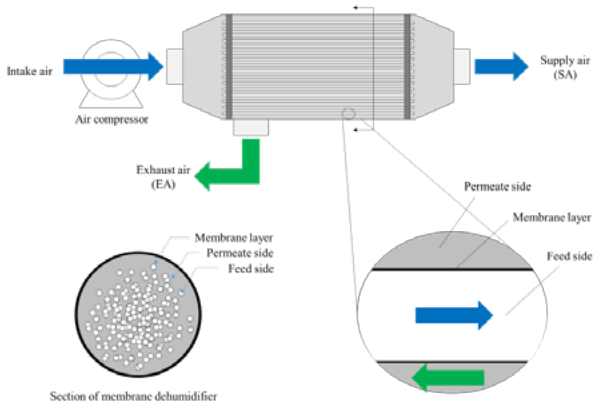

Fig. 1. Configuration of hollow-fiber-membrane dehumidifier

When the intake gas is assumed to be an ideal mixture of two gases, dry air and water vapor, the dehumidification process of the membrane dehumidifier can be represented by a solution–diffusion process between the feed side and the permeate side with a partial pressure gradient, as shown in Figure 2. When the feed-side air of the unit is pressurized for dehumidification, water vapor and dry air permeate through the membrane layer. The molar mass flow rates of water vapor and dry air (i.e., $\dot{M}'_w$ and $\dot{M}'_d$) through the membrane layer are estimated by means of the classical solution–diffusion model as represented by Equations (1) and (2), respectively. To estimate the partial pressure gradient, which acts as the force driving the dehumidification, we represent the partial pressure of each gas on the permeate side as the ratio of the molar mass flow rate through the membrane layer (i.e., y_1 and y_2) in Equations (3) and (4). The values of permeability (Per), selectivity (S), membrane area (A_{mem}), and membrane thickness (z) are determined according to the performance of the membrane materials, and these values affect the dehumidification performance along with energy consumption of the air compressor. Each molar mass flow rate is dependent on the membrane material and sweep gas used to remove the water vapor on the permeate side.

$$\dot{M}'_w = \frac{\mathrm{Per}_v A_{mem}}{z}\left(P_{f,v} - y_1 P_{p,tot}\right) \tag{1}$$

$$\dot{M}'_d = \frac{\mathrm{Per}_d A_{mem}}{z}\left(P_{f,d} - y_2 P_{p,tot}\right) = \frac{\mathrm{Per}_v}{S}\frac{A_{mem}}{z}\left(P_{f,v} - y_2 P_{p,tot}\right) \tag{2}$$

$$y_1 = \frac{\dot{M}'_v + \dot{M}'_{sweep,v}}{\dot{M}'_d + \dot{M}'_v + \dot{M}'_{sweep,d} + \dot{M}'_{sweep,v}} \tag{3}$$

$$y_2 = \frac{\dot{M}'_d + \dot{M}'_{sweep,d}}{\dot{M}'_d + \dot{M}'_v + \dot{M}'_{sweep,d} + \dot{M}'_{sweep,v}} \tag{4}$$

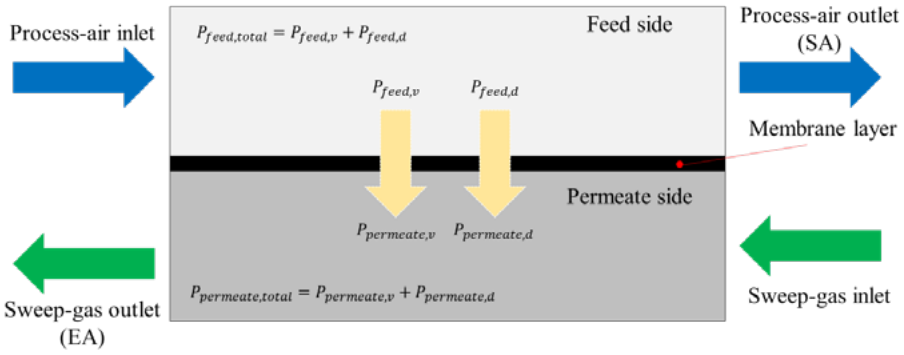

Fig. 2. Schematic of dehumidification process in membrane dehumidifier

2.2 Prototype of hollow-fiber-membrane dehumidifier

When the basic theoretical model does not consider the membrane type and configuration, it is not easy to estimate the dehumidification performance of the membrane dehumidifier under various operating conditions. Therefore, we developed a prototype hollow-fiber-membrane dehumidifier and estimated its dehumidification performance under various conditions. The configuration of the prototype unit is shown in Figure 3. The prototype unit has an inlet air channel on the feed side and sweep-gas air channel on the permeate side. In the study, the membrane module of our proposed dehumidifier was of the cylinder type, and the length of the module was 0.3 m, with the module diameter being 0.08 m. The module contained 170 hollow-fiber membranes each with a fiber inlet diameter of 1.6 mm, corresponding to a packing fraction ratio of 0.11. The hollow-fiber length was 0.23 m, and its total effective contacting area was 0.282 m^2. The specifications of our prototype module are listed in Table 1.

Table 1: Specifications of prototype unit

Design parameters	Values	Design parameters	Values
Module diameter [mm]	80	Fiber thickness [mm]	0.35
Module length [mm]	300	Contacting area of membrane [m^2]	0.282
Fiber inlet diameter [mm]	1.6	Number of fibers [-]	170
Fiber outlet diameter [mm]	2.3	Packing fraction [-]	0.11
Fiber length [mm]	230		

Fig. 3. Prototype configuration of hollow-fiber-membrane dehumidifier

3. Test setup and dehumidification performance

3.1 Experimental setup of prototype

To analyze the dehumidification performance of our prototype unit, we varied five independent parameters: air temperature, relative humidity, airflow rate, inlet air pressure, and sweep-gas ratio. The experimental setup for controlling these five independent parameters is shown in Figure 4. In the setup, the environmental chamber is used to maintain the experimental air conditions, and the air compressor maintains the airflow ratio of the conditioned air to the prototype unit. The rotation speed of the air compressor is controlled by means of a switched-mode power supply (SMPS) that controls the electric current and voltage. The pressure of the feed side is controlled by open-to-close ratio of the inlet valves to generate the partial pressure gradient. Moreover, the sweep-gas ratio, which corresponds to the ratio of the intake supply airflow rate to the sweep-gas flow rate, is controlled by the outlet valve as an adjustable open-to-close ratio. The measured data to estimate the dehumidification performance of the prototype unit are collected and saved in the data logger.

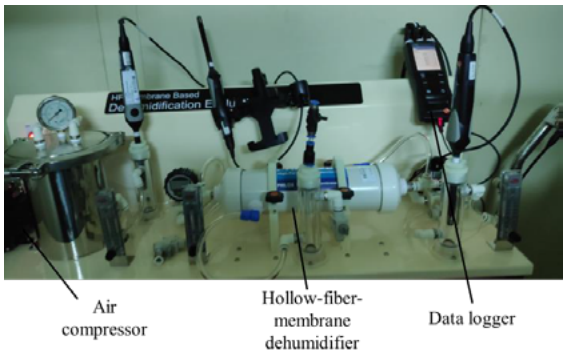

Fig. 4. Schematic of experimental setup of hollow-fiber-membrane dehumidifier

3.2 Operation conditions

In this study, we conducted 24 sets of experiments for analyzing the dehumidification performance of the hollow-fiber-membrane dehumidifier unit. The dehumidification performance of the prototype unit was estimated as the differential of the humidity ratio and amount of dehumidification, as expressed by Equations (5) and (6), respectively. The humidity ratio differential is representative of the driving force of the vapor pressure gradient, and the amount of dehumidification represents the dehumidification per unit time as a function of the latent cooling capacity.

$$\Delta w = w_{in} - w_{out} \quad (5)$$

$$\dot{m}_d = \dot{m}_{sa}\Delta w = (\dot{m}_{intake} - \dot{m}_{sweep})\Delta w \quad (6)$$

To analyze the dehumidification performance under various conditions, we acquired the performance data for various values of the five operating parameters: air temperature, relative humidity, airflow rate, sweep-gas ratio, and inlet air pressure. As the sweep-gas ratio is the airflow ratio of the intake air to the sweep-out air, a high level of sweep gas implies that the supply airflow rate is reduced for a given intake air flow rate. To estimate the differential of the humidity ratio and amount of dehumidification, each parameter was suitably varied. As the air temperature and humidity ratio were set to reflect humid and mild air conditions, these were maintained in the range of 15 to 30 ℃ and 40 to 80%, respectively. The detailed operational range is listed in Table 2. To estimate the dehumidification performance of the prototype unit, we did parametric study from the experimental results, which were based on the base case, and subsequently, only a single parameter was modulated in the operation range when all other parameters were fixed.

Table 2: Operating ranges of experimental conditions

Parameter	**Symbol**	**Input values**		
		Low	Base	High
Inlet air temperature [℃]	$T_{a,in}$	15	27	30
Inlet relative humidity [%]	$RH_{a,in}$	40	60	80
Inlet air flow rate [l/min]	$\dot{V}_{a,in}$	20	25	30
Sweep-gas ratio [−]	x	0.18	0.5	0.82
Inlet pressure [kPa]	p_{air}	101.3	101.3	260

The measurement sensors in our setup included high-precision humidity/temperature, differential pressure, and absolute pressure sensors. The high-precision humidity/temperature sensor measures the inlet and outlet temperatures and relative humidity. The airflow rate is measured by the differential pressure sensor in conjunction with a digital flow meter. The measurement points corresponding to airflow rate measurements include the inlet, outlet, and exhaust sides. The inlet air pressure is measured by the absolute pressure sensor, where the inlet air pressure is controlled by the air compressor by means of valves. To quantify the dehumidification performance, the measurement data were converted into the humidity ratio, which is affected by the air temperature, relative humidity, and pressure.

Table 3: Specifications of measuring instruments

Variable	**Device**	**Characteristics**		
Dry-bulb temperature and relative humidity of air	High-precision humidity/temperature probe	Range	Temperature	−20 ℃ to +55 ℃
			Relative humidity	0%–100%
		Accuracy	Temperature	±0.4 ℃
			Relative humidity	±2%RH
Air flow rate	Differential pressure sensor	Range	Pressure	0–1250 Pa
		Accuracy		±0.30%
Inlet air pressure	Absolute pressure sensor	Range	Pressure	0–1250 Pa
		Accuracy		±0.30%

4. Experimental results and discussion

We experimentally investigated the performance of the prototype unit considering the influences of the five air inlet parameters: inlet air temperature, relative humidity, air pressure, inlet air flow rate, and sweep-gas ratio. The influence of each of the five parameters considered was analyzed via the differential of the humidity ratio and amount of dehumidification; the results are shown in Figure 5.

We note from the figure that the air temperature and relative humidity exhibit a positive correlation with the differential of the humidity ratio and amount of dehumidification. We note that higher levels of inlet temperature and relative humidity correspond to a higher partial vapor gradient between the membrane layers. In addition, as the inlet air pressure increases, the partial vapor pressure gradient between membrane layer was increased , and the dehumidification performance improves. The sweep-gas ratio and intake airflow rate exhibit no positive correspondence with the dehumidification performance. When the sweep-gas ratio ranges from 0.4 to 0.6, the differential of the humidity ratio and the amount of dehumidification are maximal because the mass transfer between the feed and permeate sides increases as a balanced flow. When the intake air flow rate decreases, the face velocity on the feed side also decreases with increase in the contact time of the unit. The differential of the humidity ratio is strongly affected, but the amount of dehumidification is only relatively impacted by the airflow rate.

The main parameters that significantly affect the dehumidification performance of the prototype unit are the inlet air pressure and sweep-gas ratio. To increase the dehumidification performance, the inlet air pressure should be sufficiently high, and the sweep-gas ratio must be maintained around 0.5 for balanced flow. Here, we note that to control the outlet humidity ratio, a suitable rotation speed modulation strategy of the air compressor or sweep-gas ratio should be estimated.

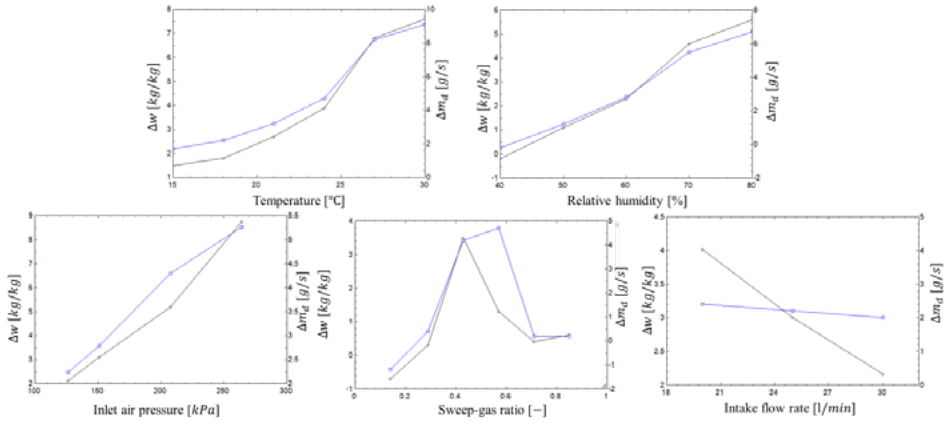

Fig. 5. Parametric analysis of hollow-fiber-membrane dehumidifier

5. Conclusions

In this study, we experimentally investigated the dehumidification performance of a hollow-fiber-membrane dehumidification unit. Our prototype unit was composed of a membrane module containing a bundle of hollow membranes and an air compressor to pressurize the inlet pressure, which forms the driving force underlying the process. Experiments were conducted using the prototype unit to estimate the differential of the humidity ratio and amount of dehumidification, and the relevant performance data were collected. The input parameters that influence the dehumidification performance are the air temperature, relative humidity, inlet air pressure, sweep-gas ratio, and intake air flow rate. The air temperature and relative humidity exhibited a positive correlation with the performance, which indicates that a larger amount of air with water vapor affords increased dehumidification performance. The inlet air pressure also positively affects the performance via increasing the driving force of the vapor pressure drop. The dehumidification performance was maximal when the sweep-gas ratio was in the range of 0.4 to 0.6 under balanced flow conditions. When the intake air flow rate was decreased, the dehumidification performance increased because of the increased contacting time of air with the prototype unit.

In future study, we plan to analyze the dehumidification efficiency under various operation conditions. In addition, the data collected in the study can be applied to extend the utilization of the control logic of the hollow-fiber-membrane dehumidifier.

Working Fluid Selection of Organic Rankine Cycle for a Liquid Desiccant System

Hye-Won Dong[a], Beom-Jun Kim[a], Li-Hua Lin [a], Jae-Weon Jeong[a,*]

[a]Department of Architectural Engineering, College of Engineering, Hanyang University, Seoul, 04763, Republic of Korea

Abstract

In this study, a working fluid selection was conducted for an organic Rankine cycle (ORC). The ORC used in this study adopted the district heat source, which is rarely utilized in the cooling season. The power and heat generated from the ORC was used for a liquid desiccant system. Considering the environmental impact, n-Pentane, R1233zd(E), and Novec649 were utilized and compared with R245fa, which is one of the hydrofluorocarbons. Thermodynamic analyses of all the fluids were conducted, and Novec649 was selected owing to the high total net power and heat output. The testbed for ORC driven liquid desiccant system was developed using Novec649, and it can provide the desiccant solution at over 50°C to enter the regenerator of liquid desiccant system without requiring an auxiliary heater.

1. Introduction

In recent years, the applications of distributed power generation systems using small-scale combined heat and power (CHP) systems have increased in commercial buildings and apartment complexes. However, the heat generated from CHP systems, which is a relatively low-temperature heat source, is insufficiently utilized in the cooling season due to the decrease in the heat demand. Integrating the CHP system with a thermally driven cooling system can be a good alternative to increase the heat demand in the cooling season [1-3].

An organic Rankine cycle (ORC), which is one of the commercial CHP systems, uses a relatively low grade heat source to produce the heat and power upon employing organic fluid, when compared with the conventional Rankine cycle. The performance of the ORC depends mainly on the working fluid; therefore, the selection of the working fluid considering the operating temperature range is important for the ORC.

* Corresponding author. Tel.: +82-2-2220-2370; fax: +82-2-2220-1945.
E-mail address: jjwarc@hanyang.ac.kr

Cho and Cho [4] recommended R245fa as the working fluid of ORC for the heat source temperature below 60°C when considering the efficiency of cycle and power generation. Darvish et al. [5] selected R134a, considering both exergy and cost at the heat source at 120°C. Gao et al. [6] selected R152a and R143a, which represent the maximum power output and minimum cost as the working fluid of ORC, respectively, using industrial waste heat.

Previous studies primarily performed the working fluid selection when using low-temperature heat sources (i.e., solar heat, industrial waste heat), but research addressing the heat produced by ORC was rare. Although employing the same heat source, various working fluids may be applied depending on the purpose of the heat from the ORC. Therefore, the selection of working fluid is required while considering the heat source, heat demand, power generation of the ORC when designing the ORC, and the environmental impact of working fluid. This study addresses the selection of low global warming potential (GWP) and ozone depletion potential (ODP) working fluid of the ORC using a district heat source for liquid desiccant (LD) system, which is one of the thermally driven cooling systems.

2. System Overview

ORCLD

The ORC used in this study consist of an evaporator, expander, condenser, and pump. Figure 1 shows the small-scale (<100 kW) ORC-driven LD (ORCLD) system as a distributed power generation system for commercial buildings and apartment complexes. The ORCLD receives the heat from the district heat source, and the heat reclaimed from the condenser is used for heating the desiccant solution in the regenerator of LD.

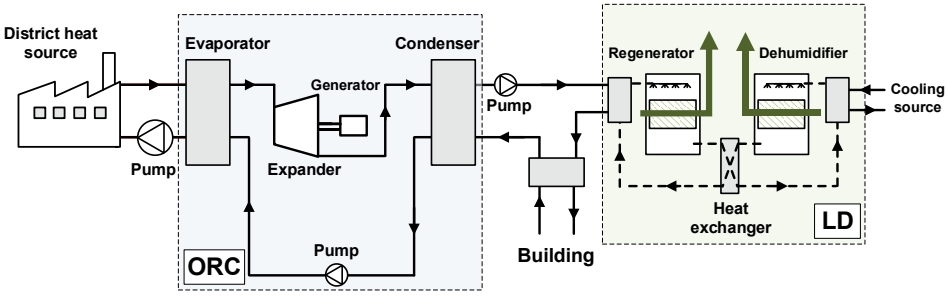

Fig. 1. Schematic of ORCLD

The district heat source was selected as a heat source for ORC operation. The hot water used for district heating, supplied at approximately 120°C, is relatively hot for direct use in apartment buildings, so hot water can be supplied upon lowering its temperature via a central heat exchanger in the apartment building. If the ORC is used instead of heat exchanger, it is possible to simultaneously supply hot water at the temperature required by the heat demand (i.e., regenerator, building) and generate electricity.

Meanwhile, the LD is a representative thermally driven cooling technology to improve the utilization of heat produced in the CHP system during summer season. The LD is mainly composed of a dehumidifier and a regenerator, with a desiccant solution circulating between them. A strong solution is required to dehumidify the process air, and it is also necessary to cool the desiccant solution for effective dehumidification. However, once the desiccant solution is used in the dehumidifier, it becomes weak; hence, a heat source is required to regenerate it.

The heat reclaimed from the condenser is preferentially utilized as the heat source for heating the desiccant solution entering the regenerator, and the remaining heat is consumed in the building. For stable ORC operation, a closed-loop system using water was applied for the heat recovery in the condenser, so the temperature of the water supplied to the condenser by the ORC was constant. The electricity produced by the ORC will be provided to run common appliances (i.e., lighting, elevator) in the building and operating pumps and fans for LD.

Working fluid selection

There are many organics that can be used as a working fluid of the ORC, and new fluids are also being developed. Because each fluid has different thermodynamic and environmental properties, the determination

of a suitable working fluid for the ORC can be an issue, and recommendations for working fluids vary among researchers. Therefore, a suitable working fluid under the given conditions should be selected. In this study, considering the environmental impact, the working fluid of ORC is recommended to heat the desiccant solution without an auxiliary heater when using the district heat source as the heat source of the ORC. The conditions for selecting a working fluid are as follows.

- Isentropic or dry fluid
- Stability
- Low flammability and toxicity
- Low cost

This work, which is built in an Engineering Equation Solver (EES) program, considered three environmentally friendly working fluids as possible alternatives to hydrofluorocarbons (HFCs). The characteristics of three working fluids are compared with those of R245fa, which is one of the representative HFCs. The characteristics of the four working fluids are listed in Table 1. All of the working fluids reviewed have zero ODP and a low GWP, except for R245fa.

Considering the operating range of the ORCLD to select the working fluids available for the given design conditions, the previous researches showed that a desiccant solution with a temperature of at least 40°C is required to sufficiently regenerate the solution in the regenerator of LD using an aqueous lithium chloride (LiCl) solution [7,8]. In the ORC evaporator, it was assumed that a heat source at 120°C, the normal maximum temperature of district heating, is supplied. The cycle efficiency and thermodynamic characteristics of working fluids were evaluated under the design conditions of ORCLD as shown in Table 2.

Table 2. Design conditions of ORCLD

Design parameter	Value
Thermodynamic power [W]	100
ORC pump efficiency [%]	70
Expander efficiency [%]	70
Cooling source (water) inlet temperature [°C]	40
Heat source (water) inlet temperature [°C]	120
Temperature difference between heat and cooling source [°C]	15
Expander inlet temperature [°C]	115
Pressure ratio [-]	3

Thermodynamic analysis

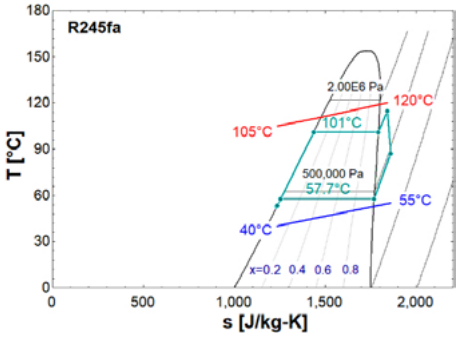
The thermodynamic properties of all the fluids were calculated using the EES program considering the thermodynamic cycle of the ORC under the design conditions. It was assumed that power output, expander and pump efficiency, district heating and cooling water supply temperature, pressure ratio ($P_{exp,in}/P_{exp,\ out}$), and pinch point were all constant. Among the design conditions shown in Table 2, the flow rates of heating, cooling, and working fluids; cycle efficiency; expander pressures; pump power consumption; and duty of evaporator and condenser for working fluids were compared. The thermodynamic equations for analyzing the ORC performance are as follows (Equations 1-4).

$$\eta_{exp} = (h_{exp,in} - h_{exp,out})/(h_{exp,in} - h_{exp,out,s}) \quad (1)$$

$$\eta_{pump} = (h_{pump,out,s} - h_{pump,in})/(h_{pump,out} - h_{pump,in}) \quad (2)$$

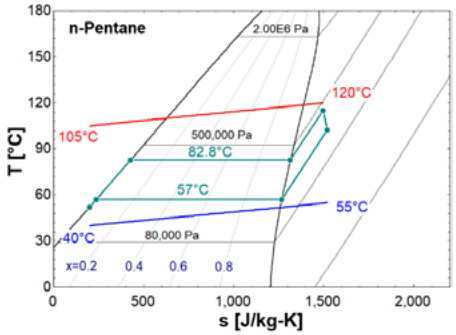
$$\dot{Q}_{evap} = \dot{m}_{orc}(h_{evap,in} - h_{evap,out}) \quad (3)$$

$$\eta_{orc} = (\dot{W}_{exp} - \dot{W}_{pump})/\dot{Q}_{evap} \quad (4)$$



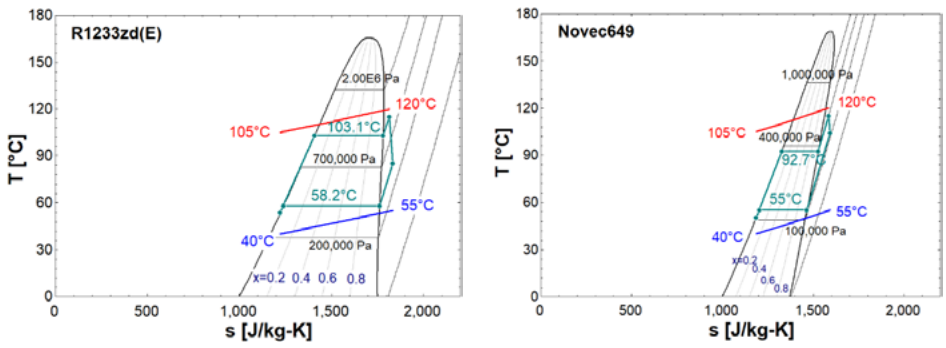
The energy inputs and outputs of the four major components of the ORC are obtained as the product of the working fluid flow rate and the inlet and outlet enthalpy differences. The enthalpy values can be obtained using the isentropic efficiency values of the expander and pump shown in Table 2 and Equations 1 and 2. Because the power generated by the expander was assumed to be 100 W, the enthalpy of each component was calculated, and the required flow rate of the working fluid could be obtained.

The heat supply in the evaporator is shown in Equation 3. Since the inlet and outlet temperature difference of heating fluid was assumed to be 15°C, the required water flow rate could be obtained. The same applied to the condenser; finally, the thermal efficiency of the cycle was calculated using Equation 4.



3. Results

The thermodynamic characteristics of the T-s diagram of the four working fluids are shown in Figure 2, and the performance characteristics of ORCLD for the working fluids are summarized in Table 3.



To produce an output of 100 W under the design conditions of Table 2, wherein 1,460 W of heat energy is shown to be required, and R245fa exhibited 6.41% of thermal efficiency. To satisfy the given design conditions, for n-Pentane, either the pressure ratio or cooling water supply temperature had to be lowered, so the pressure ratio of n-Pentane was set as 2. Although n-Pentane has the highest critical temperature and exhibits the lowest efficiency, its power output is the highest. However, n-Pentane was excluded from the final working fluid selection because it is a flammable fluid and is difficult to operate under the design conditions. The cycle efficiency was the highest in R1233zd (E), but it was determined that the actual power output was more meaningful than the cycle efficiency when utilizing wasted energy during the summer. Additionally, R245fa and R1233zd (E) operate at a relatively higher pressure to supply heat to the LD system, and it will be difficult to recover the higher temperature of water. Novec649 exhibited a relatively low efficiency due to its high molecular weight, but its actual power output was the highest, except for n-Pentane, and it was possible to obtain hotter water by increasing the pressure. It can be recommended as a suitable working fluid to be applied to the proposed system, which focuses on heat recovery.

4. Discussion

In this study, the ORCLD system was designed and developed using Novec649, which was determined to be the most suitable working fluid, and an experiment was conducted to verify the performance of the proposed system. The desired temperature of district heating was realized through the electric heater, the ORC (Figure 3) was installed at the LD part of the existing desiccant, and an evaporative cooling system called LD-IDECOAS [9] was adopted to monitor the temperature of the desiccant solution supplied to the regenerator. Therminol 55, which is a thermal fluid that attain temperatures of up to 300°C without causing toxicity to humans and the environment, was used instead of water.

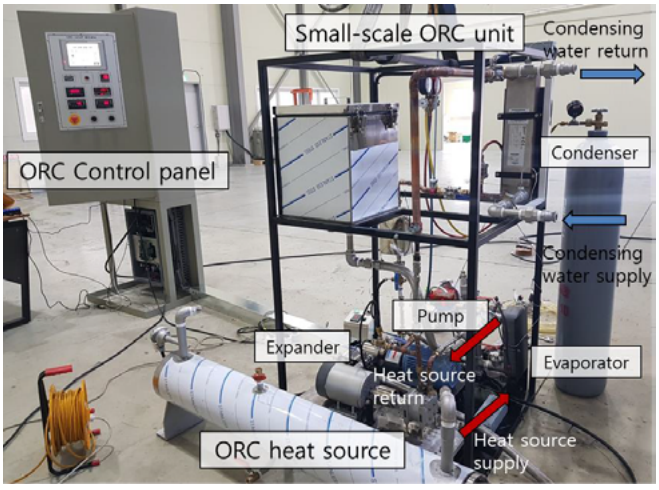

Fig. 3. Experimental setup of ORC

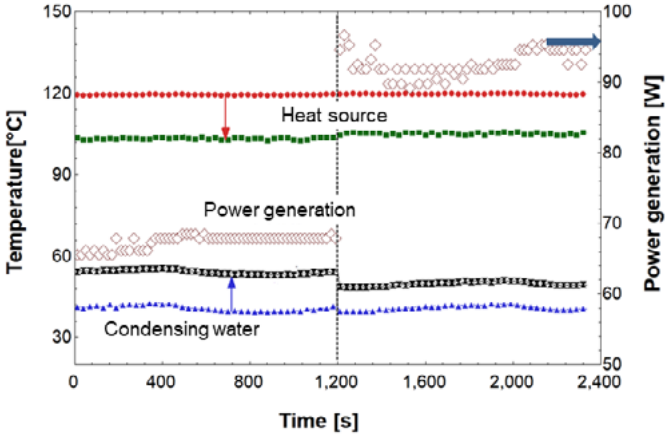

Fig. 4. Test results

The experiment result showed that the power output was 67 W, which is lower than that of the simulation condition (100 W). Moreover, the pressure ratio was 2.37 when the ORC operated with the maximum flow rate of the working fluid and heating fluid (Figure 4). In that case, the desiccant solution entering the regenerator could be supplied at a temperature of approximately 51°C. When the flow rates of the heating and working fluids were decreased while maintaining the temperature of heating fluid at 120°C, the pressure ratio was increased to 2.72, so the power output also increased to approximately 93 W. The output power in the second case was larger than that in the first case; however, in the case with higher pressure ratio, the heat transfer rate of the condenser decreased. The temperature of cooling water exiting the condenser was 50°C, which is insufficient to supply heat for regeneration in the LD regenerator.

Conclusion

In this study, the working fluid for the ORC CHP system was determined considering the environmental impact and effective utilization of the district heating, while supplying the required heat for the liquid desiccant system in the cooling season. R245fa (HFCs) and environmentally friendly working fluids such as R514A, n-

Pentane, R1233zd (E), and Nove649 were considered. When the district heat source is at 120°C, and cooling water at 40°C is supplied to the ORC, which produces 100 W of output power, Novec649 was selected as the working fluid applicable to the ORCLD. Novec649 can transfer significant heat energy to the regeneration part with the largest actual power generation, except for n-Pentane, which is a flammable fluid.

Using Novec649, a testbed for the ORCLD system was developed, and the performance of the system was investigated. The ORCLD with Novec649 could supply sufficient heat energy for the solution regeneration without requiring additional heat, and the solution inlet temperature of the regenerator was over 50°C.

Increasing the ORC power generation may also reduce the heat transfer rate that can be recovered in the condenser, so further studies must be conducted to determine an optimal operating method for the ORC to minimize the energy consumption of the LD system.

Abstract

This study aims to investigate and compare the energy performance of an air source heat pump heating system and a radiant floor heating system with an energy recovery ventilator in an apartment building. The thermal load for a conditioned zone was derived using simulation tool TRNSYS 18, and the total energy consumption of the systems was calculated using an engineering-equation-solver (EES) for each component model. The coefficient of performance (COP) of the heat pump was calculated as 3.16, and the efficiency of the boiler in a radiant floor system was established as 0.9. The results indicate that the proposed system reduces energy consumption by 21.8% compared with the conventional floor heating system. The primary reason for this result is because the COP of the heat pump is dominant, even though the primary energy factor of electricity is 2.75.

1. Introduction

Radiant floor heating systems have been developed and used in Korea for residential buildings for over 500 years. The traditional radiant floor heating system is called Ondol, and it is very efficient because the floor is heated using waste heat leftover from kitchen use in the past [1]. Furthermore, the system provides abundant thermal comfort for a sedentary lifestyle [2]. In modern times, people have applied radiant heating systems by laying water pipes under the floor, instead of using waste heat.

It is recent knowledge that energy consumption in buildings accounts for a significant portion of total energy use, and therefore, various methods to minimize building loads have been suggested. One system that can minimize load is the heat pump, which has been adapted to numerous HVAC systems and is classified as a renewable energy source in Europe [3]. Worldwide, there has been considerable research undertaken regarding the heat pump and how to improve its performance under various operation conditions [4,5]. However, in Korea, heat pumps are only installed in commercial buildings and office buildings [6,7], because radiant floor heating systems have traditionally been used in Korea and are heavily preferred for residential buildings.

In addition, apartments recently built in Korea are equipped with built-in air conditioners for cooling the air during the summer. Although a single heat pump can be used for both cooling and heating, the heat pump-based air conditioners in Korea are used for cooling in the summer; however, they are not used for heating in the winter. Instead, the space is heated by radiant floor heating in the winter. By separating the cooling and heating systems, the construction and management costs and time are increased.

In this study, the potential of integrating cooling and heating into a single heat pump system was investigated. This would eliminate the need for two different systems. Additionally, the energy use of a radiant floor heating system was compared with a heat pump air heating system.

2. System Overview

2.1. Air heating system

Figure 1 shows an air heating system with an air-source heat pump and an enthalpy recovery ventilator. Explained briefly, a heat pump used in the reverse cycle (to the vapor compression cycle) will result in the pump pulling up low heat from the source to the high heat storage. A heat pump consists of a compressor, a condenser, an evaporator, and an expansion valve. Refrigerant absorbs heat in the evaporator and releases it out to the heat sink in the condenser, using input power. The released heat is then used to heat the conditioned zone by supply air.

For this research, the type of air source was selected so that the heat pump obtained heat from the outside air. This was because the system was already installed for cooling in the summer, as is common in Korean apartments, and thus was available for both heating and cooling. Simply driving the vapor-compression cycle in the reverse direction, the air conditioner functioned as a heat pump cycle. However, it could not be used for heating due to the differences in the ambient and supply air temperatures of summer and winter. Because the amount of heat absorption and dissipation depends on the operating conditions, the design for the existing air conditioner had to be redesigned for heating use. The detailed temperature setting and design process for each component is covered in the simulation overview below. In the case that the air supply cannot reach the desired target point (due to insufficient capacity), a heating coil was added before supply to be achieved through as an auxiliary heater.

The air heating system was separated from the ventilation system, which is different from conventional heating, ventilation, and air conditioning (HVAC) systems. Thus, the heat pump only recirculates the indoor air, and effectively handles the building load.

In an enthalpy recovery ventilator (also called an energy recovery ventilator (ERV)), an enthalpy exchanger can be used to transfer the energy, including sensible and latent heat. During the heating season, the system takes heat from the return air and uses it to heat the outdoor air and supply fresh air into the room. Generally, an enthalpy recovery ventilator is used to pre-cool, or pre-heat, before air-conditioning. This process not only reduces system loads, but also satisfies ventilation requirements. For this study, the enthalpy recovery ventilator was separated from the heating systems.

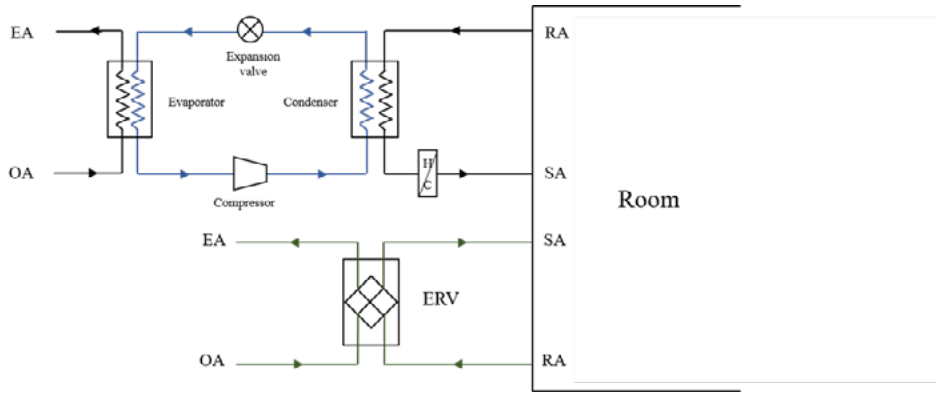

Fig. 1. Schematic of Air Heating System with an Air Source Heat Pump and an Enthalpy Recovery Ventilator (ERV)

2.2. Floor heating system

Figure 2 shows a floor heating system with a radiant floor and enthalpy recovery ventilator. Radiant floor heating system have water pipes buried in the floor. As hot water flows through the pipes, the heat is absorbed by the floor, and released to the room above.

The heat is transferred by conduction from the water pipes to the concrete layers, then by convection from the flooring to the air through natural stratification, and by radiance between the heated floor and other walls according to temperature differences. The heating capacity of the radiant floor depends on the spacing of the pipes, diameter of the pipe, heat conductivity of the pipe, heat resistance of the concrete layer and floor structures, water temperature, and the mass flow rate through the pipes. Because the process of heat transfer is complex and relies on several variables, it is difficult to calculate the heating capacity of radiant floor heating systems.

Radiant floor heating systems make structures (such as floors) warm first, and then use the structures to heat the room. This is different from heat pump heating systems that heat the air and supply directly. In terms of the energy used for heating, indirect heating systems use more energy than direct heating systems.

Similar to the air heating system described above, the floor heating system was separated from the ventilation system. Thus, the radiant floor only handles the building load and ventilation load of the space by itself. An enthalpy ventilator in the proposed floor heating system was operated in the same way addressed previously for the air heating system.

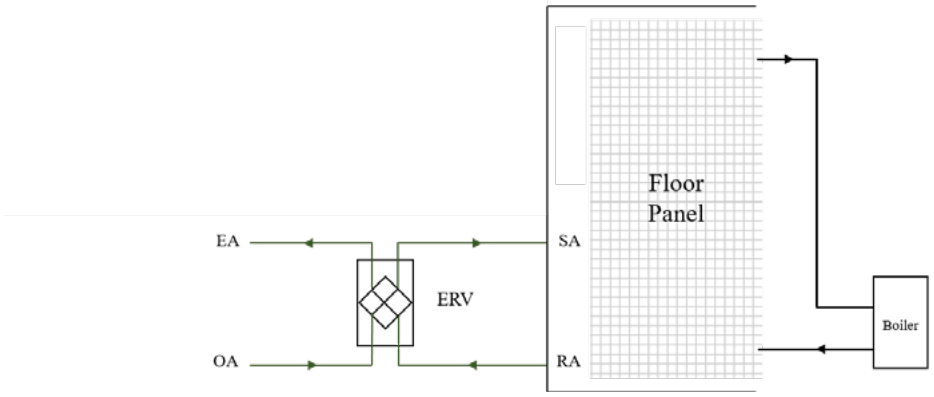

Fig. 2. Schematic of Floor Heating System with a Radiant Floor and an Enthalpy Recovery Ventilator

3. Energy Simulation

3.1. Simulation overview

The energy simulation to calculate the performance of the air heating system and the floor heating system was conducted using engineering-equation-solver (EES). The heating loads to be handled by the systems were derived through an energy simulation tool TRNSYS 18. The model space was designed to have a floor area of $100\ \mathrm{m}^2$ with $3\ \mathrm{m}$-height, located in Seoul, South Korea. Structures such as walls, floors, ceilings, and windows, were designed to satisfy the U-values of domestic legal standard. There were five occupants in the space and the room temperature was maintained at 22 ℃. For both systems, the simulation was set to turn on only when residents occupied the space. Additional physical information for the model is described in Table 1.

Table 1. Model building parameters

Location	Seoul, South Korea	
Volume	$10\ \mathrm{m} \times 10\ \mathrm{m} \times 3\ \mathrm{m}, 300\ \mathrm{m}^3$	
Window-to-Wall Ratio	0.25	
U-value	Ceiling	$0.117\ \mathrm{W/m^2}K$
	Wall	$0.117\ \mathrm{W/m^2K}$
	Window	$0.95\ \mathrm{W/m^2K}$
	Floor	$0.132\ \mathrm{W/m^2K}$

Schedule	20:00 – 8:00 on weekdays, all day on weekends

The ventilation load (Q_{vent}) was acquired by calculating the temperature of the air passing through the enthalpy recovery ventilator (T_{erv}), and the airflow rate of ventilation requirements ($\dot{V}_{vent}$) through Eq. (1). The airflow rate of ventilation to fulfill the requirements for five residents was set to follow the ASHRAE standard 62.1 [8]. The temperature passing through the enthalpy recovery ventilator was calculated for sensible and latent heat exchange efficiencies. The efficiency was set to 70%, and 50% for the sensible heat exchange and for the latent heat exchange, respectively [9]. As shown in Figs. 1 and 2, an energy recovery ventilator was included in both systems. Thus, an equal ventilation load was added to the building load for both systems. For an enthalpy recovery ventilator, the heat exchange takes place between the outdoor air and return air from the conditioned zone. The outdoor air takes heat from the return air and supplies fresh air to conditioned room.

$$\dot{Q}_{vent} = \rho \cdot \dot{V}_{vent} \cdot c_p \cdot (T_{ra} - T_{erv}) \quad (1)$$

3.2. Air heating system

In order to design the optimal heat pump size for the residential place, it was important to make the compressor small, so that the temperature to be pumped up from the heat source was reduced. The design flow rate of the supply air (V_{sa}) was set to 1000 m^3/h, adequate for residential spaces, and the design temperature of the supply air (T_{sa}) was set to 34 ℃ to manage the derived heating load. Thus, the design temperature of the condenser was set to 40 ℃. The flow rate of the supply air ($\dot{V}_{sa}$) was variable and determined by the loads to be managed, as described in Eq. (2). The design temperature of the evaporator was set to −20 ℃ because it had to absorb sufficient heat from the cold outdoor air. Assuming that the evaporator exchanges sufficient heat with outdoor air by a large enough flow rate. The flow rate of the exhaust air ($\dot{V}_{ea}$) was controlled by the amount necessary at the condenser, calculated using Eq. (3) within 1000 m^3/h, that is the design flowrate of exhaust air. The load to be absorbed from the outdoor air was acquired by multiplying the cooling capacity at the evaporator ($Q_{hp,evap}$) and circulated amount of refrigerant (G). The coefficient of performance (COP) of the heat pump was considered as a fixed value, because the inverter control of the compressor in the heat pump was adapted by calculating the amount of refrigerant circulated (G) required every hour [10]. Hence, when the amount of heat from 1000 m^3/h of outside air at the evaporator was lacking compared with the amount required at the condenser for the heating load, the heating coil was turned on to heat up the supply air. The heat exchange efficiency between the outside air and the evaporator was assumed as 70%, and the heat exchange efficiency between the return air and condenser was also assumed as 70%. The compressive efficiency of the compressor was also 70% (used commonly) and the actual enthalpy of compressor was derived using the compressor efficiency. The design parameters of the heat pump are organized below in Table 2.

$$\dot{V}_{sa} = \frac{Q_{heating\ load} + Q_{ventilation\ load}}{\rho_{sa} \cdot cp_a \cdot (T_{sa} - T_{ra})} \quad (2)$$

$$\dot{V}_{ea} = \frac{Q_{hp,evap} * G}{\rho_{ea} \cdot cp_a \cdot (T_{oa} - T_{ea})} \quad (3)$$

Table 2. Designed specifications of the heat pump

Specifications	Values
Heating capacity	4 kW
COP	3.16
Circulating refrigerant	70 kg/h
Nominal horse power	2.5 PS

As explained in the details above, the heating coil was turned on only when the supply air did not reach its desired value. The primary energy consumption of the electric heating coil was multiplied by the primary energy factor of electricity.

The power of the variable flow fans was estimated using the general variable-air-volume fan power equation stated by ASHRAE 90.1 [11]. The part load ratio of the variable flow fan is the ratio of the present airflow rate

to the design airflow rate. The efficiency of each fan was assumed to 50%. The design pressure drop of each fan was referred from previous studies [12]. In particular, for the supply fan and exhaust fan, the pressure drop was used by referring to the value from the variable air volume (VAV) system.

3.3. Floor heating system

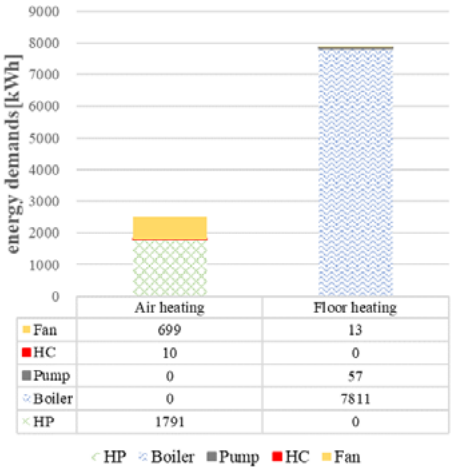
Similar to the way we calculated the performance of the heat pump system with the inverter control, the performance of the floor heating system was also calculated using the boiler by part load ratio. The performance of floor heating systems has been evaluated by several previous studies [13].

To manage the required heating load for the floor heating system, a conventional gas boiler was used to supply hot water to the pipes buried under the floor. The boiler was operated using the modulated part load ratio, depending on the heating load to be administered. The part load ratio of the boiler is the ratio of the present heating load to the design heating capacity of the boiler. It was set to 0.4 as referred to from previous studies [14].

The boiler energy ($\dot{Q}_{boiler}$) was calculated using the simple hot water boiler Eq. (4) suggested by Energy Plus, which takes into account the efficiency of boiler ($\varepsilon_{\text{boiler}}$) and the boiler efficiency performance curve (BEC). The efficiency of the boiler was set to 90% for this research.

$$Boiler\ Efficiency\ Curve = f(PLR_{boiler}) \tag{5}$$

$$\dot{Q}_{boiler} = \dot{Q}_{heating}/(\varepsilon_{boiler} \cdot Boiler\ Efficiency\ Curve) \tag{6}$$



There was only one pump in the floor heating system supplying hot water. The power calculation of the pump was estimated by the fan power equation, suggested from Energy Plus, and the efficiency of the pump was assumed to be 60%.

4. Simulation Results

The energy performance evaluation of the air heating system and the floor heating system was conducted for four months, during the heating season from December to March. Figure 3 shows the total energy demands of each system, and also the demands of each component.

In the air heating system, the heat pump was only used to heat the room, and for managing the heating load and ventilation load as indicated in the simulation overview section. As shown in Fig. 4, fan power comprised a significant amount of energy needed for the heat pump heating system. This was because the equation used was a function of the part load ratio and pressure drop of the fan. Because the fans used in the air heating system were designed to have 1000 m^3/h, a significant pressure drop was applied.

In the floor heating system, the energy consumption was calculated assuming that a boiler produces hot water for traveling through the pipes to satisfy the heating and ventilation load. Thus, a gas boiler was controlled to modulate as required to reduce energy consumption. As a result, the air heating system requires 68.3% less energy than the floor heating system.

	Air heating	Floor heating
Fan	699	13
HC	10	0
Pump	0	57
Boiler	0	7811
HP	1791	0

Fig. 3. Energy Demands of Air Heating Mode and Floor System during Heating Season (Dec, Jan, Feb, Mar)

To compare the equivalent energy performance of both systems, and because the two systems have different energy sources, primary energy factors adequate for each system were applied. For the air heating system, the heat pump, fan, and auxiliary heater (electric heating coil) all use electricity. For the floor heating system, the boiler uses natural gas, however, the fan and pump both use electricity. The applied local primary energy factors are 2.75 for electricity, and 1.1 for natural gas. Because both systems process equivalent sensible loads, including ventilation load, the energy consumption of an energy recovery ventilator (ERV) fan was applied for both systems. As seen in Fig. 4, the primary energy consumption of the air heating system became larger than energy demands for it, and yet the air heating system still consumes less energy than the floor heating system.

In conclusion, it was observed that the air heating system consumed a total of 21.8% less primary energy when compared with the floor heating system using a conventional gas boiler in total.

	Air heating	Floor heating
Pump	0	157
HC	28	0
Fan	1921	36
HP	4924	0
Boiler	0	8592

Fig. 4. Primary Energy Consumption of Air Heating Mode and Floor System in Heating Season (Dec, Jan, Feb, Mar)

5. Conclusion

For this research, an air heating system with a heat pump and floor heating system with radiant floors were compared from the view of total energy consumption. The air heating system required 68.3% less energy than the floor heating system to handle total loads. Furthermore, the air heating system consumed 21.8% less energy than the floor heating system, even though a significant energy factor was observed because electricity was adapted for the system. If a gas heat pump was to be applied, instead of an electricity heat pump, it is calculated that an additional reduction of approximately 55% or more of reduced energy will be seen.

While floor heating systems are poor choices in view of the high energy consumption they require, they still are a strong preference among building occupants in regard to thermal comfort. Further studies in terms of occupant thermal comfort are required in the future. If further studies establish that floor heating systems are preferred for thermal comfort, combined heating systems using radiant floor heating and a heat pump can be adapted to apartments in Korea.

Energy benefits of ventilation, dehumidification, and water heating system based on liquid desiccant cycle

Soo-Jin Lee[a], Hansol Lim[a], Yong-Kwon Kang[a], Jae-Weon Jeong[a,*]

[a]Department of Architectural Engineering, College of Engineering, Hanyang University, Seoul, 04763, Republic of Korea

Abstract

This study aims to propose a liquid desiccant ventilation system and investigate the energy benefits of this system in comparison with a conventional variable air volume system. The proposed system is operated to achieve ventilation, dehumidification, and water heating. An energy simulation is performed via a series using TRNSYS 18 and the Engineering Equation Solver program. The simulation results demonstrate that the proposed system can save 27% of the primary energy in comparison with the reference system. The use of tap water for solution cooling instead of a cooling device is the main reason behind the significant energy savings. The heat exchanger used to provide hot water for the building with the aid of the scavenger air also reduces the overall operating energy of the proposed system.

Keywords: Ventilation, dehumidification, evaporative cooling, water heating, liquid desiccant ;

1. Introduction

Recently, an alternative energy saving air-conditioning method has been introduced, which involves a liquid desiccant system. In a liquid desiccant system, a solution absorbs water vapor from the air in the absorber, thereby dehumidifying the air and reducing the concentration of the solution. The solution is then re-concentrated in a regenerator using solar, waste, or district heat to desorb the water vapor to the air. Previous studies have reported upon the operation of liquid desiccant systems to achieve dehumidification using variable heat sources [1-5]. Such liquid desiccant systems can significantly reduce primary energy consumption because the liquid desiccant system is a decoupled system, which can be summarized as a decoupling of the sensible and latent load functions. Dong et al. [3] suggested a desiccant-enhanced evaporative (DEVap) cooling system, and the system involving a district heat source consumed 46% less primary energy compared with the system using a conventional gas boiler. Kim et al. [6] investigated the annual operating energy performance of a desiccant- and evaporative cooling-assisted 100% outdoor air system. The proposed system showed an 82% energy saving potential over the conventional variable air volume (VAV) system during the summer. Kim et al. [7] suggested the integration of a liquid desiccant system into an evaporative cooling-assisted 100% outdoor air system. The solar water heating system used to regenerate the desiccant solution contributed to the reduction of the required operation energy. Ham et al. [8] developed a liquid desiccant and dew point evaporative cooling-assisted 100% outdoor air system (LDEOAS) and evaluated its energy saving potential. Simulation results showed that LDEOAS could save 12% of the primary energy consumption compared with a conventional VAV system.

A liquid desiccant system requires a heat source for cooling the absorber inlet solution, as well as for providing heat for regeneration. Although a cooling tower (instead of a chiller) is used to provide energy savings associated with the cooling process, chilled water is not stably produced from the cooling tower in hot and humid climates.

E-mail address: jjwarc@hanyang.ac.kr.

In this study, tap water is used for solution cooling as the water recovered the heat from the solution. After undergoing auxiliary heating to achieve a target temperature, the water is supplied into the building as hot water. Consequently, a liquid desiccant ventilation system, which can provide both ventilation and water heating, is proposed. This system consists of several components based on the liquid desiccant system and it is operated to achieve ventilation, dehumidification, and water heating. The energy saving potential of the proposed system over the conventional VAV system is estimated by conducting an energy simulation using a dynamic simulation program (i.e., TRNSYS 18 and the Engineering Equation Solver (EES)).

2. System Overview

2.1. Liquid desiccant ventilation system

The liquid desiccant ventilation system was proposed to accommodate the ventilation, dehumidification, and water heating processes that are essential for buildings in hot and humid climates. Fig. 1 illustrates the proposed system, which consists of an absorber, a regenerator, three heat exchangers, a heating coil, and an indirect evaporative cooler.

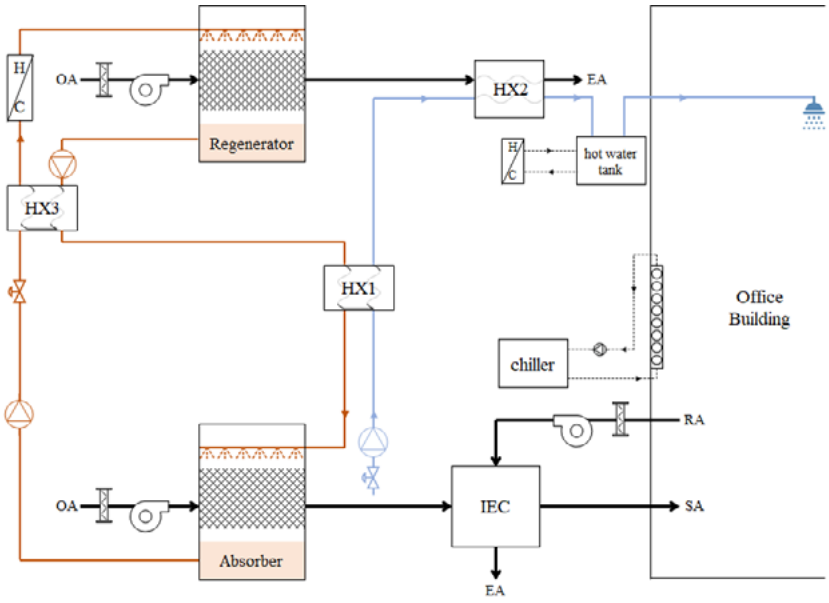

Fig. 1. Schematic of the liquid desiccant ventilation system

The process air is dehumidified by an absorber in a hot and humid climate. The air at the outlet of the absorber is dry and hot, and it must therefore be cooled to maintain the indoor air temperature. An indirect evaporative cooler is used to cool the process air. Room air is used as secondary source of air in the indirect evaporative cooler. The process air is cooled in the indirect evaporative cooler to a temperature below the average room temperature.

The process water flows into a liquid-to-liquid heat exchanger from tap water. The tap water recovers the sensible heat of the solution while the solution is cooled to available for absorber. Next, the process water passes into an air-to-liquid heat exchanger, wherein the sensible heat of the air leaving the regenerator is recovered. If the process water does not reach a set temperature, it is supplied to the building after undergoing the auxiliary heating process.

The proposed liquid desiccant system was operated for the dehumidification of the process air. A strong solution absorbs the water vapor from the process air in the absorber. Following this, a weak solution desorbs the water vapor to the scavenger air in the regenerator. These processes occur simultaneously, and the liquid desiccant system can be used continuously.

2.2. Variable air volume system

In a hot and humid climate, the supply air volume flow rate of a VAV system is determined based on the sensible and latent loads of the building. As shown in Fig. 2, outdoor air is mixed with the return air. The mixed air is cooled by a cooling coil. The cooling coil is activated to achieve dehumidification as well as cooling. The process air is then reheated after encountering the cooling coil to achieve the desired supply air conditions (i.e., 15°C, 80%).

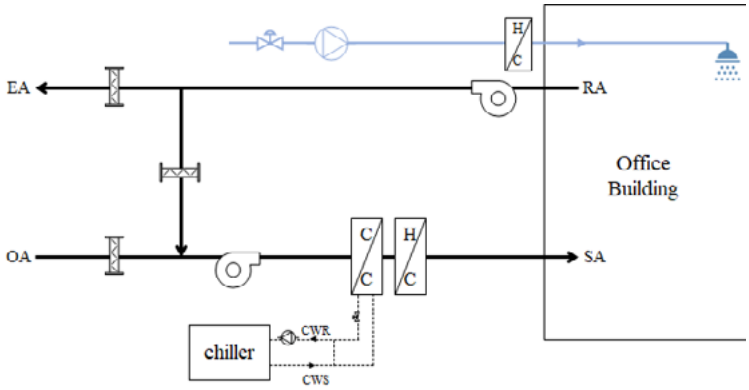

Fig. 2. Schematic of a VAV system

3. Simulation Overview

In this study, the hourly load profile of the model building was obtained by using energy simulation software (i.e., TRNSYS 18). The operating energy consumptions of both the systems required to meet the thermal load of the building were estimated using a commercial equation solver program (i.e., EES) by integrating both the system component models.

3.1. Model space

The model space was a $1{,}000\ \mathrm{m}^2$ office space with a $3\ \mathrm{m}$ ceiling height. Two $30\ \mathrm{m}^2$ windows were located on the south and north exterior walls, and the window-to-wall ratio was 0.16. The heat generation from the occupants and light were $115\ \mathrm{W/person}$ and $6\ \mathrm{W/m}^2$, respectively, and the occupancy and system schedules recommended by ASHRAE Standard 90.1 [9] for an office building were used to obtain the thermal loads by using TRNSYS 18. The room set conditions were a 26°C dry-bulb temperature and 60% relative humidity for cooling. The physical conditions of the model space are summarized in Table 1.

Table 1. Physical parameters of the model space

Location	Seoul, South Korea	
Weather data	TMY2	
Building type	Open plan office	
Geometry	31.62 m (W) × 31.62 m (L) × 3 m (H)	
U-Values	Ceiling	$0.297\ \mathrm{W/m^2K}$
	Wall	$0.252\ \mathrm{W/m^2K}$
	Windows	$1.4\ \mathrm{W/m^2K}$
Internal heat gain	Occupants	$115\ \mathrm{W/person}$ [10]
	Light	$6\ \mathrm{W/m^2}$
Room set points	Temperature	26°C
	Relative humidity	60%

3.2. Liquid desiccant unit

An empirical model for predicting the effectiveness of an absorber to absorb moisture was found in literature [11]. The effectiveness values of the absorber to affect the moisture and temperature of the input air indicate the degree of heat and mass transfer. The temperature differences between the air and desiccant solution allows for the exchange of thermal energy due to heat and mass transfer. The difference in the moisture contents between the air and desiccant solution permits mass transfer between the air and solution. In addition, the mass flow rates of the fluids and the system design parameters are also important factors in determining the effectiveness of the absorber. The initial mass flow rate and concentration of the desiccant solution are 0.5 kg/s and 42%, respectively. The absorber inlet temperature of the solution is 20-25°C. The process air that flows into the absorber is outdoor air. The equilibrium humidity ratio and enthalpy of the desiccant solution were calculated using previous studies [12,13].

The regenerator model was suggested by Martin and Goswami [13]. The equation for this model is a function of several variables. These variables are combined to form non-dimensional parameters, and this model can predict the effectiveness of the regenerator using these non-dimensional parameters. The liquid-to-gas ratio is set at 4.0, and the temperature effectiveness of the regenerator is same as the mass effectiveness [7]. The equilibrium humidity ratio of the regenerator is calculated using the same study that the absorber was based upon [12]. The inlet temperature of the solution is set at 60°C. The effectiveness of the dehumidification and regenerator were determined using Eq. 1 and 2. The absorber and regenerator outlet conditions of the process air were determined using Eq. 3.

$$\varepsilon_{abs} = \frac{\left(1 - \frac{0.024\left(\frac{\dot{m}_a}{\dot{m}_s}\right)^{0.6} exp\left(1.507\frac{T_{a,in}}{T_{s,in}}\right)}{(aH)^{-0.185}\pi^{0.638}}\right)}{\left(1 - \frac{0.192\, exp\left(0.615\frac{T_{a,in}}{T_{s,in}}\right)}{\pi^{-21.498}}\right)} \quad (1)$$

$$\varepsilon_{reg} = 1 - 48.3\left(\frac{\dot{m}_s}{\dot{m}_a}\right)^{0.396\left(\frac{\gamma_L}{\gamma_C}\right)-1.57}\left(\frac{h_{a,in}}{h_{s,in}}\right)^{-0.751}(aH)^{0.0331\left(\frac{\gamma_L}{\gamma_C}\right)-0.906} \quad (2)$$

$$\varepsilon_{abs,reg} = \frac{w_{a,in}-w_{a,out}}{w_{a,in}-w_{eq}} = \frac{T_{a,in}-T_{a,out}}{T_{a,in}-T_{s,in}} \quad (3)$$

3.3. Indirect evaporative cooler

The dry-bulb temperature at the outlet of the indirect evaporative cooler (IEC) can be estimated using Eq. 4 when the IEC effectiveness is provided. In the proposed system, the humidity ratio of the process air that leaves the IEC is identical to that of the exiting liquid desiccant because condensation and dehumidification does not occur in the IEC. The IEC effectiveness was assumed to be 0.7.

$$\varepsilon_{IEC} = \frac{T_{pri,in}-T_{pri,out}}{T_{pri,in}-WBT_{sec,in}} \quad (4)$$

3.4. Heat exchanger

Two different types of heat exchangers were used in this study for the heat recovery processes. One is a liquid-to-liquid type and the other is liquid-to-air type. The liquid-to-liquid type heat exchanger was used to transfer the heat from the solution leaving the regenerator to the solution leaving the absorber. The other liquid-to-liquid type heat exchanger was used to transfer the heat from the solution leaving heat exchanger 3 to the tap water. The liquid-to-air type heat exchanger was used to transfer the heat from the scavenger air to the process water. The outlet conditions of each exchanger were estimated using Eqs. 5 to 7 and the efficiency of each heat exchanger was assumed to be 0.8, in accordance with literature [5].

$$C^* = MIN(\dot{m}_{hot}C_{p,hot}, \dot{m}_{cold}C_{p,cold}) \quad (5)$$

$$\dot{Q}_{ideal} = C^*(T_{hot,in} - T_{cold,in}) \quad (6)$$

$$\dot{Q}_{real} = \varepsilon\dot{Q}_{ideal} = \dot{m}_{hot}C_{p,hot}\left(T_{hot,in} - T_{hot,out}\right) = \dot{m}_{cold}C_{p,cold}\left(T_{cold,out} - T_{cold,in}\right) \quad (7)$$

3.5. Supply air flow rate

In the VAV system, the supply air flow rate was determined based on the sensible and latent loads using Eq. 8. The return air flow rate was calculated using the supply air flow rate and the minimum required outdoor air ventilation rate, as recommended by the ASHRAE Standard 62.1. On the other hand, in the liquid desiccant ventilation system, the supply air flow rate was same as the minimum required outdoor air ventilation rate. The required outdoor air flow rates per person and per unit area are $2.5\,\mathrm{L/(s\,person)}$, and $0.3\,\mathrm{L/(s\,m^2)}$, respectively, based on the ASHRAE guidelines for an office space. Thus, the minimum required outdoor air ventilation rate for the both systems was $0.51\,\mathrm{kg/s}$, and the maximum supply air flow rate for the VAV system was determined to be $1.265\,\mathrm{kg/s}$.

$$\dot{m}_{sa} = \frac{\dot{Q}_{sen}+\dot{Q}_{lat}}{h_{ra}-h_{sa}} \quad (8)$$

3.6. Cooling and heating coil

A cooling coil is activated to achieve dehumidification and cooling of the process air in the VAV system. This coil performs dehumidification via condensation, as well as cooling of the process air, to satisfy the target humidity ratio of the process air. The cooling load of the coil was calculated using the difference between the inlet and outlet enthalpies. The inlet condition of the cooling coil is same the mixed air condition and the outlet condition is set to be the dew point.

A heating coil heated the solution in the regenerator of the liquid desiccant ventilation system. In the VAV system, the process air is reheated by a heating coil. The outlet temperature of the cooling coil is low such that reheating is necessary to satisfy the set point conditions. Additionally, a heating coil is used for water heating in both systems.

3.7. Parallel unit

In the proposed system, the supply air did not remove the sensible load of the conditioned zone, whereas the supply air of the reference system sufficiently removed the sensible load. Therefore, a fan coil unit was used as a parallel system in the proposed system, in which the remaining sensible load of the conditioned zone was removed. The load of the parallel unit was determined by Eq. 9.

$$\dot{Q}_{parallel} = \dot{Q}_{sen} - \dot{m}_{sa}(h_{ra} - h_{sa}) \quad (9)$$

3.8. Chiller and boiler

Energy derived from a chiller was consumed in both systems. In the proposed system, it is used as a parallel unit that is located in the building. In the reference system, it is used as a cooling coil. The air-cooled chiller model provided be EnergyPlus [14] was used for estimating the chiller energy consumption.

A conventional gas boiler was used for the reheating coil of the VAV system, heating coil of the liquid desiccant ventilation system, and water heater for both systems. The boiler was operated to achieve the heating loads required by the reheating coil, heating coil, and water heaters. The boiler was modeled using a function of boiler efficiency and the efficiency performance curve. The efficiency curve is a cubic efficiency curve of the part load ratio that was provided by EnergyPlus [14]. The part load ratio is the ratio of the current heating load to the boiler capacity. The theoretical boiler efficiency was set at 82% in this study [3].

3.9. Fan and pump

The design of the fan powers in both systems were calculated using a fan efficiency of 0.5 and Eq. 10. The maximum air flow rate was used as the volume flow rate of this design. The simulation of the proposed system was constructed using three fans: variable volume supply, return, and constant volume liquid desiccant (LD). The reference system was designed with variable volume supply and return fans. The fan power at the variable volume flow rate was estimated using Eq. 11 based on the generic fan power curve.

$$P_{fan,design} = \frac{\dot{V}_{design} \times \Delta P}{\eta} \tag{10}$$

$$P_{fan} = (0.0013 + 0.0447PLR + 0.9506PLR^2 - 0.0998PLR^3) \times P_{fan,design} \tag{11}$$

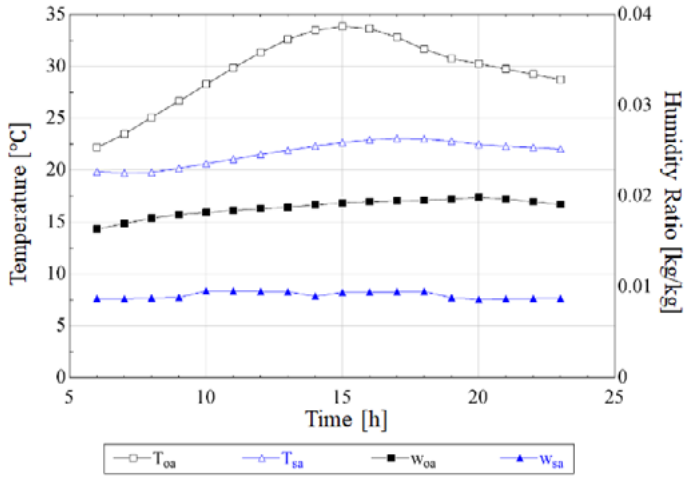
The pump powers for both systems were calculated using Eq. 12 with a pump efficiency of 0.6. In the proposed system, the constant speed pump supplies the liquid desiccant circulation, hot water, and the chilled water for the cooling coil and fan coil unit (FCU). In the reference system, the pump supplies the chilled water for the cooling coil and the hot water.

$$P_{pump} = \frac{\dot{m} \times H \times g}{\eta} \tag{12}$$

4. Simulation Results

4.1. Thermal behavior of the air

The conditions of the process air over the course of a day are depicted in Fig. 3. The hot and humid outdoor air was dehumidified to the required humidity ratio in the liquid desiccant unit and cooled to below the set temperature of the room in the liquid desiccant unit and indirect evaporative cooler. The temperature gradient of the process air was greatest in the indirect evaporative cooler. Finally, the supply air possessed approximately a 0.007 kg/kg humidity ratio and 22°C dry-bulb temperature.



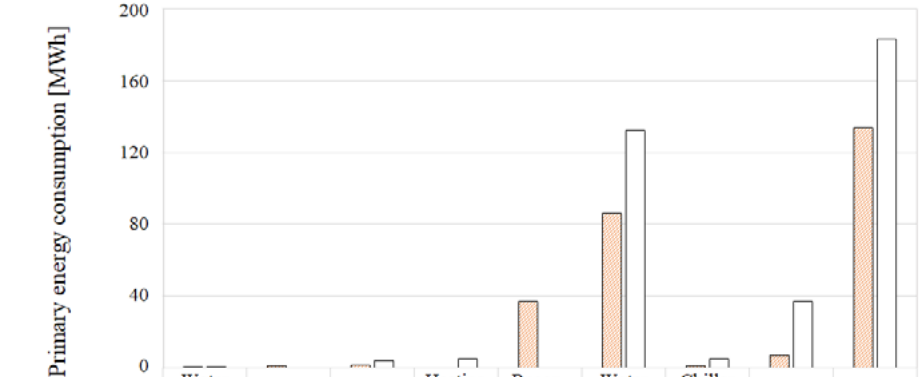


Fig. 3. Temperature and humidity ratio profile of the process air

4.2. Primary energy consumption

To compare the overall energy performances of the proposed and reference systems, the operating energy consumption was converted into the primary energy consumption for each heat source.

Fig. 4. shows the comparison of the primary energy consumptions in the proposed and reference systems. The water-heating energy is lessened in the proposed system as heat from the two heat exchangers is recovered by the process water, while the reference system consumed this heat. Although the proposed system consumed the heat for the regenerator, the total heating energy of the proposed system is less than that of the reference system because the recovered heat from the solution was used for water heating in the proposed system. The proposed system also demonstrated the requirement of a lower amount of cooling energy for the solution because tap water is used for solution cooling. Additionally, the indirect evaporative cooler was used to supply air cooling. The fans consumed energy in the supply, return, and liquid desiccant cycle processes in the proposed system. The fans in the reference system consumed energy for only the supply and return processes. The proposed system consumed less fan energy than the reference system because the air flow rate was equal to the minimum ventilation rate. In contrast, the reference system air flow rate was much greater than the minimum ventilation rate. Although the proposed system used more pump energy than the reference system because of the liquid desiccant circulation, the pump energy of the proposed system is less than that of the reference system. The chiller pump of the reference system consumed more energy than that required liquid desiccant circulation in the proposed system. Consequently, the proposed system consumed 27.0% less primary energy compared with the reference system, as shown in Fig. 4.

	Water pump	LD pump	Air fan	Heating coil	Regen-erator	Water heating	Chiller pump	Chiller	Total
Proposed system	0.5	1.0	1.3	0.0	37.0	85.9	1.0	7.1	133.8
Reference system	0.5	0.0	4.1	4.9	0.0	132.0	4.7	37.1	183.3

Fig. 4. Comparison of the primary energy consumptions of the two systems

5. Conclusion

This study proposed a liquid desiccant ventilation system that can provide both ventilation and water heating. The energy savings associated with the operation of the proposed system was quantitatively analyzed through comparison with a VAV reference system using a TRNSYS 18 and EES simulation. The integration of the liquid desiccant and water heating cycles was proposed to recover the heat required for water heating and reduce the cooling energy required for dehumidification. The possibility of maintaining the required supply-air conditions using an indirect evaporative cooler was investigated through a detailed energy simulation.

The operating energy consumption of the liquid desiccant ventilation system revealed that the proposed system can provide operating energy savings of 27.0% during the summer in comparison with the reference system. The potential for such significant energy savings is mainly due to the heat transferred from the liquid desiccant to the water heating cycle. This strategy also contributes to reducing the cooling energy required for the solution.

Considering the proposed system for use as a ventilation system, energy benefits were achieved in a hot and humid climate. Heat may be recovered from the solution to the water when the liquid desiccant and water heating cycles are operated simultaneously. This system should next be tested for use in dry and cold climates.

Energy Performance Comparison of Two Different Types of Heat Pump-Driven Liquid Desiccant-Assisted Air-Conditioning Systems for an Apartment Building

Jae-Hee Lee[a], Hansol Lim[a], Hye-Won Dong[a], Jae-Weon Jeong[a,*]

[a]Department of Architectural Engineering, College of Engineering, Hanyang University, Seoul, 04763, Republic of Korea

Abstract

The purpose of this study is to compare the energy performance of two heat pump-driven liquid desiccant (HPLD) systems that use different mechanisms for solution pre-conditioning. The design and operating logic of the HPLD systems were proposed for an apartment building. The HPLD system comprises a liquid desiccant (LD) unit for dehumidifying the process air, and a heat pump (HP) unit for cooling and heating the LD solution and cooling the process air. In Case A, the temperature and concentration of the solution can be controlled simultaneously in the HPLD system using a single sump, whereas in Case B, they are controlled separately using a dual sump that uses an additional simple device. The load of the target zone and energy performance of the HPLD system were analyzed using TRNSYS 18 and commercial engineering equation solver (EES), respectively. The results showed that the method used in Case B saved 77 % of the operating energy. The mean system COP in Case B was three times higher compared to that in Case A owing to the decrease in the solution cooling and heating loads.

1. Introduction

Recently, a liquid desiccant air conditioning (LDAC) system has emerged as an interesting system among independent handling devices for latent and sensible loads of air conditioning in terms of energy saving potential and improvement in indoor air quality [1,2]. The desiccant solution should be pre-cooled before entering the absorber and preheated before entering the regenerator to widen the difference in vapor pressure between the solution and air for enhanced dehumidification and regeneration effectiveness [3]. This process is the major factor for operating energy consumption in LDAC, and it can be realized by using low-grade heat sources [4] Heat pump systems have drawn attention because it can cover the solution cooling and heating loads simultaneously by the heat absorption process of the evaporator and heat release process of the condenser [5]. Hence, a heat pump-driven liquid desiccant (HPLD) system is considered as an efficient LDAC application owing to its ability of independent temperature and humidity conditioning and energy efficiency [6]. Additionally, a capacity matching of the HPLD system between the solution cooling and heating loads of the LD unit and the evaporator and condenser loads of the HP unit was considered [7].

On the other hand, LDAC applications have the drawbacks of large scale production and high initial cost, which hinder its potential for widespread utilization. Hence, LDAC applications were initially targeted toward commercial buildings and not residential buildings despite the distinct advantages of independent temperature and humidity control. To make LDAC applications attractive for the residential market, the LDAC applications should be improved through products focusing on the simplicity and compactness of the system [8,9]. The

HPLD system has been recognized as a compact one among the LDAC applications. However, there is a lack of research regarding its applicability in an apartment building [10].

In this research, two HPLD systems that used different mechanisms for pre-conditioning the solution temperature and concentration were designed for an apartment building, and the overall operation strategies were explained. Energy simulation for air conditioning during the summer operation period was performed using the commercial engineering equation solver (EES) program and TRNSYS 18. The applicability of the two HPLD systems in an apartment building was compared based on their performance in terms of energy saving potential and system coefficient of performance (COP).

2. System Overview

The system consists of a heat pump (HP) unit and a liquid desiccant (LD) unit. The LD unit dehumidifies the process air to remove the indoor latent load. The HP unit pre-cools or preheats the desiccant solution and cools the dried process air to remove the indoor sensible load. To cool the solution and air simultaneously, the refrigerant from the HP unit is driven in parallel to two evaporators. Thus, the system can operate as a dehumidifying and cooling device in summer without a separate air handling device.

2.1. Heat pump unit

The heat pump (HP) unit consists of a solution-side evaporator to pre-cool the solution before entering the absorber, an air-side evaporator to cool the dried air returning from the absorber to meet the design target temperature of the supply air, a compressor using a frequency inverter for part-load operation, a solution-side condenser to preheat the solution before entering the regenerator, and an electric expansion valve (EEV) for controlling the refrigerant flow rate. The refrigerant absorbs heat from the heat sources of the evaporators (i.e., cooling capacity) and releases the heat to the heat sink of the condenser (i.e., heating capacity) through the phase change process. Considering the part-load operation mode to cover the variation of cooling loads of the desiccant solution and air, the compressor with inverter control and EEV are used. Then, a required electrical input power of the compressor by the load control can be estimated [11].

2.2. Liquid desiccant unit

The LD unit consists of an absorber (ABS) that operates as a dehumidifying device in summer, and a regenerator (REG) that makes strong solution. The outdoor air and return air are mixed and passed through the absorber to discharge its moisture to the cooled desiccant solution. The temperature of the dried absorber outlet air can be separately controlled by the air-side evaporator of the HP unit. After the dehumidification process, the absorber outlet solution becomes diluted and heated compared to the inlet state because the cooled absorber inlet solution is in contact with the hot and humid air that releases exothermic heat as the solution absorbs the moisture from the air [12]. The scavenging air that adopts the outdoor air, passes through the regenerator and absorbs the moisture from the heated desiccant solution. After the regeneration process, the regenerator outlet solution becomes strong and cool compared to the inlet state; because the heated regenerator inlet solution is in contact with the relatively cold air.

2.3. Heat pump driven liquid desiccant system

In this research, two HPLD systems are discussed: an HPLD system using a single sump i.e., Case A, (Fig. 1), and an HPLD system using dual sump i.e., Case B, (Fig. 2). In Case A, the cold and dilute absorber outlet solution, and the hot and strong regenerator outlet solution are mixed in a single sump. Hence, the concentration and temperature of the outlet solutions can be pre-conditioned simultaneously in the single sump by the mixing process that replaces the function of a conventional heat exchanger between the absorber and regenerator outlet solutions.

In Case B, the outlet solutions from the absorber and regenerator flow toward the respective sump and then circulate to each packed bed. The solution is cooled and diluted in the absorber sump. Whereas, the solution is heated and concentrated in the regenerator sump. An additional condenser is required for releasing the remaining heat to the regenerator outlet air considering the capacity matching between the HP unit (evaporator and condenser loads) and the LD unit (cooling and heating loads of the desiccant solution and air). Moreover, an additional simple device is required for exchanging the solutions between the absorber and regenerator sumps to maintain the solution concentration of each sump constant. Hence, two pipes are placed between the

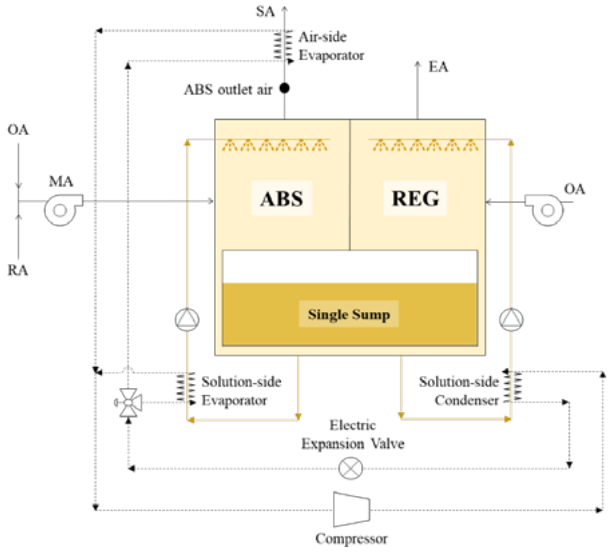

Fig. 1. Schematic diagram of a single sump HPLD system (Case A)

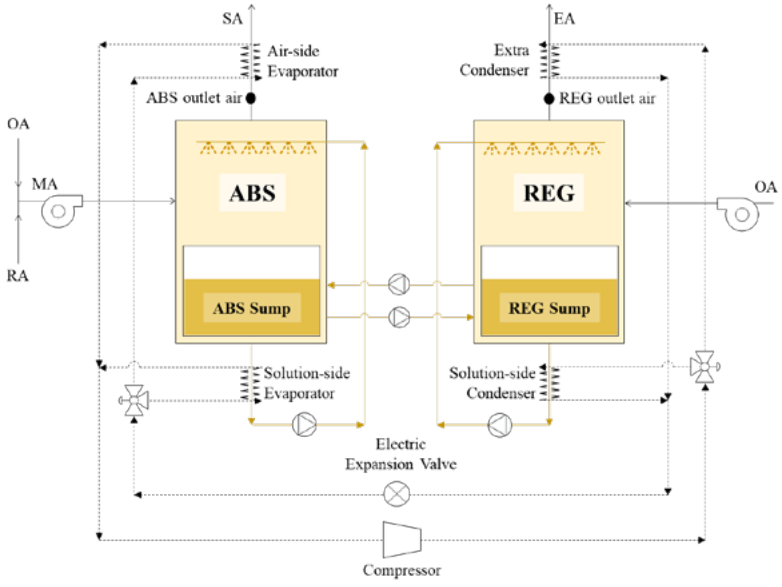

Fig. 2. Schematic diagram of a dual sump HPLD system (Case B)

dual sump for solution exchange after the dehumidification and regeneration process. The temperature and concentration of the outlet solutions can be pre-conditioned separately using the additional device. Then, it can be predicted that the compressor will work in the part-load operation mode deriving the energy consumption saving owing to the decrease in the solution cooling and heating loads.

3. Simulation Overview

3.1. Model building

A single-storey household with 4 occupants in an apartment building located in Seoul, South Korea was selected as the model building for the simulation. Table 1 summarizes the detailed information of the model building that was based on passive house design standards. The indoor target condition was set at 26 °C (T_{ra}) with 50 % relative humidity (RH_{ra}) as per the comfort zone of ASHRAE standard 55. TRNSYS 18 was used for obtaining the hourly thermal load profile of the model during the summer operation period (i.e., June–September). Considering the system compactness for the apartment building, the design flow rate of the supply air ($\dot{V}_{sa,design}$) was assumed as 800 m^3/h and the real time flow rate was variable according to the hourly thermal load. The design target condition of the supply air was determined as 15 °C ($T_{sa,design}$) with 10 g/kg humidity ratio ($\omega_{sa,design}$) based on the peak sensible load and peak latent load. The overall energy simulation was conducted using EES.

Table 1. Model building parameters

Parameters	Conducted values
Simulation period	Cooling season (June-September)
Location	Seoul, South Korea
Occupant/Schedule	4 people/ HVAC schedule addressed in ASHRAE standard 90.1
Volume	192 m^3 (10 m (W) × 8 m (D) × 2.4 m (H), a household on one floor in an apartment building)
Window-to-wall ratio	South: 0.44, North: 0.05
U-value	Floor: 0.39 W/m^2·K, Exterior wall: 0.15 W/m^2·K
Internal heat gains	Lights: 2.7 W/m^2, Equipment: 8 W/m^2, People: 70 W/person of sensible heat, 45 W/person latent heat
Indoor air set conditions	26°C dry-bulb temperature, 50% relative humidity
Supply air target conditions	800 m^3/h, 15°C dry-bulb temperature, 10 g/kg humidity ratio

3.2. Liquid desiccant unit model

Lithium chloride (LiCl) was the solution selected in this research. The absorber and regenerator solution were circulated at a constant mass flow rate of ($\dot{m}_s$) 0.26 kg/s to meet the target condition of the supply air in the proposed system. The regenerator inlet air was blown at a constant rate of 1000 m^3/h to achieve a satisfactory regeneration rate and treat the extra condensing load.

The dehumidification effectiveness (ε_{abs}) in the absorber and regeneration effectiveness (ε_{reg}) in the regenerator are defined as the ratio of the humidity ratio change between the packed bed inlet and outlet air to the maximum change with respect to the equilibrium humidity ratio ($\omega_{eq,s}$) of the inlet solution (Eq. (1) and (2)). Additionally, the dehumidification and regeneration effectiveness can be defined as the temperature change in the inlet and outlet air with the inlet solution temperature (Eq. (1) and (2)). The equilibrium humidity ratio ($\omega_{eq,s}$) of the inlet solution can be estimated with its equilibrium vapor pressure (p_s) (Eq. (3)), which is expressed as a second-order polynomial function established by Fumo and Goswami [13].

$$\varepsilon_{abs} = \frac{\omega_{abs,i,a}-\omega_{abs,o,a}}{\omega_{abs,i,a}-\omega_{abs,eq,s}} = \frac{T_{abs,i,a}-T_{abs,o,a}}{T_{abs,i,a}-T_{abs,i,s}} \quad (1)$$

$$\varepsilon_{reg} = \frac{\omega_{reg,o,a}-\omega_{reg,i,a}}{\omega_{reg,eq,s}-\omega_{reg,i,a}} = \frac{T_{reg,o,a}-T_{reg,i,a}}{T_{reg,i,s}-T_{reg,i,a}} \quad (2)$$

$$\omega_{eq,s} = 0.622 \times \frac{p_s}{101.325-p_s} \quad (3)$$

When the conditions of the packed bed inlet solution ($T_{i,s}$, $\chi_{i,s}$) and air ($T_{i,a}$, $\omega_{i,a}$) are given, the dehumidification effectiveness (ε_{abs}) and regeneration effectiveness (ε_{reg}) can be predicted, and the temperature and humidity ratio of the outlet air ($T_{o,a}$, $\omega_{o,a}$) can be estimated using Eq. (1) and Eq. (2). To

predict the dehumidification effectiveness (ε_{abs}), the model derived by Chung and Luo was used [14]. The regeneration effectiveness (ε_{reg}) was fixed at 0.3 because its experimental value in the previous literature slightly fluctuated from 0.3 to 0.4 under variable operating conditions [15].

The dehumidified moisture rate ($\dot{m}_{dehum}$) from the humid air in the absorber can be calculated by multiplying the mass flow rate of the inlet air and the humidity ratio change before and after passing through the absorber. Similarly, the regeneration rate ($\dot{m}_{regen}$) in the regenerator can be calculated by multiplying the mass flow rate of the scavenging air and its humidity ratio change. The conditions of the absorber and regenerator outlet solution can be estimated based on the mass balance and energy balance.

Considering the compactness of the system, the volume of the dual sump was set at 20 L and that of the single sump at 40 L. It was assumed that the initial conditions of the desiccant solution in the sump can be affected by the indoor set conditions. Therefore, the initial temperature ($T_{sump,old}$) and concentration ($\chi_{sump,old}$) of the solution in the sump was set to 26 °C and 30 %, and initial solution weight of the sump was set to 26 kg ($W_{sump,old}$) based on the LiCl density. It was assumed that the real-time state of the single sump can be constant at 26 °C with 30 % concentration and 26 kg of weight because the opposite outlet solutions were mixed in the single sump. On the other hand, the conditions such as temperature, concentration, and weight of the dual sump changes whenever the system operates. Hence, the conditions were calculated with transient analysis using EES. Additionally, the appropriate rate for the solution exchange was estimated to be 4 L/h, which is sufficient to cover both the dehumidification and regeneration rate.

3.3. Heat pump unit model

The refrigerant type selected in this research was R410A. To analyze each component of the heat pump (HP) unit, several assumptions were made as follows: 1) the evaporating temperature (T_{evap}) and condensing temperature (T_{cond}) of the refrigerant are constant during its phase change. 2) The effectiveness of the heat exchange of the evaporator (ε_{evap}) and condenser (ε_{cond}) is constant at 0.7, and the isentropic efficiency (η_{comp}) of the compressor is 0.75. 3) The superheating and subcooling degree can be neglected.

The evaporating and condensing temperature were determined as 12 °C and 55 °C based on several requirements as follows: 1) the estimated temperature and humidity ratio of the supply air should approach the target conditions of 15 °C and 10 g/kg. 2) The estimated temperature of the solution before entering the regenerator should be above 40 °C. 3) The required input power of the compressor should be below 4 horsepower for an apartment building. 4) After compression, the refrigerant should completely release its heat to the heat sink to avoid extra condensing load.

The thermodynamic properties of R410A of each state in the HP cycle were acquired by intrinsic function of the EES based on the determination of the evaporating and condensing temperature. The actual compressor outlet enthalpy ($h_{act,comp,o}$) can be calculated by Eq. (4), with the compressor isentropic efficiency (η_{comp}).

$$h_{act,comp,o} = \frac{h_{ideal,comp,o} - h_{evap,o}}{\eta_{comp}} + h_{evap,o} \tag{4}$$

Figure 3 shows the calculation process of the cooling capacity of the evaporator, required input power of the compressor, and the heating capacity of the condenser. The actual cooling capacity of the solution-side evaporator ($\dot{Q}_{act,evap,s}$) and air-side evaporator ($\dot{Q}_{act,evap,a}$) can be calculated using Eq. (5) and (6), based on the evaporating temperature (T_{evap}) and heat exchange effectiveness (ε_{evap}). Then, the actual cooled temperature of the absorber inlet solution ($T_{abs,i,s}$) and supply air (T_{sa}) can be obtained by Eq. (7) and (8).

$$\dot{Q}_{act,evap,s} = \varepsilon_{evap}\left(\dot{m}C_p\right)_{abs,i,s}\left(T_{abs,sump,old} - T_{evap}\right) \tag{5}$$

$$\dot{Q}_{act,evap,a} = \varepsilon_{evap}\left(\dot{m}C_p\right)_{abs,o,a}\left(T_{abs,o,a} - T_{evap}\right) \tag{6}$$

$$\dot{Q}_{act,evap,s} = \left(\dot{m}C_p\right)_{abs,i,s}\left(T_{abs,sump,old} - T_{abs,i,s}\right) \tag{7}$$

$$\dot{Q}_{act,evap,a} = \left(\dot{m}C_p\right)_{abs,o,a}\left(T_{abs,o,a} - T_{sa}\right) \tag{8}$$

The total cooling capacity ($\dot{Q}_{act,evap,tot}$) of the evaporator can be expressed as the sum of the actual cooling capacity of the solution-side evaporator and air-side evaporator. The refrigerant flow rate ($\dot{m}_{ref}$) required to treat the cooling capacity can be calculated by Eq. (9), using the enthalpy change before and after passing

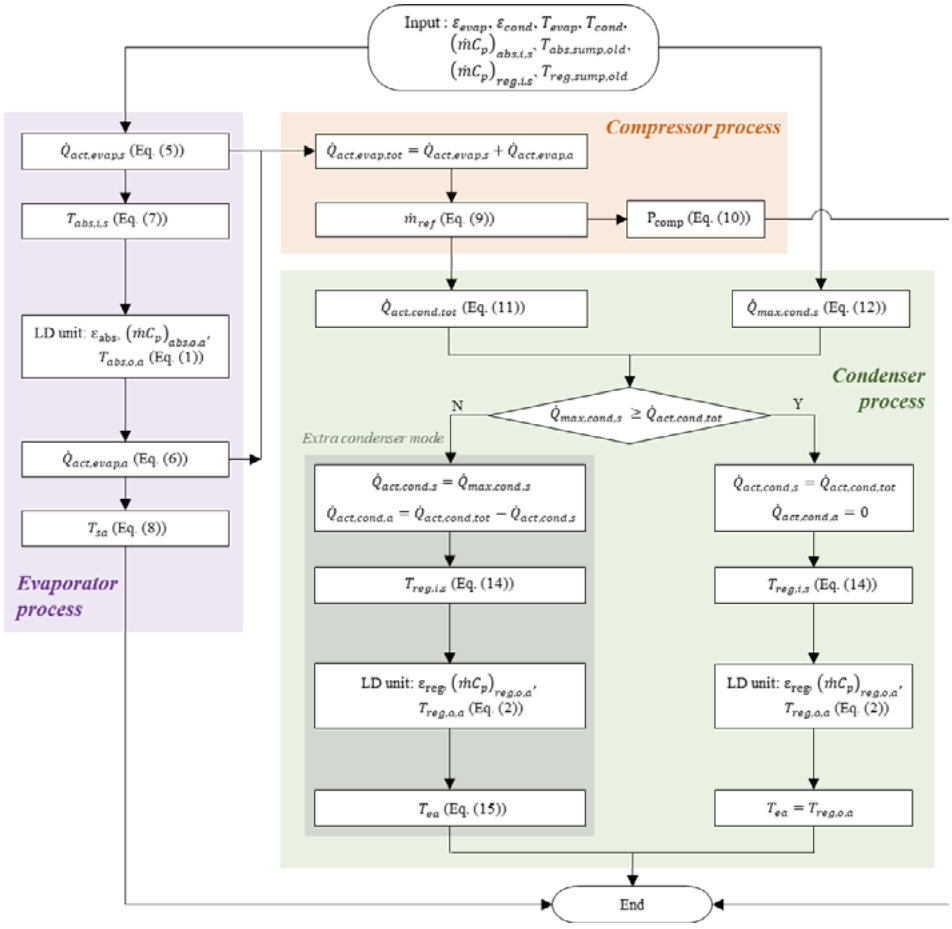

Fig. 3. Flow chart of the calculation process of the heat pump unit

through the evaporator. Then, the required input power (P_{comp}) to the compressor can be assessed by Eq. (10) with the calculated refrigerant rate.

$$\dot{Q}_{act,evap,tot} = \dot{m}_{ref}(h_{evap,o} - h_{evap,i}) \tag{9}$$

$$P_{comp} = \dot{m}_{ref}(h_{act,comp,o} - h_{evap,o}) \tag{10}$$

The total heat that should be completely released to the heat sink ($\dot{Q}_{act,cond,tot}$) can be estimated by Eq. (11) using the calculated refrigerant rate and the enthalpy change before and after passing through the condenser. The maximum heat transfer rate of the solution-side condenser ($\dot{Q}_{max,cond,s}$) and air-side condenser ($\dot{Q}_{max,cond,a}$) can be estimated by Eq. (12) and (13) based on the condensing temperature (T_{cond}) and heat exchange effectiveness (ε_{cond}). When the total heat to be released ($\dot{Q}_{act,cond,tot}$) is higher than the maximum heat transfer rate of the solution-side condenser ($\dot{Q}_{max,cond,s}$), extra condensing load occurs, which should be released to the air-side condenser. Otherwise, the solution-side condenser releases all the heat to the solution. According to the decision of the actual heating capacity of each condenser ($\dot{Q}_{act,cond,s}$,$\dot{Q}_{act,cond,a}$), the heated regenerator inlet solution ($T_{reg,i,s}$) and exhaust air (T_{ea}) can be obtained by Eq. (14) and (15).

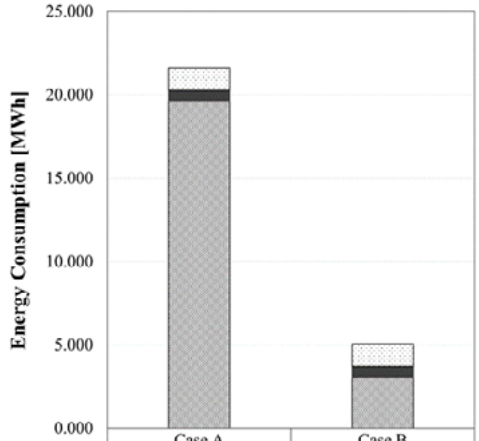
$$\dot{Q}_{act,cond,tot} = \dot{m}_{ref}(h_{act,comp,o} - h_{cond,o}) \tag{11}$$

$$\dot{Q}_{max,cond,s} = \varepsilon_{cond}\left(\dot{m}C_p\right)_{reg,i,s}\left(T_{cond} - T_{reg,sump,old}\right) \quad (12)$$

$$\dot{Q}_{max,cond,a} = \varepsilon_{cond}\left(\dot{m}C_p\right)_{reg,o,a}\left(T_{cond} - T_{reg,o,a}\right) \quad (13)$$

$$\dot{Q}_{act,cond,s} = \left(\dot{m}C_p\right)_{reg,i,s}\left(T_{reg,i,s} - T_{reg,sump,old}\right) \quad (14)$$

$$\dot{Q}_{act,cond,a} = \left(\dot{m}C_p\right)_{reg,o,a}\left(T_{ea} - T_{reg,o,a}\right) \quad (15)$$



The system COP was defined as the ratio of the heat capacity of the supply air to the total electric energy consumption, as shown in Eq. (16). The total electric energy consumption was derived by the compressor, fans, and pumps. The energy consumption of the fans and pumps was predicted by an empirical model from open literature.

$$COP_{sys} = \frac{\dot{m}_{sa}(h_{ra} - h_{sa})}{P_{comp} + P_{fan} + P_{pump}} \quad (16)$$

4. Simulation Results

4.1. Energy consumption comparison

Figure 4 shows the total energy consumption converted to primary energy for the two HPLD systems using the local conversion factor of 2.75 for electricity. Case A consumed 21.6 MWh of total energy, whereas Case B consumed 5.06 MWh of total energy. The energy consumption of the fan was same for the two systems because the air flow rate of the absorber and regenerator was the same for the two systems. The pump energy consumption was 4 kWh higher in Case B due to the need for solution exchange at 4 L/h. In Case A, the temperature of the solution in the single sump can be constant at 26°C by mixing the cold absorber outlet solution and the hot regenerator outlet solution. Then, the compressor should work in full-load to cool the solution in the single sump of 26°C and heat the solution in the single sump of 26°C. In Case B, the solution in the absorber sump becomes cooled below 26°C (i.e., 15°C) and the solution in the regenerator sump becomes heated above 26°C (i.e., 45°C). Then, the compressor can work in part-load to cool the solution in the absorber sump of 15°C and heat the solution in the regenerator sump of 45°C. The compressor energy consumption saved 16.6 MWh in Case B because the compressor can work in part-load operation mode owing to the decrease in solution cooling and heating loads. Hence, Case B saved 77 % of the total energy consumption than Case A and the key factor of this result is the energy consumption of the compressor.

	Case A	Case B
Pumps	1.368	1.372
Fans	0.608	0.608
Compressor	19.662	3.083

Fig. 4. Energy consumption comparison

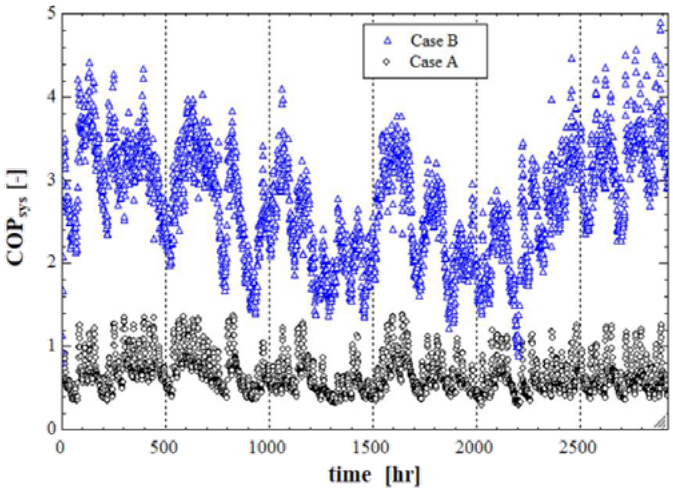


Fig. 5. System COP comparison

4.2. System COP comparison

Figure 5 shows the system COP comparison of the two HPLD systems. In all cases, Case B had a higher system COP than Case A. The mean system COP was 0.7 for Case A and 2.7 for Case B. The reason for this tendency is that both the systems satisfy the target temperature and humidity ratio of the supply air similarly. However, Case B can save operating energy consumption compared to Case A. According to the result, if the heat capacity matching between the HP unit and LD unit is achieved and the solution concentration of each sump is constant, Case B can generate the desired supply air by consuming less operating energy.

5. Conclusion

In this study, two HPLD systems, one using a single sump and another using a dual sump were suggested for an apartment building. The two systems have different mechanisms for pre-conditioning the temperature and concentration of the desiccant solution. The energy consumption and system COP for cooling and dehumidifying were compared between the two systems to analyze the applicability. The results showed that Case B reduced 77 % of the total operating energy consumption. Its system COP was always higher than that of Case A, (mean value of 2.7 against 0.7). The greatest energy-saving component was the compressor that operated in the part-load mode. Therefore, Case B can be an appropriate HPLD system for an apartment building in terms of its productivity and energy efficiency by satisfying the capacity matching and constant solution concentration.

Although, the performance comparison during the summer operation period was conducted in this study, the HPLD system can be reversible and annually operated. Therefore, additional performance comparison during the intermediate and winter season should be conducted and an optimal sequence for annual operation should be considered. In addition, an experimental verification of the simulation results in this study should be conducted in the future.

Abstract

Energy demands grow every year, and a significant amount of energy consumption is used for buildings cooling and heating. Since heat pump systems have high efficiency and can be utilized for buildings cooling and heating, they are commonly used around the world. Many studies show heat pumps have the best COP at the optimal refrigerant charge. Therefore, it is imperative to monitor the current refrigerant charge of the system and maintain it optimally in view of energy saving. However, some researches show that many heat pumps in the field have refrigerant leakage fault or overcharge fault. The refrigerant charge error can cause energy waste and thermal discomfort. Hence, many researchers have conducted studies for refrigerant charge fault detection (RCFD) method. In recent years, RCFD methods based on deep learning technology have been developed actively. This paper suggests a novel and efficient RCFD strategy using convolutional neural network (CNN). The CNN based multiple outputs regression model shows excellent results for predicting power consumption, cooling capacity (heating capacity), and the refrigerant charge amount simultaneously with a single model.

1. Introduction

The US Energy Information Administration presented that 39.7% of US total energy consumption in 2015 was used in commercial and residential buildings, and about 40% of it was spent on buildings heating and cooling [1]. Since heat pumps have high efficiency and can be utilized for buildings cooling and heating, heat pump systems are widely used all over the world. Therefore, many researchers have conducted studies to increase the efficiency of heat pump systems for energy saving.

Optimum refrigerant charge is essential in vapor compression systems [2-4]. However, Jacob et al. [5] found that 46% of HVAC systems installed in 75 buildings in California did not have an appropriate refrigerant amount, reducing performance and consuming unnecessary energy. Therefore, in terms of energy, a technique for detecting undercharge or overcharge of refrigerant is essential, and many studies for RCFD methods have been conducted so far [6-8]. Recently, due to the improved computational power of computers and big data, data-driven researches such as an artificial neural network (ANN) are trendy in refrigerant charge prediction techniques [9-12].

However, there are some limitations to the conventional ANN-based RCFD method. First, due to simple classification such as undercharge and overcharge, it was not possible to provide a quantitative refrigerant amount. Second, many conventional ANN-based RCFD methods only took one operation mode (cooling or heating mode) into consideration. Finally, many ANN-based RCFD articles provided only information on the refrigerant charge amount. However, the essential things that we want to know are the cooling or heating capacity and the efficiency of the heat pump systems according to the change of the refrigerant charge amount.

The predictive ability for these three attributes can help determine the urgency of whether or not current refrigerant fault needs repairing right now.

In order to improve these limitations, this paper proposes a novel RCFD technique using CNN based multiple outputs regression model. Since the refrigerant charge amount, power consumption, and cooling capacity (heating capacity) of the heat pump system are substantially real numbers, the prediction for the three targets is a multiple outputs regression task [13-14]. The contributions of this proposed method are as follows. First, it provides quantitative information about the current amount of refrigerant in the heat pump system. Second, it also predicts the current heating capacity (cooling capacity) and the power consumption of the heat pump quantitatively. Thus, the current COP of the system can be calculated. In addition, the prediction for these three attributes can give information on the severity of the refrigerant charge fault. Third, both heating and cooling modes were considered, and a single model was used.

Briefly describing the results, including both cooling and heating mode, the refrigerant amount prediction error is within RMS error of 4.9%, the power consumption prediction error is within RMS error of 3.8%, and the cooling capacity (heating capacity) is below RMS error of 3.4% with a single model.

2. Methodology

2.1. Convolutional neural network (CNN)

The basic structure of CNN, one of the deep learning technologies, is composed of a convolutional layer, a pooling layer, and a fully-connected layer.

The convolutional layers and the pooling layers extract the features from the original raw data together [15]. After the input images and several filters perform a convolutional operation, the convolutional layer extracts a feature map by applying an activation function.

The pooling layer plays a role to reduce the size of the extracted feature map and to alleviate the sensitivity according to the location. Among the pixel values in the region of interest of the feature map, acquiring the largest value is called max-pooling, and calculating the average value is called average-pooling. Generally, max-pooling is widely used for CNN. Therefore, it is used for the RCFD model in this study.

The convolutional layers and the hidden layers of the fully-connected layers require a nonlinear function as the activation function. Mainly the rectified linear unit (ReLU) function is used.

The fully-connected layers have a similar structure to the existing ANN. All pixel values of the feature map after the pooling layer are connected to the input nodes of the fully-connected layer. After going through several hidden layers, the predicted value for each output node in the output layer is calculated using a linear activation function instead of the softmax function. In this study, the output layer has three output nodes to predict power consumption, cooling capacity (heating capacity), and the refrigerant charge amount.

The architecture of the CNN-based RCFD regression model used in this article is described in Table 1.

Table 1. The architecture of CNN-based RCFD multiple outputs regression model

Layer name	Input size	Filter size	Filter number	Stride	Output size	Activation function
Input	29×30×1	-	-	-	-	-
Convolutional 1	29×30×1	3×3	8	1	27×28×8	ReLU
Convolutional 2	27×28×8	3×3	8	1	25×26×8	ReLU
Max-pooling 1	25×26×8	2×2	-	2	12×13×8	-
Convolutional 3	12×13×8	3×3	8	1	10×11×8	ReLU
Convolutional 4	10×11×8	3×3	8	1	8×9×8	ReLU
Max-pooling 2	8×9×8	2×2	-	2	4×4×8	-
Flatten 1	4×4×8	-	-	-	128×1	-
Fully-connected 1	128×1	-	-	-	50×1	ReLU
Output	50×1	-	-	-	3×1	Linear

Since the proposed model was a CNN-based regression model, we used a linear activation function instead of the softmax function at the output layer and a mean squared error as a loss function. A loss function using a mean squared error is depicted as follows.

$$E(\boldsymbol{w}) = \frac{1}{2N}\sum_{n=1}^{N}\sum_{k=1}^{K}(y_{nk} - d_{nk})^2 \qquad (1)$$

where $\boldsymbol{w}$ is the weight of a neural network, N is the total number of samples, K is the total number of output nodes, d_{nk} is the correct answer of the k_{th} output node in the n_{th} sample, and y_{nk} is the output value of the k_{th} output node in the n_{th} sample.

The learning process is to update the weights of each layer so that the value of the loss function is minimized. Stochastic gradient descent and backpropagation methods are widely used. We shuffled the training data randomly, and the shuffled data for learning was divided by mini-batch size. Since early stopping is widely utilized to prevent overfitting that deteriorates the generalization of a learned model [16], the early stopping algorithm was considered in this research.

2.2. Time-domain data to 2-D image data conversion method

Generally, CNN uses 2-D image data as input. Therefore, It is needed a process of converting time-series data of various sensors installed in the heat pump into 2-D image data. Although there are many conversion methods, in this study, the values of multiple sensors measured at fixed time intervals were stacked in chronological order and were converted to the 2-D image data [17]. Twenty-nine features were collected at two-second intervals and converted to one image data using the dataset obtained for 60 seconds. Therefore, one 2-D data sample size is 29×30.

Data normalization is essential for convergence and performance in neural network methods. In general, the min-max scaling method and the standardization method are used widely. In this study, training, validation, and test data were preprocessed with the min-max scaling method.

3. Experimental setup

3.1. Experimental setup and conditions

Experiments were carried out using a commercial 30 kW heat pump system with two indoor units and one outdoor unit. The heat pump is equipped with a variable-speed scroll compressor, three inverter fans, multiple EEVs, and a 4-way valve. Fig. 1 shows a schematic of the experimental setup [18].

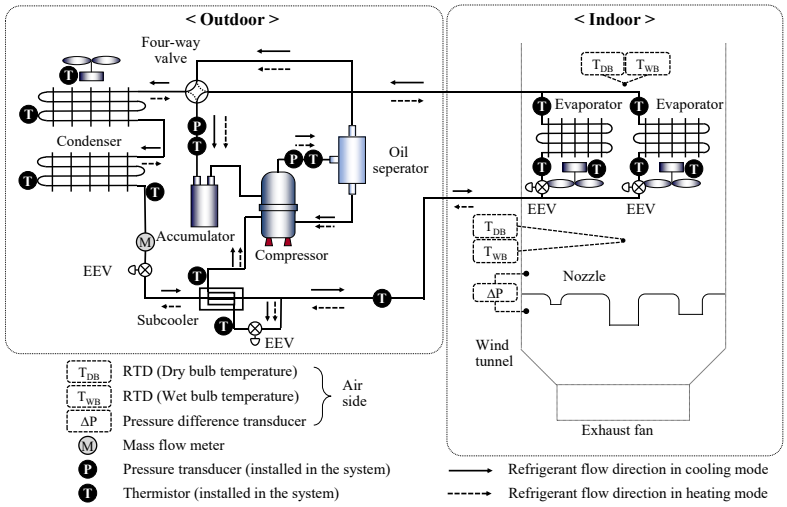

Fig. 1. Schematic of an experimental setup [18]

The sensors in black circles are initially installed sensors by the manufacturer. A pressure difference transducer, mass flow sensor, and RTD sensors are installed additionally for this research. However, it was noted that the measured values acquired from the additional sensors were not utilized for learning the CNN-based models. The nominal charge amount of refrigerant is 6 kg in heating mode and 9 kg in cooling mode. The outdoor unit was installed in the chamber to simulate the outdoor temperature and humidity conditions, and the two indoor units were installed in the chamber to create the indoor temperature and humidity conditions.

The experiments were carried out in both the cooling and heating mode. In the heating mode, the experiments started with 3 kg of refrigerant charge. After obtaining experimental data while changing the DSH for at least two hours in each refrigerant charge, an additional 1 kg of refrigerant charge was added. This process was repeated until the final refrigerant amount reached 8 kg. In cooling mode experiments, the refrigerant charge was added step by step from 6 to 11 kg, as mentioned above. When the target DSH was changed, or the refrigerant of 1 kg was added, the heat pump system became a transient state for about five minutes. This transient-state data was included in the training and test data with the steady-state data together.

The operation mode, various air conditions, compressor rotating speed, and target DSH were variables for the validation of this new RCFD method under various experimental conditions. The fan RPM in the outdoor unit was fixed at all experimental conditions, and two indoor units were always operated. In heating mode, the EEVs of both indoor units were fully opened, and the EEV of the outdoor unit was activated with the manufacturer's control logic.

In contrast, in cooling mode, the EEVs of the two indoor units were controlled, and the EEV of the outdoor unit was fully opened. Considering ANSI / AHRI standard 1230 [19], four air temperature conditions for cooling mode, and two air temperature conditions for heating mode were chosen. The experiment test conditions are described in detail in Table 2.

Table 2. Experimental conditions for cooling and heating mode

Variables	Value					
Refrigerant	R410A					
Lubricant	Polyvinyl ether(PVE) type					
Lubricant charge amount (kg)	3					
Operation mode	Cooling mode				Heating mode	
Refrigerant charge amount (kg)	6 - 11 (Δ=1)				3 - 8 (Δ=1)	
Target DSH (K)	5, 10, 15 (or maximum EEV opening)				5, 10 (or maximum EEV opening)	
Air condition (ANSI/AHRI 1230)	Rating	Low temp.	Condensate	Max load	Rating (low temp.)	Rating (high temp.)
ID inlet DB (˚C)	26.7	19.4	26.7	26.7	21.1	21.1
ID inlet WB (˚C)	19.4	13.9	23.9	19.4	15.6 (max)	15.6 (max)
OD inlet DB (˚C)	35.0	19.4	26.7	46.1	-8.3	8.3
OD inlet WB (˚C)	23.9	13.9	23.9	23.9	-9.4	6.1
Compressor speed (Hz)	60, 100	60	60, 100	60, 100	60, 100	60

The 29 features were selected based on previous studies [6-8], experimental conditions, and the attributes required to analyze the thermodynamic properties of the heat pump system. All the features utilized in the development of the model in this research can be acquired from the monitoring variables that the manufacturer provides.

3.2. Splitting of training, validation, and test data

In general, three datasets, such as the training data, the validation data, and the test data are required to improve the prediction performance of machine learning-based models. The total number of two-second interval data in this study is 223,590. To estimate the generalization error of this proposed model, experimental data, including refrigerant charges of 8 kg and 9 kg at condensation condition in cooling mode, were previously

separated into test data. Besides, experimental data with the refrigerant charge of 4.5 kg, 5.5 kg, 6.5 kg, and 7.5 kg at rating conditions (high temperatures) under heating mode were added into test data in advance. The number of previously prepared test data mentioned above is 31,140. The number of rest data is 192,450. The rest of the data were split into three groups as 7 vs. 2 vs. 1. So, there were 134,700 for training data, 38,670 for validation data, and 19,080 for testing. Therefore, the number of training data is 134,700, the number of validation data is 38,670, and the number of final test data is 50,220. Finally, the number of 2-D converted training data is 4,490, the number of 2-D validation data is 1,289, and the amount of 2-D test data 1,674.

4. Results and discussion

The quantitative prediction of refrigerant levels is essential for proper monitoring and management of heat pump systems. Besides, if the power consumption and cooling capacity of the system can be predicted, it is possible to know the effect of the refrigerant charge fault on the heat pump system. This prediction can help determine the urgency of repairing a refrigerant fault. In this paper, we suggest a novel method that can predict power consumption, cooling capacity (heating capacity), and the refrigerant charge amount quantitatively and simultaneously using a single model.

Fig. 2 shows the prediction results for the power consumption values and cooling capacity (heating capacity), and the refrigerant charge amount of the heat pump systems. From Fig. 2 (a), the performance of power consumption prediction is within an RMS error of 3.8%. The error in the prediction of cooling capacity and heating capacity is an RMS error of 3.4% from Fig. 2 (b). Fig. 2 (c) shows that the CNN-based model achieved the predictive performance on the refrigerant charge amount with an RMS error of 4.9%.

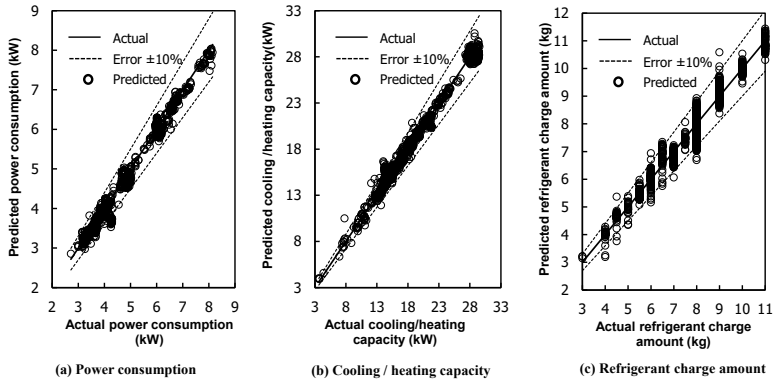

Fig. 2. Actual and predicted power consumption, cooling/heating capacity, and refrigerant charge in CNN-based regression model

The COP of a heat pump can be calculated because power consumption and cooling capacity are predicted according to the refrigerant amount change.

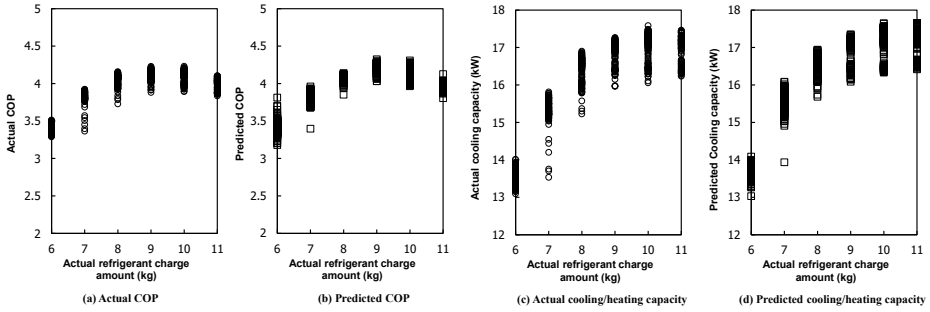

Fig. 3. Actual and predicted COP and cooling/heating capacity at the rating condition in the cooling mode

Fig. 3 (a) and (b) show the COP change of the system according to the amount of refrigerant at the rating condition in the cooling mode. They show that the predicted COP is similar to the actual COP. From Fig. 3 (c) and (d), it can be known that the cooling capacity of the heat pump with the refrigerant charge amount of 8 kg is reduced by about 2.4% compared to the nominal refrigerant charge amount of 9 kg. However, the cooling capacity in the refrigerant charge amount of 7 kg is reduced by about 8.8%. In this case, consumers may feel thermal discomfort due to reduced cooling capacity. When the refrigerant charge is 7 kg, the urgency of repairing the fault is much higher than 8 kg.

5. Conclusions

This research proposes a novel CNN-based RCFD multiple outputs regression method which has excellent quantitative prediction accuracy. This multiple outputs regression model can predict power consumption, cooling or heating capacity, and the refrigerant charge amount with a single model quantitatively. Therefore, it can provide helpful information for the severity of the refrigerant charge fault to the manufacturer or the service engineer. This comprehensive information can help manufacturers or maintenance engineers decide whether to fix a refrigerant charge defect urgently. In addition, this suggested model can predict three target variables in both the cooling and heating mode. The prediction errors for power consumption, cooling or heating capacity, and refrigerant charge amount are RMS errors of 3.8%, 3.4%, and 4.9%, respectively.

Analysis of a steam generating high temperature heat pump for industrial waste heat recovery

Sabrina Dusek[a,*], Michael Lauermann[a], Franz Helminger[a], Veronika Wilk[a]

[a]AIT Austrian Institute of Technology GmbH, Giefinggasse 2, 1210 Vienna, Austria

Abstract

Steam is one of the most important energy carriers in industrial processes. For example, steam is used for sterilization, cooking and drying processes and as a heat transfer medium for various processes. Fossil fuels are often used to generate steam, but the use of fossil fuels, especially in industry, must be reduced in the future to reduce CO_2 emissions and to achieve climate targets. Heat pumps are already being used successfully in industrial applications, valorizing waste heat. With a high temperature heat pump, waste heat can be used to generate steam. This extension of the application range of heat pumps will provide a further contribution to achieving climate targets. A model of a steam generating high temperature heat pump was elaborated to study the technology under different operating conditions. This contribution shows the simulation results of a steam generating high temperature heat pump system with different refrigerants. The results are compared in terms of COP and compressor displacement. The goal is to identify the most appropriate refrigerant for a specific steam pressure.

1. Introduction

All over the world, industrial processes are rejecting large amounts of low temperature waste heat in the form of exhaust gases and waste water. According to an analysis of Forman et al [1], a total of 29 539 TWh of energy was supplied to industrial processes worldwide in 2012, but only 49% were actually used. The remaining 51% were identified as losses in the form of waste water and hot off gases (about two thirds of the losses) and other losses such as radiation, friction, resistance, etc. Due to the low temperature level, these waste heat streams can no longer be used in an efficient way and are released unused into the environment. High temperature heat pumps allow for using these waste heat streams because they provide process heat at a higher temperature level. Heat pumps that provide steam are of particular interest to the industry because steam generation has a significant share in process heat. For example, steam generation accounts for 27% of the useful energy in industry in Austria (92 PJ). A total of 45% of the steam was generated by combustion of natural gas (41 PJ). [2] If heat pumps are used for low pressure steam generation instead of steam generators operated with fossil fuels, significant reductions in primary energy and CO_2 emissions are achieved.

For steam production, high temperature heat pumps are required with supply temperatures up to 150°C, which are mainly determined by the choice of the refrigerant. Conventional industrial heat pumps can reach temperatures up to 90-100ºC, but new developments have raised the working temperature to above 100ºC in the last years (e.g. CO_2 based heat pumps from Engie Refrigeration [3] and Mayekawa (Japan) [4], R245fa heat pumps for the supply of hot water at 130°C by Ochsner Energietechnik GmbH (Austria) [5], heat pumps from Viking Heat Engines AS (Norway) with supply temperatures above 150ºC).

Nomenclature

Abbreviations

COP	coefficient of performance
GWP	global warming potential
NBP	boiling point at nominal pressure
ODP	ozone depletion potential
SPHE	shell and plate heat exchanger

Roman symbols

a	pattern amplitude, m
A	heat transfer area, m^2
d	plate diameter, m
h	specific enthalpy, Jkg^{-1}
h"	specific enthalpy of dry saturated steam, Jkg^{-1}
m	mass, kg
$\dot{m}$	mass flow, kgs^{-1}
n	number of plates
l	length of the plate pack, m
p	pressure, bar_a
P_{el}	electrical power, W
$\dot{Q}_H$	heating capacity, W
$\dot{Q}$	heat flow, W
s	plate thickness, m
t	time, s
V	volume, m^3
X	wave number

Greek symbols

Λ_P	wave length, m
Φ	area extension factor

Subscripts

in	incoming
out	outgoing

Heat pumps for steam generation are still very rarely used in industrial processes. A 200 kW pilot plant was integrated into the Smurfit Kappa Roermond paper mill in the Netherlands by TNO (former ECN), which proved the ability to deliver steam at 120°C from a waste heat source at 60°C with R600 (critical temperature 152°C) as refrigerant. Based on the results of this project a roadmap for industrial heat pumps was created. [6-7] In 2011, a heat pump with R245fa was launched on the Japanese market under the brand name Kobelco, which supplies steam at 120°C and has a heating capacity of around 370 kW. The critical temperature of R245fa is 154°C. To achieve higher steam temperatures of 165°C, a vapour compressor can be connected downstream (SGH 165) [8]. Recently, Kaida published an overview on industrial applications of SGH heat pumps in Japan, reporting end user satisfaction and positive effects of the heat pump integration. The heat pump steam generators are applied in the chemical industry for distillation of ethanol (5 units supplying 2t/h of 120°C steam), sterilization of chemical containers (1 unit, 165°C steam) and for sewage sludge drying (1 unit, 165°C steam). [9] Those heat pumps are currently only available in Japan.

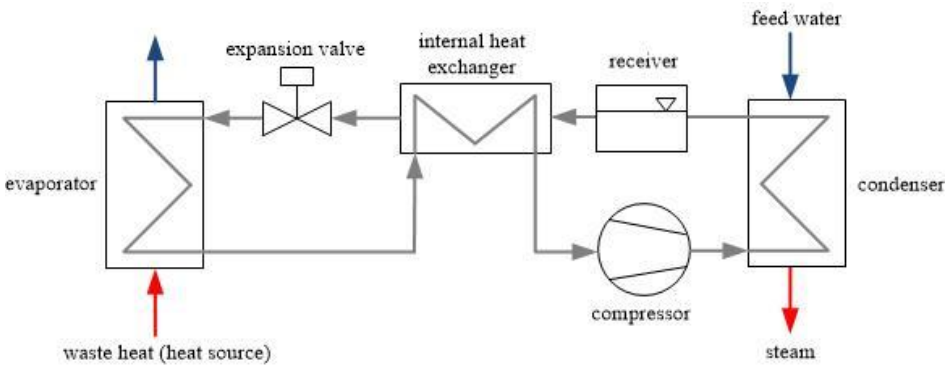

Fig. 1. Schematic representation of the steam generating heat pump cycle

In the BAMBOO project, the prototype of a heat pump is developed, which provides low-pressure steam with up to 5 bar_a (152°C) for industrial steam networks. A novel HFO-refrigerant, R1336mzz(Z) is applied that has no negative impact on the environment. It is well suited for high supply temperatures of up to 160°C, thus for the production of saturated steam at up to 5 bar_a. A novel type of piston compresssor is selected as the compressor, which is already operating successfully on R1336mzz(Z). An innovative condenser is developed, where steam is generated directly on the secondary side. Thereby the heat pump becomes more efficient, compact and cost-effective. The heat pump prototype has a nominal heating capacity of 200 kW and can be easily scaled up to higher heating capacities. The heat pump will be thoroughly tested in the lab and then implemented in real industrial environment to demonstrate functionality at TRL7.

All the above-mentioned examples for steam generating heat pumps are subcritical processes. Subcritical processes are well suited for steam generation because the majority of heat is transferred at constant temperature. In this work a simulation model for a subcritical steam generating heat pump cycle is discussed. Fig. 1 illustrates the layout of the heat pump cycle. A shell and plate heat exchanger (SPHE) is used as the condenser and it is also the steam generator. The simulation model was used to compare different refrigerants, in terms of coefficient of performance (COP) and compressor displacement, using the same heat pump cycle. The analysis was carried out for three different steam pressures. The aim of this investigation was to find the most suitable refrigerant for a specific steam pressure.

2. Steam generating heat pump model

The steam generating heat pump cycle was modeled in the simulation environment Dymola/Modelica [10]. The TIL-Library [11] was used to model the components in the cycle. For the evaporator, the internal heat exchanger, receiver and the expansion valve standard components from this library were used. The condenser and the compressor were modeled in a custom way. The models of the individual components are described in more detail in the following chapters. A receiver after the condenser (see Fig. 1) enables the lowest possible condensation temperature for a wide range of operating conditions. For determining the required thermal-physical properties of the involved media (Refrigerants, Water) the TILMedia-Library [11] was used. Both thermal and pressure losses were neglected in this model. In addition, constant values were assumed for the heat transfer coefficients between the media and the heat transfer area of the heat exchangers.

2.1. Shell and Plate heat exchanger model

As mentioned before, in the steam generating heat pump a SPHE is used as condenser. This particular type of heat exchanger is a combination of a shell and tube and a plate heat exchanger [12]. In this heat exchanger arrangement, the rounded corrugated plate pack is surrounded by a cylindrical shell filled with the secondary fluid as it is shown in Fig. 2. The plate pack is welded so that the primary and secondary fluid streams flowing through the channels do not come into contact. [12–14] The welded construction has the advantage that significantly higher operating temperatures and pressure levels are possible [13-14]. However, the disadvantage is the limited accessibility which makes cleaning more difficult [14].

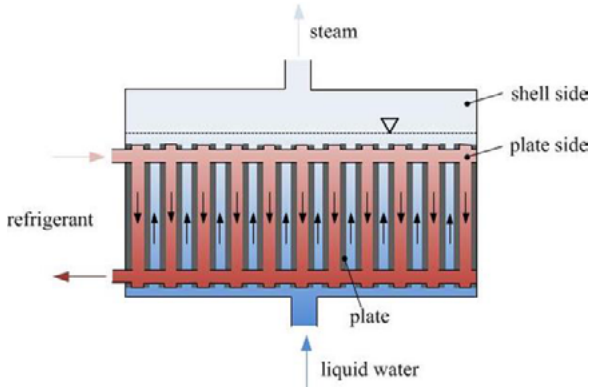

Fig. 2. Schematic representation of the modelled plate-and-shell heat exchanger

In the steam generating heat pump the steam is produced with the SPHE, therefore the shell side of the heat exchanger contains a two-phase fluid of liquid water and steam. The condensing refrigerant is located at the plate side (see Fig. 2). The following assumptions for modelling the SPHE were made:

- Heat exchange between the refrigerant and the water was entirely done via the plates
- Only the vertical flow of the refrigerant between the plates was considered
- In each refrigerant channel the same mass flow with the same temperature enters
- In each refrigerant channel the same mass flow with the same temperature exits
- Thermodynamic equilibrium between the two water phases on the shell side
- Plates are not contact with the steam phase

The length of the plate pack l, which is equal to the length of the cylindrical shell was calculated as shown in equation (1), where the number of plates n, the plate thickness s and the pattern amplitude a are needed.

$$l = (n-1) \cdot 2a + n \cdot s \tag{1}$$

The heat transfer area A between water and refrigerant can be calculate with equation (2).

$$A = (n-2)\frac{d^2}{4}\pi \cdot \Phi \tag{2}$$

The calculation of the area extension factor Φ (equation (3)), which occurs in equation (2), was done as it is presented in the VDI Heat Atlas [15]. The area extension factor describes the ratio between the wavy plate surface and the plane surface projection. For the calculation a sinusoidal corrugation of the plates was assumed. For the calculation of the area extension factor the wave number X is needed, which depends on the plate amplitude and the wavelength Λ_P (equation (4)).

$$\Phi = \frac{1}{6}\left(1 + \sqrt{1+X^2} + 4\sqrt{1+\frac{X^2}{2}}\right) \tag{3}$$

$$X = \frac{2\pi a}{\Lambda_P} \tag{4}$$

In Fig. 2 horizontal feedthroughs of the refrigerant, which are arranged at the plate side of the SHPE, are shown, which reduce the surface area. This reduction is neglected in equation (2). The shell side contains a two-phase fluid of liquid water and steam. The incoming mass flow of liquid water $\dot{m}_{in}$ enters the liquid water

volume and the outgoing steam mass flow $\dot{m}_{out}$ exits the steam volume. A thermodynamic equilibrium between the two phases is assumed. Therefore, only one energy and mass balance equation according to equation (5) and equation (6) must be fulfilled. Both phases on the shell side have the same pressure and are connected by an evaporating mass and energy flow. The evaporating mass flow has the specific enthalpy of dry saturated steam.

$$\frac{dm}{dt} = \dot{m}_{in} + \dot{m}_{out} \tag{5}$$

$$m\frac{dh}{dt} = \dot{m}_{in}(h_{in} - h) + \dot{m}_{out}(h_{out} - h) + \dot{Q} + V\frac{dp}{dt} \tag{6}$$

2.2. Plate heat exchanger model

For modeling the internal heat exchanger and the evaporator, the standard plate heat exchanger model from TIL-Library was used. This model is based on the geometry of the heat exchanger described by the number of plates, length and width of the plate and other properties, and two heat transferring fluids. In addition to that, the heat transfer model and pressure drop model can be chosen for both heat transferring fluids separately. Different correlations to describe the heat transfer and the pressure drop are available. In order to describe the heat conduction mechanism within the plate, it can be chosen as a constant heat resistance value or the heat conduction is calculated based on the given plate geometry and material. In this work the geometry based method was used.

2.3. Compressor and expansion valve model

In order to reduce the complexity of the steam generating heat pump model, the compressor was modelled based on isentropic and volumetric efficiency instead of using a physical approach as in the positive displacement compressor model from the TIL-Library. Therefore, the efficiencies are given as a function of pressure ratio. Furthermore, an electrical efficiency must be defined in the model. The pressure difference between discharge and suction side are given by the evaporator and the condenser model. Therefore, the electric power is calculated in the compressor model with a given swept volume and the actual efficiencies.

For the expansion valve an orifice valve component based on the equation of Bernoulli from the TIL-Library was used. An effective flow area of the valve must be given in this component.

3. Numerical simulations

The aim of the investigation was to assess the suitability of different refrigerants for three different steam pressures provided by the steam generating heat pump. Table 1 presents the properties of the considered refrigerants in terms of critical temperature, critical pressure, global warming potential (GWP), ozone depletion potential (ODP) and boiling point at nominal pressure (NBP).

The refrigerants listed in Table 1 are not all suitable for each studied steam pressure. Therefore, Fig. 3 illustrates the estimated possible steam temperatures for each of the selected refrigerants. Moreover, the saturation temperature for each studied pressure is shown by the vertical dashed lines. The diagram starts at 100°C, because this is equal to the saturation temperature for steam at atmospheric pressure. Only subcritical processes are considered in this work, therefore the upper limit is defined based on the critical temperature of the refrigerant and the assumption of a minimum temperature difference between refrigerant and steam temperature of 10 K. R601, R601a and R1336mzz(Z) are suitable for all steam pressures. R1233zd(E) and R1224yd(Z) are suitable for 2 and 4 bar_a steam. R600, R1234ze(Z) and R600a can only be used for 2 bar_a steam.

Table 1. Properties of the used refrigerants

Refrigerant	Critical temperature, °C	Critical pressure, bara	GWP	ODP	NBP °C	Reference
R601	196.6	33.7	5	0	36.1	[16]
R601a	187.3	33.8	5	0	27.9	[17-18]
R1336mzz(Z)	171.3	29	2	0	33.4	[16]
R1233zd(E)	166.5	36.2	1	0.00034	18	[16]
R1224yd(Z)	155.5	33.3	<1	0.00012	14	[16]
R600	152	38	4	0	-0.5	[16]
R1234ZE(Z)	150.1	35.3	<1	0	9.8	[16]
R600a	134.7	36.3	3	0	-11.8	[16]

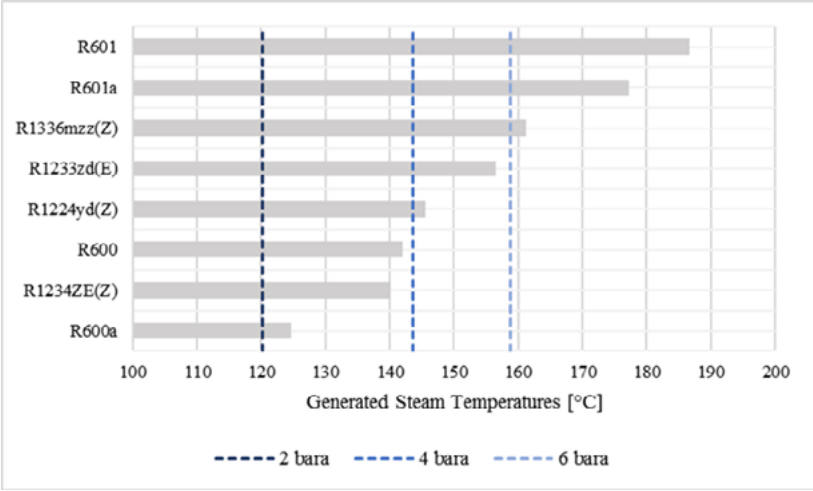

Fig. 3. Possible generated steam temperatures for the used refrigerants

3.1. Boundary conditions and control strategy

For all refrigerants and steam pressures the same model settings were used for geometry, heat transfer coefficients, liquid feed water temperature (85°C), heat source temperature (85°C) and generated steam mass flow (200kgh^{-1}). Only the heat transfer area of the internal heat exchanger has been adapted to achieve a superheating of approximately 15 K after the compressor, which is exemplarily shown in the log(p), h-diagram of R601 in Fig. 4.

Moreover, the mass flow of the source fluid was controlled in such a way that the heat source will be cooled down by 5 K in the evaporator, under the restriction of a heat source mass flow higher than 0.4 t/h. The expansion valve is regulated so that saturated vapour is present at the outlet of the evaporator. The compressor displacement is controlled according to the desired steam pressure at the outlet of the condenser, it is equal to the pressure on the shell side of the SPHE. The liquid feed water mass flow is set to a constant value for the filling level in the SPHE. The liquid filling level is the ratio between the liquid water volume and the total shell side volume of the SPHE. It is assumed that the plate pack of the SPHE is only in contact with the liquid water phase for the chosen liquid filling level. All the control mechanisms explained before are realized as continuous control with PI controllers from the TIL-Library.

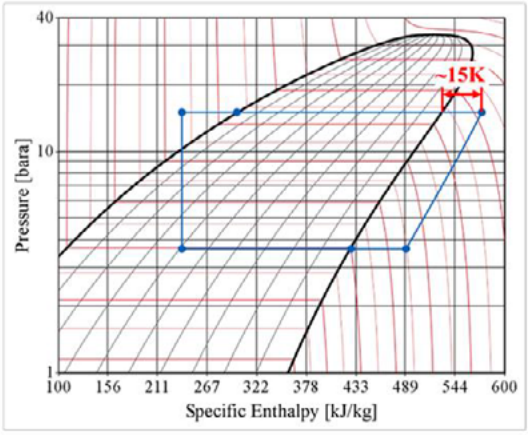

Fig. 4. Log(p), h diagram of R601 and refrigeration cycle for 4 bara generated steam pressure

3.2. Results

The different refrigerants are compared in terms of COP and compressor displacement, the corresponding results are shown in Fig. 5 and Fig. 6. The COP is calculated as it is presented in equation (9), where the heating capacity $\dot{Q}_H$ and the electrical power of the compressor P_{el} are needed.

$$COP = \frac{\dot{Q}_H}{P_{el}} \tag{9}$$

If 2 bar_a steam is produced, the COP is in the range of 3.26 and 4.3. For a steam pressure of 4 bar_a the COP is in the range of 2.28 and 2.89. A COP in the range of 1.93 and 2.29 is reached for a steam pressure of 6 bar_a. R601 has the highest critical temperature and provides the highest COP for all steam pressures (see Fig. 5).

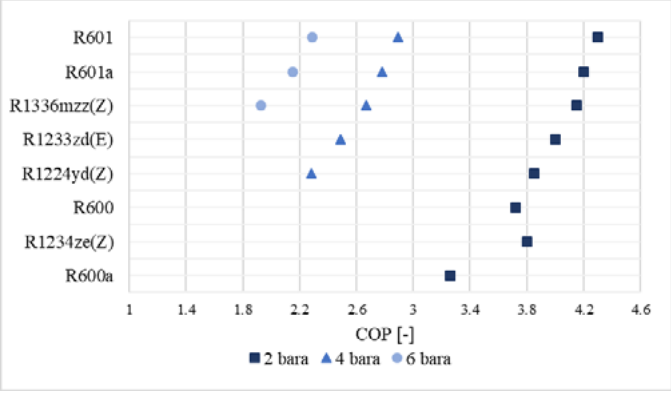

Fig. 5. COP for different refrigerants and steam pressures

The choice of refrigerant influences the COP to large extent. For example, using R1233zd(E) instead of R1224yd(Z) for a steam pressure of 4 bar_a results in an increase in COP of 9%. Comparing R600a and R601 for the production of 2 bar_a steam, the difference in COP amounts to about 24%. These differences can hardly be overcome only by adjusting the design of the refrigeration cycle.

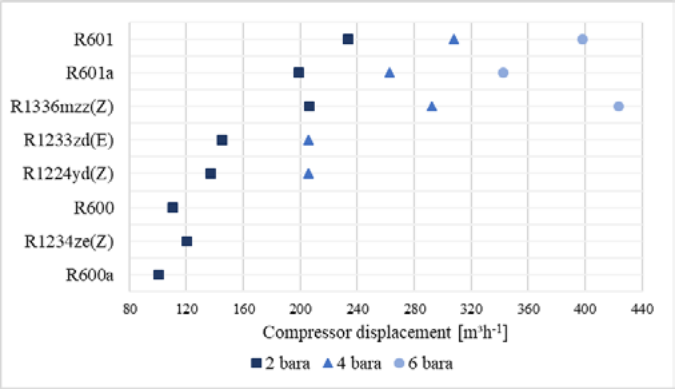

Fig. 6. Compressor displacement for different refrigerants and stem pressures

Furthermore, the results in terms of compressor displacement (Fig. 6) shows that R601 has the highest compressor displacement for all steam pressures except at a steam pressure of 6 bar_a. For this steam pressure the compressor displacement of R1336mzz(Z) is higher than for R601. In Fig. 5 it can be seen that the COP significantly decreases for higher steam pressures and the compressor displacement increases more or less with increasing steam pressure as it can be seen in Fig. 6.

Generally, it is easy to see that the choice of refrigerant is a trade-off between COP and compressor displacement, which leads to larger compressors. For example, for a steam pressure of 2 bar_a the COP of R1233zd(E) is 7% smaller than the COP of R601, but the compressor displacement of R1233zd(E) is 38% smaller than the compressor displacement of R601. This leads to a significant smaller compressor, where the COP is not decreasing that significantly. For the steam pressure of 6 bar_a R1336mzz(Z) shows the lowest COP but the highest compressor displacement.

In Fig. 7 the condensation enthalpy as a function of suction gas density for a steam pressure of 2 bar_a and all tested refrigerants are presented. The condensation enthalpy is equal to the width of the two-phase area in loq(p),h-diagram at condensation pressure. As it can be seen, R601 and R601a have the highest condensation enthalpy but also the lowest suction gas density. The high COP of R601 can among others be explained by the high condensation enthalpy. For R600 and R1336mzz(Z) the suction gas density is similar, but the condensation enthalpy of R600 is significantly higher than that of R1336mzz(Z). The suction gas densities of R600a and R1233zd(E) and the condensation enthalpies are very similar to each other. Fig. 7 illustrates the differences in material properties of the refrigerants, that have an important impact on the performance in a heat pump.

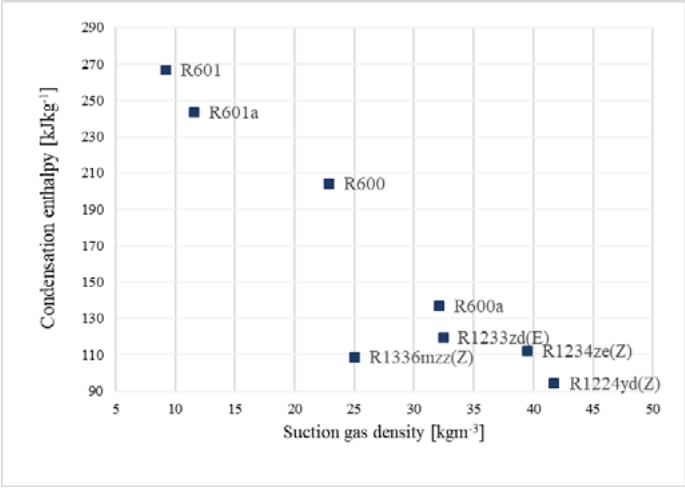

Fig. 7. Condensation enthalpy as a function of suction gas density for all investigated refrigerants and a steam pressure of 2 bar_a

4. Conclusion

In this work a model for a steam generating heat pump is presented. Simulations are an important tool for the design of heat pump systems and help to optimize the refrigeration cycle in an efficient way. This model was used for studying the suitability of different refrigerants for different generated steam pressures in a specified steam generating heat pump. The investigation has proven that the model is well suited to design the steam generating heat pump for different applications or requirements.

Furthermore, the simulation results show for the different preselected refrigerants and steam pressures, a range of 1.93-4.3 in terms of COP and a range of 101-424 m^3h^{-1} in terms of compressor displacement. R601 has the highest COP of 4.3, 2.89 and 2.29 for the three chosen steam pressures of 2 bar_a, 4 bar_a and 6 bar_a. This refrigerant shows also the highest compressor displacement for a steam pressure of 2 bar_a and 4 bar_a, which results in the largest required compressor volume. The choice of refrigerant is a trade-off between COP and compressor displacement. The choice of refrigerant also has an important influence on both investment and operation cost. The COP mainly determines the operation costs, the compressor displacement is an indicator of the size of the heat pump and therefore impacts on the investment costs. However, when selecting the refrigerant for a real implementation, attention must be paid to the fact that market-ready components are not available for all refrigerants. For example, R1336mzz(Z) and R600 are refrigerants which are already used in heat pump cycles and therefore all components are available. In contrast to R600, which is only suitable for a steam pressure of 2 bar_a, R1336mzz(Z) is suitable for all three investigated steam pressures. Therefore, in the project BAMBOO R1336mzz(Z) is used in the refrigeration cycle to generate steam at 5 bar_a. In the next step a prototype will be realized in the project BAMBOO which will be tested in a laboratory environment as well as in a real industrial process. Moreover, different heat pump cycle configurations and further operating conditions will be investigated in future investigations.

As an outlook for future technological developments, it should not go unmentioned that further industrial users can be gained by expanding the range of available industrial heat pumps. The investment decisions of industrial users are ultimately influenced by economic aspects. Therefore, optimized design of the industrial heat pumps and the use of standard components to lower the costs are important. Current technical limitations, such as maximum possible steam pressures, should be overcome by further efforts.

Abstract

In the case of building retrofitting, the integration of ground source systems with heating/cooling solutions and heat pumps to achieve maximum performance is a great challenge that demands a solution. In order to find a suitable solution for a given building retrofit scenario, two different heat pump configurations are numerically analysed and compared to each other in terms of heating capacity and coefficient of performance (COP). As working fluid, the Low Global Warming Potential (GWP) refrigerant R1234ze(E) with a GWP smaller than 10 will be used to meet with the current F-Gas regulation by reducing the GWP of fluorinated refrigerants. One favourable heat pump configuration is a twin-cycle system. Alternatively, a single-stage configuration which uses a significantly larger condenser for enhanced subcooling in the refrigeration circuit is also analysed. Both systems allow a more efficient operation compared to state-of-the-art heat pump systems in the case of building retrofitting. In that way, the COP increase in relation to a standard heat pump cycle with typical subcooling is in the range of 10-15% depending on the operating point.

Keywords: Geothermal systems; building retrofitting; ground source heat pumps; twin-cycle configuration; enhanced subcooling

1. Introduction

In Europe, the building sector is responsible for 40 % of the total energy consumption and represents about a third of Europe's CO_2 emissions. This is a huge socioeconomic and environmental problem, more if we consider that almost half of the EU buildings have boilers installed before 1992, with an efficiency rate of below 60 % [1]. Although energy renovation of existing buildings could help to achieve the EU climate and energy tar-gets, the refurbishment rate is currently below 1 % and renewables are not widely used in the building sector. Within the H2020 project GEOFIT, easy-to-install, economical and enhanced geothermal systems for energy efficient building retrofitting are going to be implemented and demonstrated at five dedicated pilot sites across Europe - a historical building (ITA), a primary school (ESP), an indoor swimming pool (IRL), an office building (FRA) and a single-family house (IRL).

2. Low GWP refrigerants

Component providers and heat pump manufacturers are currently facing new challenges with the so-called F-Gas regulation, which provides for a gradual reduction in emissions of fluorinated greenhouse gases by 2030. Since beginning of 2018, the number of refrigerants that can still be used in the medium term has been drastically reduced, which has led to a significant increase in the price of fluorinated refrigerants.

The GEOFIT heat pump concept is generally foreseen for retrofitting the heating system of existing buildings. The working medium or refrigerant has a major influence on the area of application and the desired

temperature levels. The prohibition of chlorofluorocarbon (CFCs) and hydrochlorofluorocarbons (HCFCs) has severely restricted the availability of suitable working media. According to the EU Regulation No. 517/2014 on F-gas reduction (which came into force throughout the EU on 1.1.2015) [2] to reduce greenhouse gas emissions, a drastic multi-stage phase-down of HFCs (hydrofluorocarbons) applies until 2030, with the first significant stage already coming into force at the beginning of 2018. This will exacerbate the shortage of available working media and refrigerants.

For this reason, more and more companies and consumers are looking for alternatives. One option is based on natural refrigerants. Natural refrigerants include hydrocarbons, CO_2, ammonia and water. The most common hydrocarbons are isobutane and propane. However, propane is highly flammable and can form an ignitable and explosive gas mixture with the ambient air. A third generation of synthetic refrigerants, hydrofluoroolefin (HFOs), has recently launched on the market. A candidate would be the low-GWP refrigerant R1234ze(E) with a GWP smaller than 10. However, the core component in a heat pump system – the compressor – lacks approval from the manufacturers for these new refrigerants, e.g. due to technological barriers regarding the long term long-term stability of the seals.

3. Heat pump systems – the different technologies

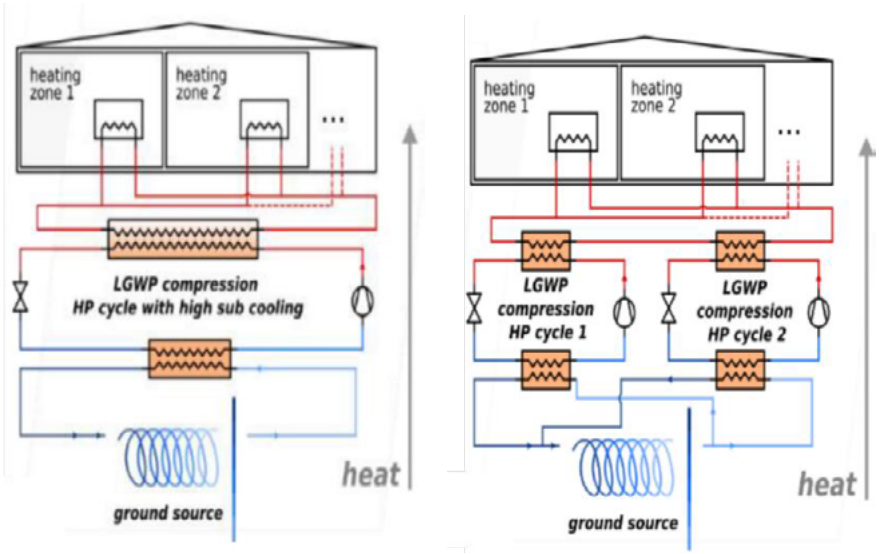
A technology comparison in Table 1 provides an excerpt and overview of the state of the art for the relevant heat pump technologies, where brine/water and air/water heat pumps are compared with each other. The advantages and disadvantages of brine/water or air/water systems as well as the requirements of the various heat sources are shown. The annual performance factor (SCOP) is the benchmark for the efficiency of a heat pump system over a whole year. It indicates how much heating energy is delivered by the heat pump in relation to the electrical energy used over the course of a whole year. The so-called COP indicates a snapshot of the ratio of heating power to electrical power used. Modern heat pumps achieve COP values of 4 to 5 under standardized test conditions for supply temperature in the range of 35 °C for space heating. For hot water production the COP drops down to values below 3 at a temperature level of 55 °C.

Table 1: Comparison of the relevant technologies and state of the art of ground source and air-based heat pump systems in Austria, adapted from [3].

Heat source	Boreholes	Ambient air
General requirements	• Suitable ground • Required depth: 25 m/kW	• Sufficient distance between supply and exhaust air duct • Split-device: Ensure sound insulation, frost-proof condensate drain
Space requirements (outside the technical room)	• Borehole distance: approx. 10 m • 2.5 m Distance to property boundary • 1.5 m distance to supply and disposal lines (sewer, water, etc.)	• Split device: manufacturer-specific • Indoor installation: none
SCOP	3.5 – 5	2.5 – 3.5
Advantages/Disadvantages	+ high, stable source temperature throughout the year, high efficiency, low space requirement - higher investment costs	+ Low additional installation effort - strongly dependent on temperature level and amount of exhaust air - Sound emissions

The dimensioning of the heat pump in the case of retrofitting depends, among other things, on the previous oil or gas consumption. These values can be used to determine the effective heating energy required. The flow temperature plays an important role in the operation of the heat pump. For well renovated apartments with underfloor heating 35 °C is sufficient. If the heat transfer area of existing radiators is large enough, the temperature should be 50 °C, and in the case of an older building standard 65 °C can be regarded as a guide value. However, the efficiency of the heat pump deteriorates with increasing flow temperature. At this point, the GEOFIT solution comes in.

4. Description of the heat pump system



The GEOFIT heat pump system uses a low GWP refrigerant R1234ze(E) with a GWP<10 instead of state-of-the art refrigerants like R134a which has for example a GWP of 1430. The system makes uses of cost effective heat exchangers (e.g. heat exchangers made of Aluminum) that due to the lower raw material costs

of Aluminum compared to Copper (about of a third), represent a potential to lower the costs of the heat pumps without performance loss. Since, high temperature differences can be required for retrofit heating systems; we investigate two alternatives to provide them within the project. (1) One solution is based on using two heat pumps with different condensation temperatures but with the same evaporation temperature (see Figure 1 right). (2) The other solution uses a significantly larger condenser compared to a state-of-the art heat pump condenser to make use increase the sensible subcooling of the refrigerant (see Figure 1 left).

The general idea behind the first mentioned configuration is to split up a single refrigeration cycle into two cycles. In that way, one of the two refrigerant cycles does need not to overcome the entire temperature lift. Hydraulically, the two condensers are connected in series, whereas the two evaporators are connected in parallel. Assuming a similar compressor scale on both cycles, roughly half of the total heating capacity can be delivered at a higher COP than the other. This configuration is referred as "Twin-cycle" heat pump configuration depicted in Figure 4. The second configuration is a "Single-Stage" heat pump configuration. In contrary to the Single-Stage heat pump configuration, the Twin-cycle heat pump configuration shows considerable advantages regarding safety, start-up time and legal requirements, as the refrigerant charge for each cycle is only half compared to the Single-Stage configuration. Those advantages and disadvantages are summarized in Table 2.

Table 2: Advantages and disadvantages of the considered heat pump configurations.

Configuration	Advantages	Disadvantages
Single-Stage	• Simplest refrigeration cycle → Low invest costs • Good overall performance in terms of COP and energy cost savings from very low to medium temperature lifts	• Higher refrigerant charge per cycle • Start-up time • Legal requirements due to refrigerant charge • Lower efficiency at high temperature lifts • No part load possible without speed control
Twin-cycle	• Lower refrigerant charge per cycle • Best overall performance from very low to medium temperature lifts • Without speed control, still 50% part load possible	• More complex refrigeration cycle →Higher invest costs

Single-Stage Twin-cycle

Figure 1: GEOFIT concepts for the heat pump systems.

5. Operating modes

When talking about operation of a heat pump, its actual heating capacity in the design point[1] plays a significant role. There is a certain degree of flexibility regarding heat pump sizing. According to that, the following two operating modes will be discussed:

- Monovalent
- Bivalent

5.1 Monovalent operation

A heat pump is usually sized to at least 100% heat demand of the heating season for any given house, meaning that the heat pump should be able to entirely heat the house without electric or other back up system except under the most extreme conditions. In practice, this translates to systems being designed to a target external design temperature[2], depending where the property is located. This type of application should therefore be preferred as far as possible. Brine/water or water/water heat pumps in a state of the art building standard are usually operated monovalently. Monovalent operation of air/water heat pumps is also possible, but not always feasible.

5.2 Bivalent operation

The heat pump covers most of the heat demand on its own. At very low outside temperatures, the heat pump and the supplemental heat generator, work together. This temperature is known as the bivalent point (BP). This operating mode is used when renovating existing buildings while retaining the installed gas boiler. If the heat pump could not cover all the heat load and is also restricted to its maximum supply temperature at extreme outdoor conditions, the additional heating system will pick up the shortfall in terms of increased capacity and increased supply temperature. In the case of building retrofitting, it is usually the existing gas boiler. Figure 2 shows an overview of the different operating modes.

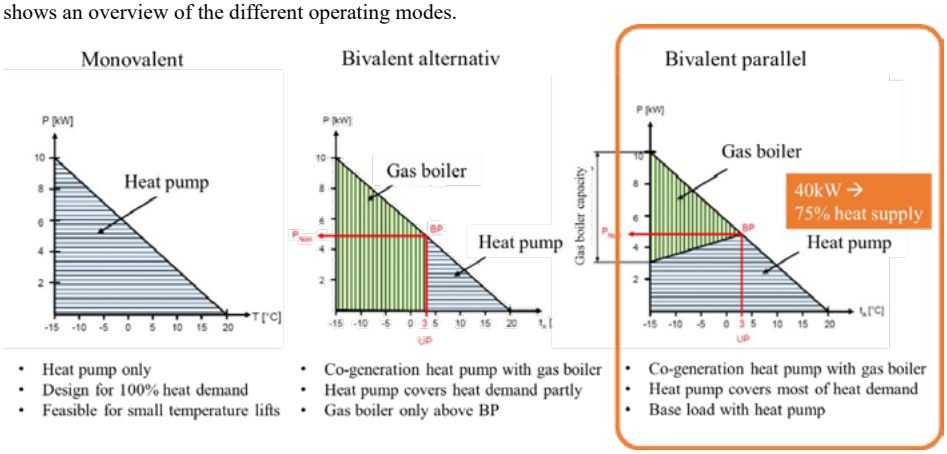


Figure 2: Heat pump operating modes. Monovalent, Bivalent alternative and Bivalent parallel. For the GEOFIT case, a heat pump with 40kW heating capacity is able to deliver 75% heat demand.

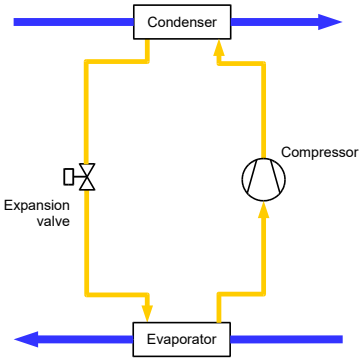
If gas boilers are already installed, the bivalent parallel is a favorable option, where the heat pump acts as base load system and the existing gas boilers are switched on below the bivalent point as discussed in [4]. With such operating control, the maximum operating hours of the heat pump can be achieved, having the most economical solution for retrofitting. However, this operating mode poses a great challenge regarding the hydraulic integration and the control of the two coupled systems in order to avoid derogating the heat pump efficiency when the gas boiler turns on. Though, the hydraulic integration is not part of this work as we address the refrigeration circuit layout assuming a correct integration and operating control.



[1] The design point for a heat pump system is usually given by the most extreme operating condition, i.e. coldest day of the year.
[2] This is the target minimum low external temperature as established according to National Building Codes or based upon statistical or historical meteorological data available for each location.

6. Simulation environment

The numerical simulations are performed in Dymola. Dymola is a commercially available simulation environment to solve actual problems written in the modelling language Modelica. It is suited for multi-domain modelling, (e.g. thermal, mechanical, electrical and hydraulic). Modelica is an equation-based object-oriented modelling language, which allows reproducing complex physical systems and solving time-dependent problems in mechanical, electrical, hydraulic, thermal, fluid and control fields, with the help of algebraic, differential and discrete equations [5].

The heat pump modelling in general takes place in the thermo-hydraulic domain. A heat pump system is built up by standard components, such as heat exchangers, compressors, expansion valves, control systems, sensors, etc. These components can be custom written or selected from either free or commercial libraries written in Modelica. Within the GEOFIT project, we use the TIL-Library [6] for the thermal component modelling as it is widely used and proven by the refrigeration industry. The specific modelling approach allows for a detailed representation of the physics and parameterization of each heat pump component from the compressor to the heat exchangers up to the entire piping of the refrigerant cycle, if necessary. Furthermore, an extensive database of refrigerants is available in TIL libraries. Figure 3, Figure 4 show the different heat pump configurations as simple schematic view and model representations in Dymola.

Schematic view of a Single-Stage cycle

Graphical view of the Modelica model in Dymola

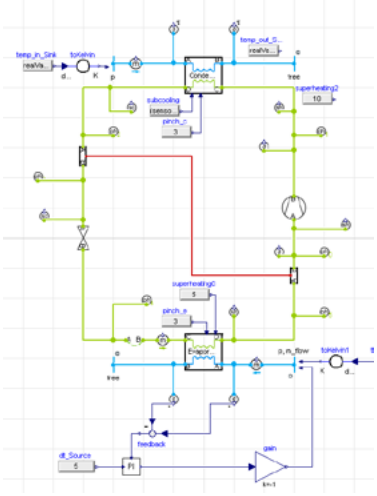


Figure 3: Schematic view (left) and Modelica model in Dymola (right) of a single-stage heat pump.

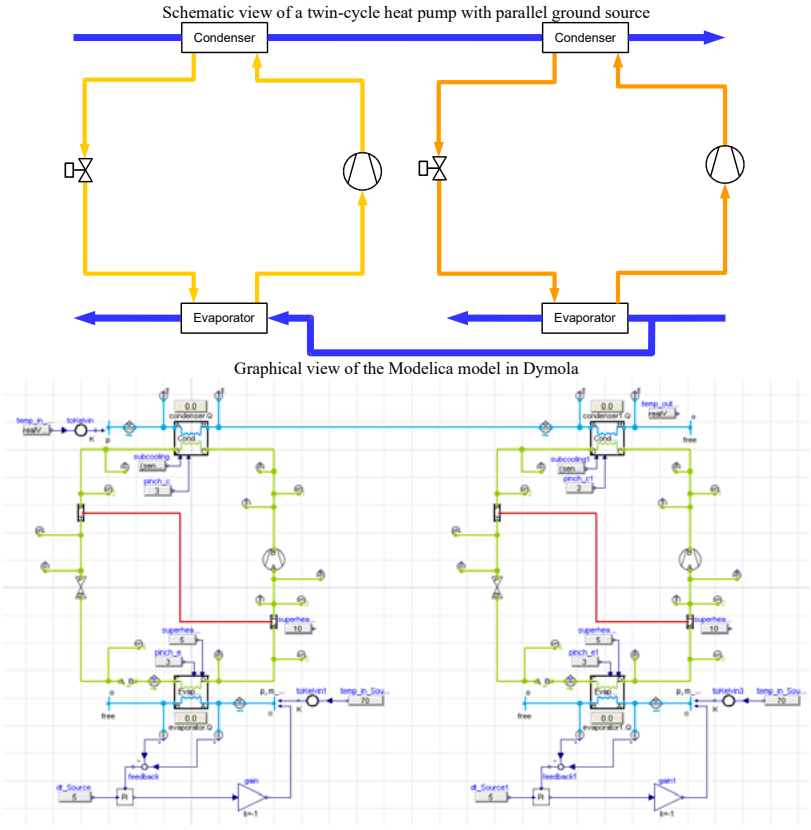

Figure 4: Schematic view (top) and Modelica model in Dymola (bottom) of a twin-cycle heat pump cycle with parallel source.

7. Methodology

The methodology for the layout and design of heat pump system is roughly depicted in Figure 5. After the implementation and model setup phase, the model parameters are set to manufacturer data. A critical role is played by the compressor characteristics, which are usually given for a standard refrigerant with high-GWP values (e.g. R134a). At present, efficiency data for low-GWP refrigerants, such as R1234ze(E) is not yet available for the chosen compressor type. The Bitzer refrigerant report states [7], that operating experiences gained from laboratory and field trials to date allow a positive performance assessment on the efficiency behavior compared to R134a. For the usual operation range, the COP is within a range of 5 %. Therefore, it is expected that simple system modifications will provide the same efficiency as with R134a. However, R1234ze(E) is sometimes called an R134a substitute, the resulting heating capacity is the range of 20 % below that of R134a. With this information and the proper heat pump configuration, we changed the refrigerant from R134a to R1234ze(E) in our models keeping the efficiency values from R134a. We are aware that an accurate quantitative assessment is not possible with this methodology but a qualitative comparison of different heat pump configurations.

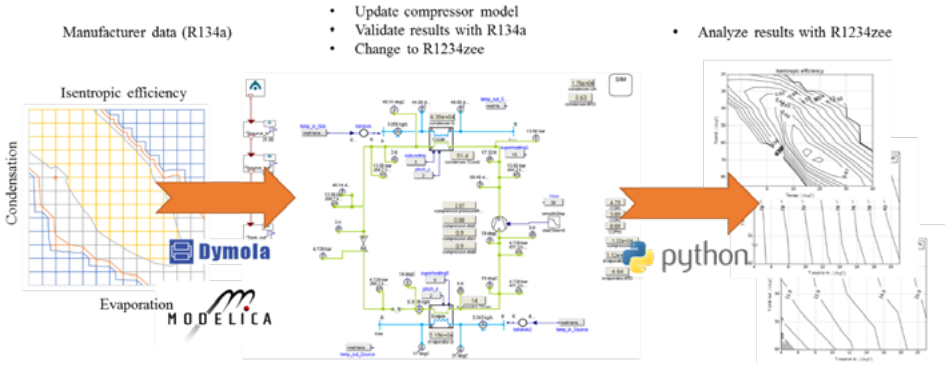

Figure 5: Methodology for the evaluation of the heat pump system.

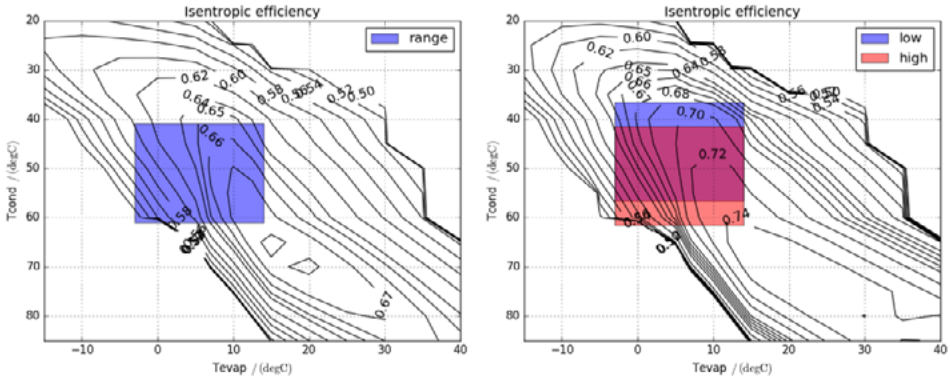
Six typical operating states were simulated and the parameters such as heating capacity of the heat pump ($\dot{Q}_{heat}$), electricity consumption of the compressor (P_{el}) and COP were used to compare to each other. Those operating states are given in the Table 3. The temperature conditions on the source and on the sink – assuming a proper control strategy and hydraulic integration for the retrofit case - are the inputs for the numerical models.

Table 3: Temperature boundary conditions for the typical reftofit case.

Operating point	T_{source_in}	T_{source_out}	T_{sink_in}	T_{sink_out}
-		degC		
1	4	2	35	40
2	4	2	45	50
3	11	7	35	40
4	11	7	45	50
5	21	17	35	40
6	21	17	45	50



In GEOFIT, the compressor type of the electrical driven heat pump system is chosen to be a scroll compressor. This specific compressor type is a positive displacement compressor. We chose to follow the efficiency-based modeling approach. In order to describe the compression cycle, the isentropic and the volumetric efficiency are prescribed. They are usually given as a function of pressure ratio and condensing or evaporating temperature. An ideal isentropic compression is complemented by different physical effects:

- pressure drop suction side
- pressure drop discharge side
- internal leakage
- re-expansion of the compressed fluid
- mechanical friction
- heat losses

The volumetric efficiency gives the relation between the geometrical mass flow and the actual mass flow over the compressor. The geometrical mass flow can be calculated with the known refrigerant properties on the suction side and the swept volume. For the specific scroll compressor in GEOFIT, the manufacturer provides efficiency curves for R134a. While the isentropic efficiency is used to calculate the discharge enthalpy of the refrigerant, the effective isentropic efficiency represents the electric power consumption of the motor. Usually, it's the effective isentropic efficiency which is experimentally identified, as the measurement of electric power is more accurate, than the measurement of the discharge temperature. However, for the sake of simplicity, both efficiencies are considered equal for the considerations in this work.

Figure 6 shows the compressor characteristics based on manufacturer data for the two heat pump configurations. The blue region for the Single Stage system (left) show the resulting operating window based on the values in Table 3 for a single compressor. For the Twin-cycle system (right), the blue region reflects the lower cycle and the red region the higher cycle. Both compressor types are from the same compressor series, but only differ in displacement. The compressor for the Single-stage system has approx. twice the displacement than one of the two compressors for the Twin-cycle system. Even though the compressors belong

to the same compressor series, when comparing the isentropic efficiencies in Figure 6, it can be seen, that the qualitative behavior is similar but the peak value for the Twin-cycle compressors is at 0.74 while for the Single-stage compressor it is at 0.67. This difference is directly affecting the resulting COP as it can be seen in the next section.

Single Stage Twin-cycle

Figure 6: Compressor characteristics for the Single-stage system (left) and the Twin-cycle system (right).

8. Results

Before comparing the two heat pump configurations, a general remark on operating a heat pump in building retrofitting. The lower the return flow temperature, the higher the efficiency of the heat pump. Together with an existing gas boiler, the interaction between those two heating elements must be even more carefully considered in order to avoid high return flow temperatures when operating in bivalent parallel mode. In GEOFIT a top-level control for the two heating systems will be implemented to ensure an energy efficient operation.

Figure 7 shows the results for the Single-stage system and Figure 8 the results for the Twin-cycle system. The contour plots with the isolines allow for a quick assessment of the characteristics at different operating points. For both systems, the heating capacity depends almost only on the source temperature. The sink temperature has a minor impact where the heating capacity slightly decreases with increasing sink temperature. Comparing the different configurations, the Twin-cycle shows the best results in terms of COP. Due to reduced temperature lift on the low cycle, less electricity is consumed by the compressors compared to the Single-Stage configuration. For both configurations, the overall heating capacity varies from roughly 42 kW down to 26 kW depending on the source temperature level with slightly higher values for the Twin-cycle configuration. The COP values are in the range of 2.2 to 5.8 for the Single-stage system and 2.5 to 6.5 for the Twin-cycle system. Therefore, the COP increase for the Twin-Cycle is approx. 5 to 15% according to the operating point, which is a significant improvement considering long term operation and energy costs. In Figure 9, the increase is depicted for all operating points.

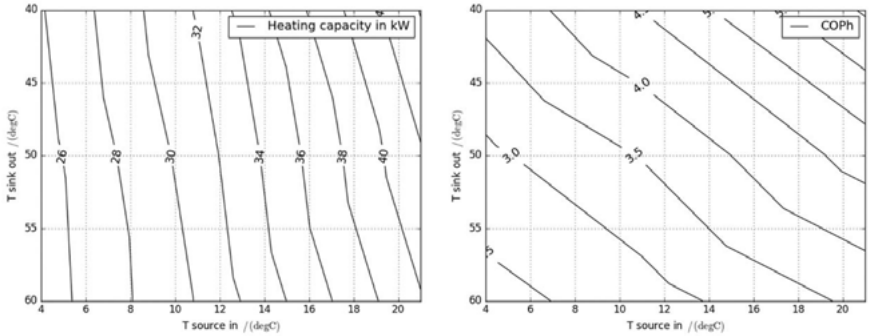


Figure 7: Results for the Single-Stage system.

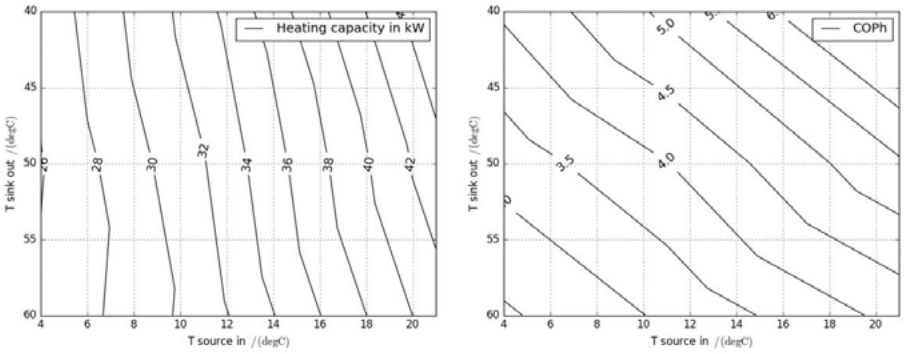

Figure 8: Results for the Twin-cycle system.

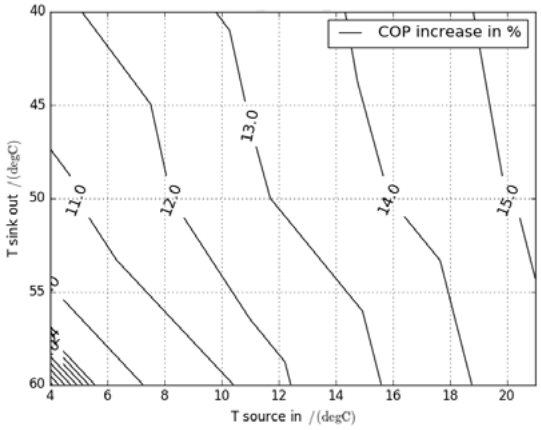

Figure 9: COP increase of the Twin-cycle system compared to a Single-stage system.

9. Conclusion

This paper presents a numerical comparison of two different heat pump configurations for a specific building retrofitting case in the framework of the H2020 project GEOFIT. The compressor characteristics were taken from manufacturer data for R134a and transferred for the use of the low-GWP refrigerant R1234ze(E). The results show a significant COP increase in the range of up to 15% for a Twin-cycle configuration compared to a Single-stage heat pump with enhanced subcooling.

The results are based on a given temperature spread on the supply side of 5K by preserving the installed radiators in the building. Increasing the heat transfer area of the heat distribution system in the building by either changing the radiators or upgrading them with a ventilation system, can lower return temperatures significantly. This has a positive effect on the heat pump efficiency by lowering the mean supply temperature between flow and return side.

In this work we outline a possible way to increase the heat pump efficiency by a twin-cycle system. There are also other ways for an improved heat pump cycle, e.g. a two-stage with EVI-injection. But all those enhancements come along with increased investment costs compared to a Single-Stage system. These additional costs need to be contrasted with the efficiency gain and is part of the future work within the GEOFIT project. In the case of building retrofitting, a parallel operation with an existing gas boiler is the most economical solution. A great challenge is the hydraulic integration and the control of the coupled systems in order to avoid derogating the heat pump efficiency when the gas boiler turns on.

A successful integration of ground source heat pumps systems in existing buildings needs an integral approach where the ground source, the heat pump and the hydraulics in the building receive equal attention. In that way it is possible to increase the commercial attractiveness of geothermal energy in combination with ground source heat pumps and therefore increase the penetration of this renewable source in building retrofitting.

Test results of a Rotation Heat Pump and further developments

Andreas Längauer[a*], Bernhard Adler[a], Christian Rakusch[a]

[a]ecop Technologies GmbH, Perfektastraße 73/Top A1, 1230 Vienna, Austria

Abstract

Strict regulations for refrigerants in terms of global warming potential (GWP) force industries and suppliers to develop new compressors, working fluids and lubrication systems. In contrast of solving these challenges, the Rotation Heat Pump (RHP) is based on a completely new principle and design which eliminate them via a fully integrated system. The compression in a RHP, which uses a nontoxic, ecologically friendly and not flammable working fluid, is based on centrifugal forces. This results in a very high compression efficiency of more than 99% and furthermore in a high coefficient of performance (COP). The process itself relies on a Joule cycle where the heat transfer is sensible and the working fluid is always gaseous. As a consequence, the process is not depending on the critical point of the fluid. A Rotation Heat Pump K7, developed during the last few years, was installed in January 2019 at the customers site and performance data has been collected since then. These results will be shown additionally to further examples of tests which have been done at a test rig. The advantage of flexibility in terms of temperature as well as the performance (COP) are shown in different charts. The next step of engineering is the development of a RHP-M2, which will provide a maximal thermal power at the sink of 2 MW. Additionally, some new arrangements will allow a temperature spread between sink and source of about 100 K. Another new feature will be special heat exchangers which will enable advanced operation modes. A further possibility for a new design is the downscaling to a 10 kW RHP, which would be possible to use in a standard household.

Keywords: Rotation Heat Pump, High Temperature, COP, Energy Efficiency

1. Introduction

Reducing CO_2-Emissions has to be the main target to keep the global warming in a bearable range for mankind to save biodiversity and human well-being. Many different aspects have to be accounted, processes have to be optimized and new technologies need to be applied to use renewable energy. Knowing that heat takes a major part of emitting CO_2, it is essential that heat pumps find their way not only further to space heating but also to industries and district heating. Additionally, it is necessary that heat pumps are using refrigerants with a very low Global Warming Potential (GWP) to ensure an environmentally friendly implementation. During the last years a lot of engineering has led to different low-GWP working fluids which may have some kind of disadvantage in terms of flammability and toxicity. In contrast to those fluids a Rotation Heat Pump (RHP) is using a mixture of noble gases, which GWP is zero and is neither flammable nor toxic. This is possible due to the used counterclockwise thermodynamic cycle, based on the Joule process. It means that the working fluid is always gaseous and is not condensing or evaporating in the heat exchangers. The big challenge to ensure an efficient system is, as for commercial heat pumps as well, the efficiency of the compression. In a RHP this challenge has been overcome by using centrifugal forces in a rotating domain to compress the gas. A short introduction how this compression has been realized and how it works will be given in the next section, details about that can also be found in [1], [2], [3] and [4].

This paper deals mainly with measured results, gained at a test rig as well as in a final application, to demonstrate the function and advantages of this principle.

2. Function and Design

A Rotation Heat Pump is based on two main components which are the rotor and the housing. The rotor is the essential part for the realization of the thermodynamic cycle because it provides through the rotation the compression and expansion of the working fluid. Also, the heat exchangers are mounted on the rotor which means that they are in motion during the process. The housing and additional components ensure the electrical supply, encapsulate the rotor and transfer the process fluids of sink and source into the rotating domain. In Figure 1 the design of a RHP is shown, on the left hand side the entire machine with the upper case removed and on the right hand side a pair of heat exchangers and the pipe system.

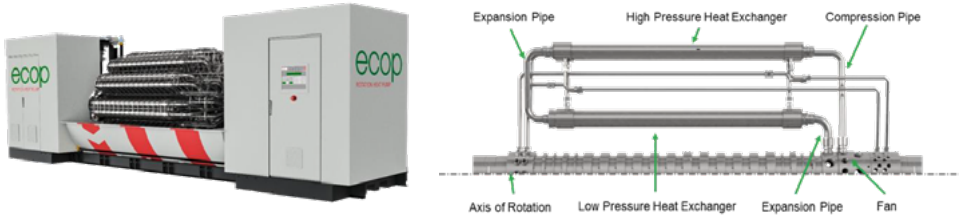

Figure 1: Design of a Rotation Heat Pump

In addition to the mechanical design, the following Figure 2 shows the Temperature-Entropy diagram (left) corresponding to the design and presents the thermodynamic cycle of the working fluid in the rotor (right) based on CFD (Computational Fluid Dynamics) calculations. The shown temperatures are just an example, the process can be shifted to different temperature levels easily, while the Coefficient of Performance (COP) remains almost constant. The temperature increase (5.2 to 2) is caused by the compression based on the centrifugal forces and vice versa the expansion (3 to 4 and 5 to 5.1). Heat is transferred from the working fluid to the sink (2 to 3) and from the source to the working fluid (4 to 5). A fan ensures the mass flow in the system and provides the exergy to the process via an electrical motor. The rotational speed of the fan can be controlled independently of the speed of the main rotor by using a separate frequency converter for this engine. The fan basically acts like a commercial compressor but consists of special designed blades. More details about the function and design are represented in [2] and [4].

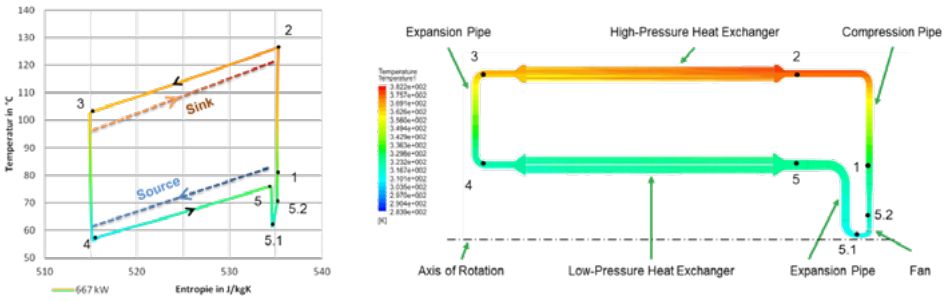

Figure 2: Joule cycle (left) and corresponding design (right) of a Rotation Heat Pump

2.1. Calculation of the Coefficient of Performance (COP) for a RHP

A common used, representative parameter for characterizing the efficiency of a heat pump is the Coefficient of Performance (COP). Also, for the Rotation Heat Pump the COP can be calculated by using the thermal power at the output and the electrical power consumption. The ratio of those values represents how many times thermal power is provided at the output (sink) compared to the input of electrical power. The electrical power consumption of a RHP is mainly caused by the engines of the fan and the rotor. Since they are measured

separately, a COP of the thermodynamic process itself can be calculated as well when considering only the power of the fan. The used expression for calculating the COP is

$$COP = \frac{\dot{Q}_{sink}}{P_{electric}} \quad (1)$$

where $\dot{Q}_{sink}$ is the thermal power at the sink and $P_{electric}$ is the electrical power consumption, all given in W. If only the fan is used for the power consumption and calculation the efficiency is named $COP_{Process}$.

3. Testing

To test the Rotation Heat Pump two different ways are presented, first the combination with a test rig to show short term tests and second the results of an operation period of three days in the final application at the customer site. The data of the test rig arrangement should give an initial impression about how the system responses to planned changes while the second data set points out possible boundary conditions in the field application and how a RHP can deal with them.

3.1. Test rig

As already presented in [5], the test rig and Rotation Heat Pump are installed like shown in Figure 3 for testing and evaluating data. Different sensors to measure mass flow, temperature, pressure, rotation speed, electrical power and so on, are installed and values are stored on a flash device. Since for the evaluation and testing of specific design points it was not necessary to run the system for long time at constant parameters. Those tests are therefore considered as short-term tests in contrast to the following section about the installation at the customer site where data of the RHP over 72 hours is shown.

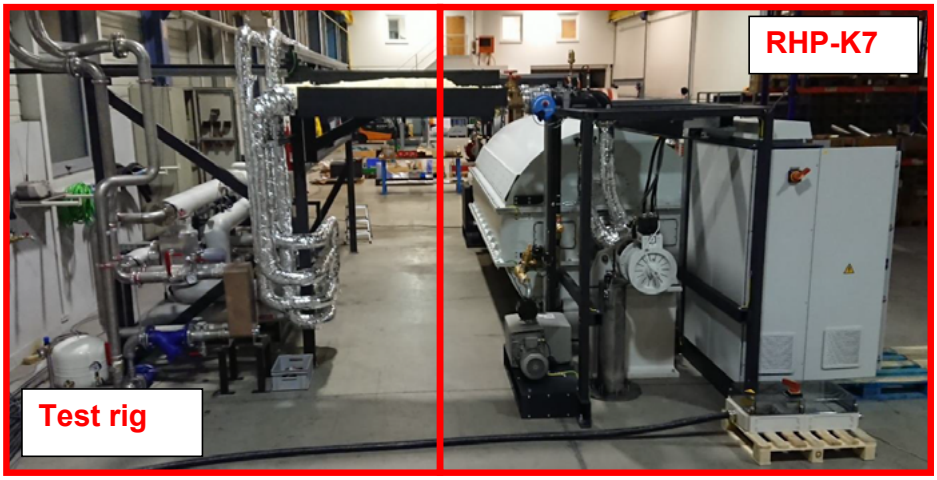

Figure 3: Overview test rig and RHP-K7 [5]

The test setup shown in Figure 3 can be represented as a scheme including sensors and hydraulic connections as well. The scheme (Figure 4) also includes all heat exchangers and pumps which are used for heat recovering/transferring and providing fluid flow. To adjust temperatures and thermal power of the system to a certain design point, the valves V1 and V2 can be controlled via remote control or the touch panel. The positions of the mentioned sensors are shown as well as the engines. For evaluating the electrical power consumption, the frequency converters have been used. Details about the test rig can be found in [5].

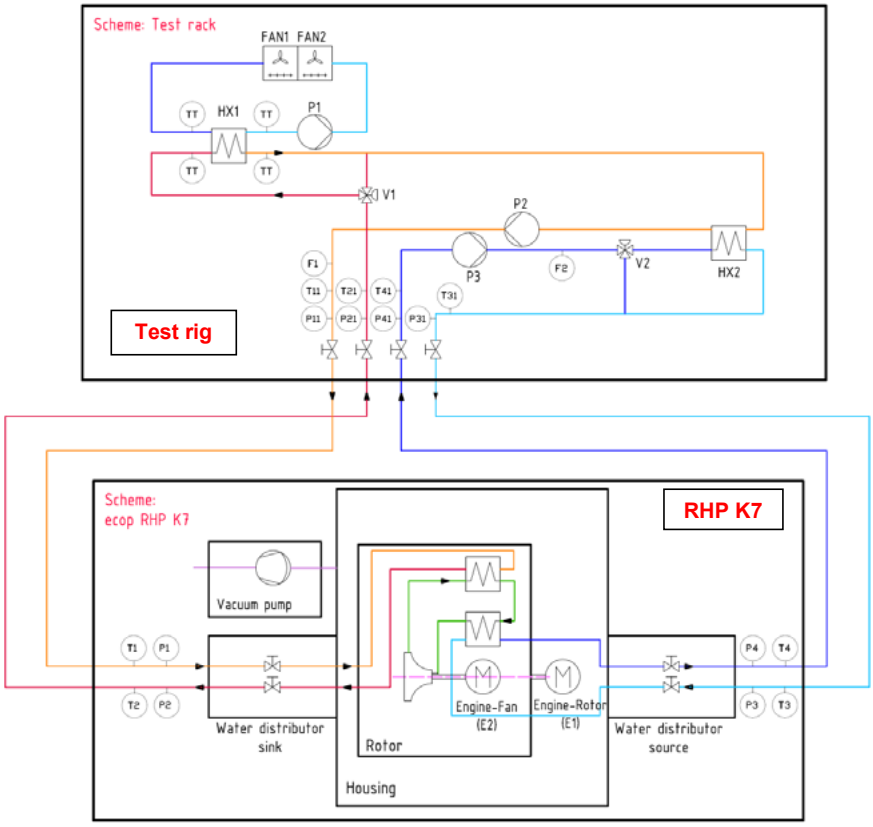

Figure 4: Simplified scheme of the test rig and RHP-K7

The collected measurement data was used to evaluate the COP corresponding to the temperature of sink and source and the rotational speed. The temporal development of temperatures, speed, mass flow, power and COP are stated in the following diagrams.

The first arrangement of measurement curves shows the response of the system to slow changes in temperature, see Figure 5 and Figure 6. Due to the fact, that the temperature spread between sink and source is constant as well as the mass flow and the rotational speed, the COP is remaining almost constant. The temperature level as displayed is changing to some of 15K at sink and source which is representative for changing conditions due to a day-night cycle for example. Further information about the dependence of the COP to the thermal power and the temperature lift will be discussed later with respect to the results of the field application. The results of the test rig demonstrate mainly the flexibility in terms of temperature level and the possibility to reach high temperatures.

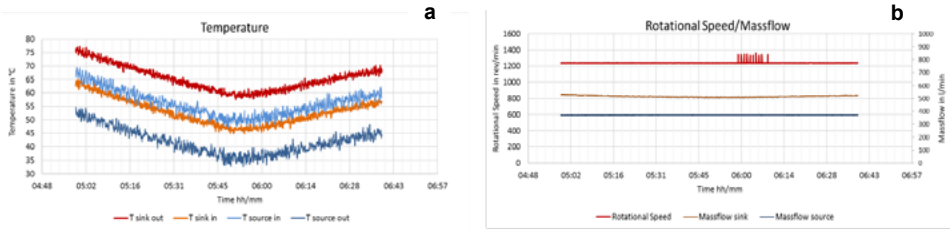

Figure 5: Temperature of sink and source (a), mass flow and rotational speed (b)

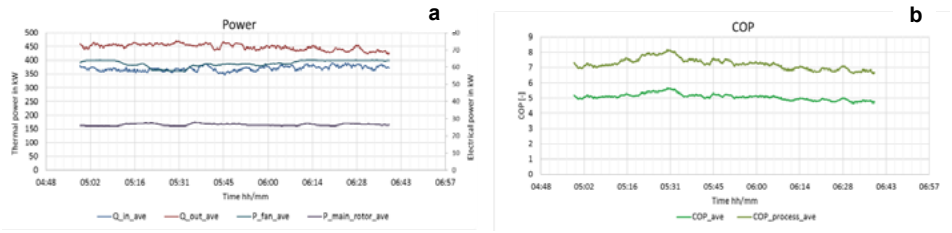

Figure 6: Thermal and electrical power (a), COP (b)

To demonstrate the possibility of switching from a lower temperature level to a higher one, the following figures show the temperature drift from around 65°C to about 90°C output temperature at the sink. The spread between sink and source is again kept constant and so the COP is at an almost constant level. The reason for differing to the constant operation mode (04:19h to 05:02h, Figure 7 and Figure 8) is caused by the fact, that the system is not balanced in terms of energy. To increase the temperature level more energy input is necessary than at the output appears. Thus, the power at the output is less than at constant conditions and also the COP is affected. However, when reaching a steady state, the power and COP are at the same level as before the dynamic increase. Figure 7 and Figure 8 show the described behavior.

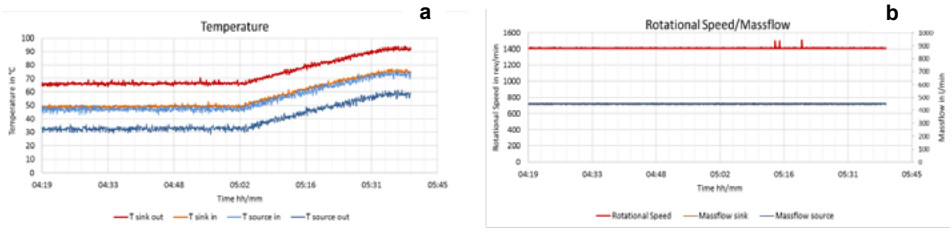

Figure 7: Temperature of sink and source (a), mass flow and rotational speed (b)

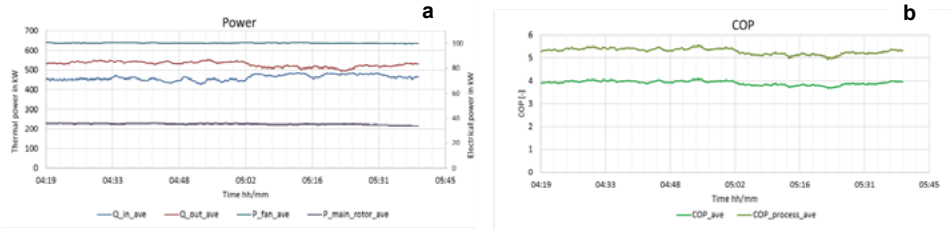

Figure 8: Thermal and electrical power (a), COP (b)

Further data of tests from the test rig are mentioned in [5] where some representative test cases have been analysed additionally.

3.2. Field application

After the previous described tests in combination with a test rig, the RHP has been installed at the customers site where further tests have been performed. Of course, it is not possible to provide boundary conditions as flexible as at the test rig but it is also essential to validate the function in field applications. In the following Figure 9 the field installation of the first RHP-K7 is shown. On the left-hand side the control cabinet for power supply including frequency converters is represented while on the right-hand side the control cabinet for the programmable logic controller is installed. The closed main housing including the rotor is located in between. The data of the following paragraphs show measured values of three consecutive days.

Figure 9: RHP-K7, field installation

Results in terms of measured data of the field installation show the daily variation of temperatures and also, since the mass flow was kept almost constant, the variation of power and COP. This is based on the fact, that the RHP has not been run in optimization mode. To ensure a maximum COP the mass flow as well as the rotational speed can be dynamically adjusted by a programmable logic controller. This feature has not been used during the measurement period and so the COP is sometimes dropping to a lower level and also rising to a higher one. Another fact which should be mentioned, is the general operation at an off-design point. The designated thermal power of the RHP-K7 is 700 kW at the sink, for this power all components are designed and optimized for. Since during the time of testing only 100-600 kW have been needed at the sink, the optimal operation point has not been reached.

The following figures show always a measuring duration of 24h, each day is constituted by a set of 4 diagrams including same measurands and calculated values as in the test scenario described in the previous section. Each figure states out, that the temperature of the source is increasing after appr. 07:00h until it remains almost constant after approximately 13:00h. The decreasing of the source temperature begins at around 17:00h on day two and three while on the first demonstrated day it starts more spontaneous at around 14:00h. The drop of source temperature at 14:24h is caused by switching on an internal fan of the CHP plant, where the RHP is integrated, for cooling the source. Thus, it is a change of boundary conditions due to external circumstances which results in this stairstep for the supply temperature. But, as the diagram shows as well, it is not a problem to keep the thermodynamic process ongoing.

The peak of thermal power always corresponds with an increased electrical power consumption of the fan while the power for the main rotation is always almost constant. The reason for this behavior of power consumption of the fan engine is the divergence of the isobars. If more heat is transferred from the working fluid to the process fluid, it is necessary that the fan overcomes the increased pressure difference caused by this divergence. This can be seen in Figure 2 where the pressure increase by the fan is shown from point 5.1 to 5.2 in the T-s-diagram. It is the same effect as it is used in turbines for power transformation based on the clockwise Joule-cycle. For the Rotation Heat Pump, it means, that the more thermal power is transferred, the more electrical power is necessary. Furthermore, this divergence also depends on the temperature lift between the source and the sink provided by the rotational speed of the main rotor. It can be stated, that the higher the temperature lift and the more heat transferred, the higher is the necessary pressure increase and the electrical power consumption of the fan. The power consumption of the main rotor in turn is always constant at a certain rotational speed. This value mainly depends on the friction of sealings and bearings.

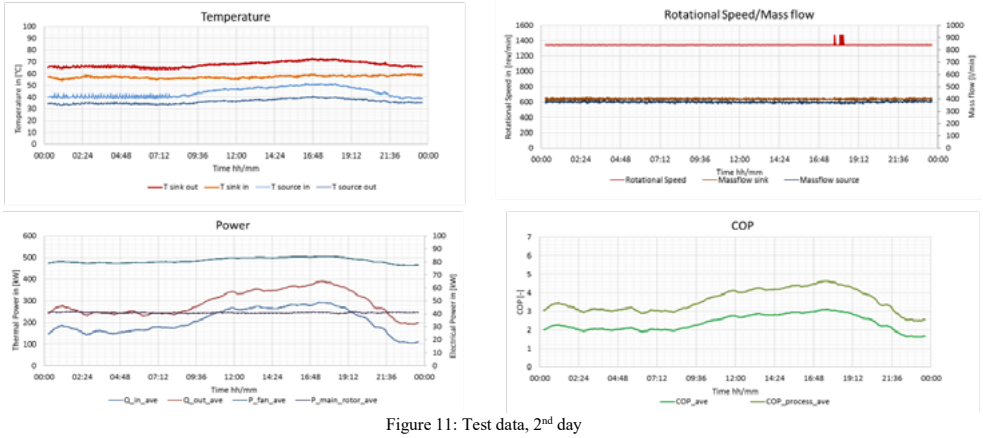

Figure 11: Test data, 2nd day

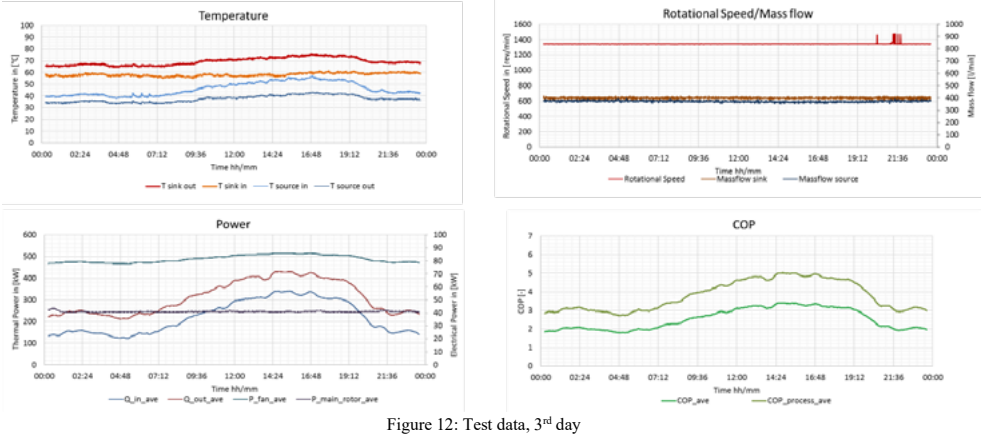

Figure 12: Test data, 3rd day

4. Further developments

To show the potential of a rotation heat pump and the joule-cycle based on centrifugal compression, some further developments will be shown. Right now, the focus is based on industrial applications, which make sense because there is a huge potential to reduce CO_2 emissions in this area. This fact is targeted by the development of a RHP-M2 which will provide 2 MW of thermal power at the sink. This type of machine will also allow a temperature lift of appr. 100K because internally there are two separated gas-cycles which can be switched from parallel to serial operation mode. Therefore, the mass flows of sink and source are split up and an intermediate circuit of process water is used. This operation mode allows a high lift but, in this case, the thermal power output at the sink is reduced to 1 MW.

However, the aim is also to reduce refrigerants with a high GWP in the field of space heating and refrigeration. Compared to the design of actual Rotation Heat Pumps, supplying 700 kW thermal power, it needs just some adaptions for downscaling to smaller machines of around 1- 10 kW. This power range is fitting good for household installations. The main principle, the compression via centrifugal forces, will not change but in terms of size those machines will be quite smaller. Another promising approach would be the development of a “Rotation Chiller” for supplying cold in refrigeration systems in combination with an environmentally friendly working fluid. In Figure 13 the actual designs are shown as well as the planned developments corresponding to the temperature level at the sink and the thermal output.

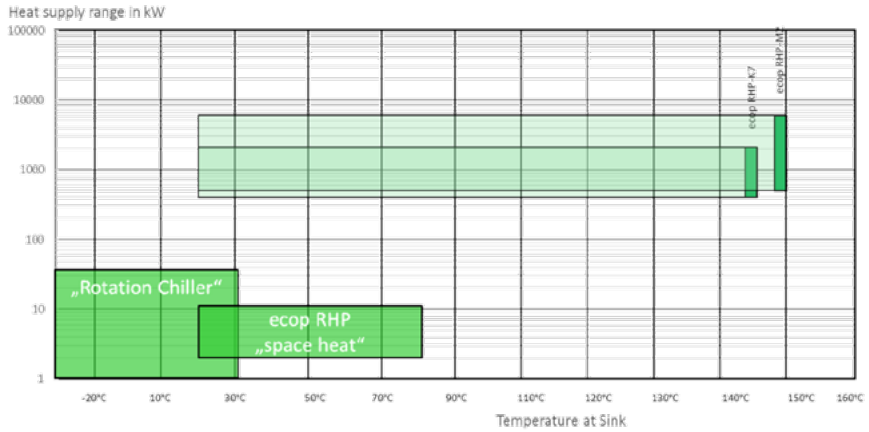

Figure 13: Actual designs and further developments

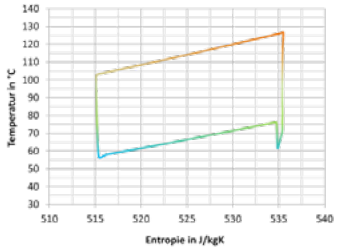
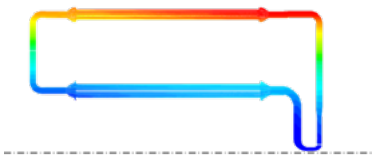
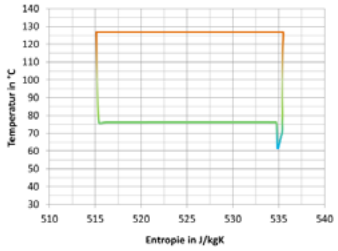
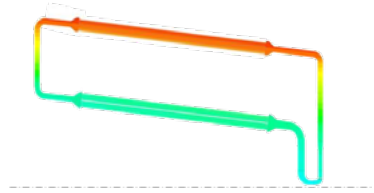
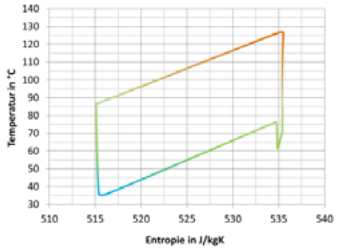
One further advantage is the design flexibility concerning the arrangement of heat exchangers. Right now, they are installed in parallel to the axis of rotation which makes sense for transferring sensible heat with an optimal temperature spread of sink and source according to the mass flow of the working fluid. But, since the incline of the heat exchangers can be seen as a degree of freedom to adjust the process, the thermodynamic cycle can be optimised for many different operating conditions (Table 1). It is a big advantage, that the heat capacity rates need not to be equal for minimizing exergy losses of the heat exchangers. The drawback of this layout is finally, that the design is more complex compared to the standard layout.

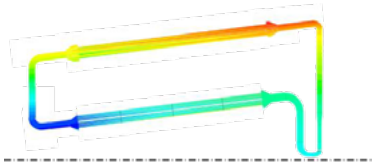


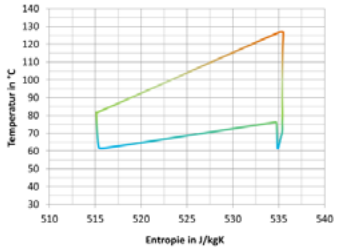


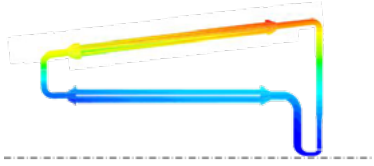


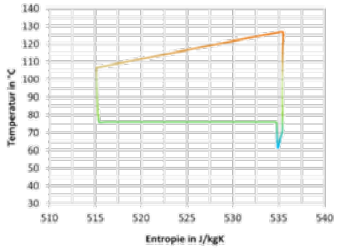


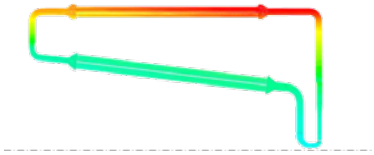












A positive incline of both, the low-pressure and high-pressure heat exchanger, enables the possibility to realize a thermodynamic process quite close to the Carnot-cycle. The reason therefore is the heat transfer during the working fluid is further compressed in the heat exchanger. That arrangement would fit perfect for high mass flows at sink and source while the temperature spread is quite low for a certain power output.

The opposite, the negative incline of the heat exchangers uses the cooling based on the expansion of the working fluid during the flow to a lower diameter of the rotor. The transferring of heat during this expansion allows further cooling and therefore a high temperature spread of sink and source is possible. So, the thermal power can be provided by having a low mass flow but high spread in terms of temperature.

The last two examples shown in Table 1 demonstrate the possibility to incline only one heat exchanger. This may be an advantage if there is a sink with low mass flow and high temperature spread in combination with a moderate cool down of the source, demonstrated by the negative incline of only the source. The last

case presents the positive incline of the source-heat exchanger, this would be most efficient if the mass flow of the source is high and the temperature spread is low. The sink in this case is not adjusted.

Table 1: Possible arrangements of the heat exchangers and corresponding T-s-Diagrams (schematic)

	T-s-Diagram	Heat exchanger arrangement
Standard design		
Positive incline (small spread of sink and source)		
Negative incline (large spread of sink and source)		
Positive incline at sink (large spread of sink)		
Negative incline at source (small spread of source)		

5. Conclusions

After different studies about the principle and function of a Rotation Heat Pump (RHP) have been published, test results are now available. In addition to the measurement data, gained at a test rig and a field installation, also a short introduction about the main principle and design of a RHP is given in this paper.

The first reference plant of a RHP-K7 has been manufactured and assembled as well as been tested. For simulating various operation modes by providing different boundary conditions in terms of temperature and mass flow of sink and source, a custom test rig was used. All necessary sensors have been installed while by using different heat exchangers, pumps and control valves the system was controlled and measurement data was collected. A scheme of the test rig and RHP present the setup and allow to comprehend the system. The focus of this installation was put on showing the flexibility in terms of temperature but also to verify the achievement of high temperatures at the output. Both cases are visualized via measurement data in diagrams and confirm these functions. Further, it is demonstrated, that at constant mass flow and rotational speed the temperature level can be easily adjusted without affecting the efficiency.

Beside the test application, the field installation was used to gain data of three consecutive days of operation. Relevant sensors have been logged again and measurement values have been analyzed in each case to calculate the Coefficient of Performance as a representative value for the efficiency. Since the system was not run in an optimization mode, the mass flow was kept constant and also the rotational speed. The input temperatures have been varying as they where depending on the operation of a CHP-plant where the RHP is implemented. In contrast to the boundary conditions at the test rig, the input temperature of sink and source have been changing not in a uniform way but much more irregular. Thus, the supplied thermal power and also the electrical power consumption where affected. The relation of those values to the temperature is analyzed and discussed where the divergence of the isobars plays a key role.

To give an outlook for further development possibilities, new fields of application are listed as well as design studies to optimize the thermodynamic process. Because the principle of centrifugal compression is also efficient in small scales, besides the upscaling of the RHP-K7 (700 kW) to the RHP-M2 (2 MW) the downscaling for space heating is of major interest. The changing of design parameters like the incline of the heat exchangers is a new degree of freedom for a heat pump and is introduced. Because of this option, it is possible to adjust the thermodynamic process exactly for individual implementations. These research projects are discussed in a last section where advantages and disadvantages are mentioned.

An air-water dual-source heat pump system for shrimp ponds

Jia-Hao Cheng, Peng Gao, Xiang Cao, Peng Shao, Liang-Liang Shao*, Chun-Lu Zhang*

School of Mechanical Engineering, Tongji University, Shanghai 201804, China

Abstract

Ponds in farmland have been widely used for shrimp culture in eastern coastal regions of China. To maintain the pond water temperature in winter, an environment-friendly, energy-saving and low-cost heating system is urgently needed. This paper proposed a new air-water dual-source heat pump system (AWDSHPS), which is equipped with two parallel evaporators, one taking heat from air and the other from water in idle ponds. The two heat sources can be used separately or simultaneously, based on ambient conditions and heating demand. A validated load model is built to calculate heating demand accurately. Another simulation model is applied to fulfill system design and performance prediction. Furthermore, operational strategy of full growing season is optimized. The results showed that, compared with the same system in which only air source is used, the AWDSHPS has higher evaporating temperature. That increases from -7.7°C to -3.2°C at ambient temperature of 0°C, resulting in 7% increase in energy efficiency and 27% increase in heating capacity. Therefore, system energy performance becomes more stable, reducing the heat pump size to lower both initial investment and operating costs.

Keywords: heat pump; shrimp pond; dual heat sources; energy saving

1. Introduction

To meet the growing market demand, a vast quantity of whiteleg shrimp, *Litopenaeus vannamei*, is farmed in humid and cold eastern coastal regions of China. In there, thousands of farming ponds have been excavated in farmland. There are three growing seasons every year. Two are in winter, one from November to January and the other from February to April. To maintain the normal growth of shrimp, an acceptable pond water temperature range is 20°C~32°C [1]. This range is much higher than local average ambient temperature of 5° C in winter. Thus, additional heat input is urgently needed.

Thanks to inexpensive investment and low operating costs, the coil-fired boilers were popular among local farmers in the past few years. However, given the serious pollution to the environment, regional authorities banned coil-fired boilers for shrimp culture. Therefore, an alternative heating system is urgent to be designed. It should be environment-friendly, energy-saving and low-cost.

Among the existing heating technologies, heat pump is the first choice. Depending on the heat source, traditional heat pump technologies are divided into various types, among which ground source heat pump (GSHP) and air source heat pump (ASHP) is most popular. The former takes ground, groundwater, or surface water as heat source and sink. It is widely used owing to high thermal-efficiency and relatively low operating costs [2, 3]. However, inappropriate application of GSHP may cause environment risks, including thermal pollution and groundwater contaminations [4]. Other potential risks also have been pointed out by many researchers [5-7]. As for ASHP, which takes air as heat source, is also favorable for its simple structure, low initial cost and high energy efficiency [8]. But in practical applications, energy performance of ASHP is often unsatisfactory [9]. The sensitivity to environmental temperature and heating capacity attenuation caused by frosting are two main problems [10, 11]. Besides, some dual-source heat pump (DSHP) systems have been proposed, mainly for producing domestic hot water, space heating and cooling for buildings [12-14].

* Corresponding author. Tel.: +86-136-71825-133.
E-mail address: shaollpaper@gmail.com (L.-L. Shao), chunlu.zhang@gmail.com (C.-L. Zhang).

However, the various traditional heat pump system mentioned above is not suitable for local shrimp culture. If GSHP is used, thermal imbalance will be a problem because there is no heat injected back to ground in summer. The shrimp pond needn't be cooled at that time. Groundwater contamination is another concern. Regional authorities have banned groundwater heat pumps. As for ASHP, oversize scale is needed as a result of its unstable poor performance under low temperature conditions, which brings about a higher initial investment.

To solve the above problems, in this paper, we proposed a new air-water dual-source heat pump system (AWDSHPS) according to local practices. It can absorb heat from air and water in idle ponds separately or simultaneously, based on weather condition and heating demand. With water as additional heat source, the system benefits from more stable energy performance, lower investment and operating costs. In order to achieve these, a load model of shrimp pond was built and validated first, as shown in section 2. In section 3, with the help of load model, heating demand was calculated accurately. Then the new AWDSHP system was designed and optimized using GREATLAB. In section 4, the system energy performance was analyzed in different modes under various working conditions. Based on that, in section 5, the operational strategy of full growing season in winter was optimized to minimize power consumption. Lastly, the conclusions were provided in section 6.

2. Load model

In this section, based on the principles of thermodynamics and heat transfer, load model of shrimp pond was built first, and then validated with experimental data. This model will be used to calculate heating demand for system design, as shown in section 3.2. Moreover, in section 5, it will be used to simulate pond water temperature of full growing season.

2.1. Modeling

The typical ponds we studied here are of uniform size, about 40m long, 9m wide and 1m deep. At the top, the pond is covered with one or two layers of transparent plastic film for insulation. The bottom is directly the soil. The real picture is shown in Fig. 1.

Fig. 1. Picture of shrimp pond in farmland

The energy balance of the shrimp pond is made up of multiple heat transfer processes. Heat input is mainly from solar radiation and external equipment, while heat loss from conduction through soil, heat transfer between water and inner cover (convection, radiation, evaporation and condensation), convection with air outside, and sky radiation.

Fig. 2 demonstrates the energy fluxes in the water volume and at the covering surface. Note that the heat capacity of plastic surface is ignored because of its small thickness (about 1×10^{-4}m) and negligible heat mass. Considering the energy balance, we have,

$$Q_{r,w,f} + Q_{a,w,i} + Q_{c,w,g} + Q_{l,w} - Q_{sr,w} - H = c_w m_w \frac{dT_w}{d\tau} \quad (1)$$

$$Q_{r,w,f} + Q_{a,i,f} + Q_{l,f} + Q_{sr,f} - Q_{r,f,o} - Q_{a,f,o} = 0 \quad (2)$$

where every term of equation represents a kind of heat transfer. $Q_{r,w,f}$, for example, is the radiation between water and film. All symbols can be found in Nomenclature.

Each of heat transfer processes, listed in Eq.1. and Eq.2. above, can be defined by a mathematical expression. Since this paper mainly focuses on the performance of the new proposed system, specific methods are not introduced here. Relative information can be easily found in professional books and papers [15, 16].

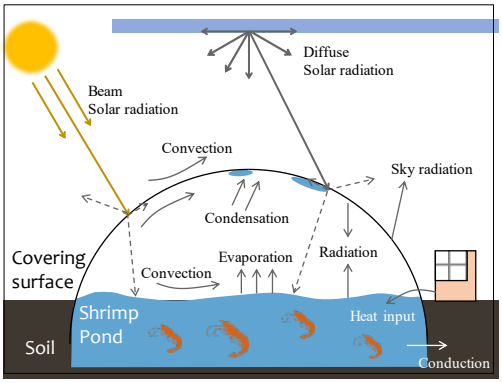

Fig. 2. Energy fluxes in the water volume and at the covering surface

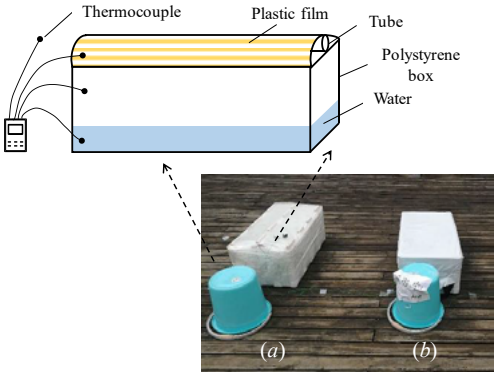

Fig. 3. Shrimp pond model (a-covered with 2 layers transparent PE film, b-covered with 1 layer)

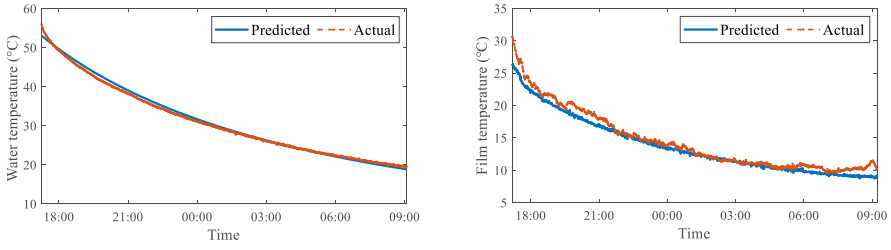

Fig. 4. Comparison of simulation and test data

2.2. Model validation

In order to validate the accuracy and reliability of load model, an experiment was conducted. We first made a simple shrimp pond model, as shown in Fig. 3. The open polystyrene box is used to simulate the pond. Some water is stored inside. Plastic film covers it on top, supported by a horizontal tube. The film material is the same as the actual use. To acquire data for further validation, temperatures of stored water, covering film, internal and external air were measured once a minute. A simple digital thermometer, coupled with K-type thermocouples, was used. Measurement uncertainty of ±1°C is acceptable here. Besides, this experimental model can be employed to compare effect of various insulation schemes, such as covering different layers of film.

By modifying relative geometric parameters and boundary conditions of the original load model, we achieved a suitable model for the polystyrene box. Then above experimental data were used to calibrate the property parameters of film, including thermal conductivity, radiation transmittance and so on. The model after calibration can well predict the water and film temperature, as shown in Fig. 4. Later, these calibrated parameters will be substituted into the original load model.

3. System design

In this section, the working principle for the new AWDSHPS is first introduced, and its simulation model is developed later using GREATLAB [17]. This simulation model can predict system performance, as shown in later sections 4 and 5.

3.1. System description

Fig. 5 is the schematic diagram of the new AWDSHPS. The heat pump unit is composed of two parallel evaporators (fin-tube type for air-cooled one and brazed plate type for water-cooled one), a rotary compressor, a brazed plate condenser, two expansion valves, a reserving valve, etc. Unlike the traditional system, another evaporator is adopted to absorb heat from water in heat storage ponds. These ponds are idle in winter because less shrimp are farmed to reduce risk and achieve higher market price. Having heat taken from the heat storage ponds, the water temperature should not be below 0°C. They keep energy balance by absorbing solar energy at daytime. Heat absorbed, together with the power input, is then transferred to the secondary refrigerant (25% ethylene glycol solution with a freezing point of -10°C) in the condenser. The heated secondary refrigerant flows through the bottom pipes to provide heat, keeping shrimp pond water temperature above 20°C. In addition, the shrimp pond is covered with one film more than the heat storage pond to achieve a balance between energy-saving and investment.

By closing and opening the expansion valves, the unit can take heat from air and water separately or simultaneously. Thus, three heating modes can be fulfilled: (a) air source heating mode, ASHM; (b) water source heating mode, WSHM; (c) air-water source heating mode, AWSHM. With water as additional heat source, the heating system benefits from higher surrounding temperature, therefore, better system performance would be obtained from higher evaporating temperature. Moreover, the heating capacity attenuation caused by defrosting, which is common in air source heat pump system, can be mitigated.

3.2. System modeling

Based on the validated load model in section 2 and meteorological data from the past 5 years, we accurately calculate heating demand of shrimp pond. The result shows, with heat input at a constant level of 16kW, the water temperature of shrimp pond can be maintained in the range of 20°C~31°C during full growing season. Fig. 6 is the simulation result of the typical growing season in 2017. Consequently, the heating capacity of heat pump is designed at 16kW.

As to design conditions, extremely serious ones that possibly encountered in future operation, are usually adopted. Design conditions in this case are listed in Table 1. For heat sink, the water temperature of shrimp pond is set to 20°C. For heat source, both air and water of heat storage pond should be considered. For one thing, in the worst case, water temperature of heat storage pond is the freezing point, 0°C. For another, although the lowest ambient temperature is roughly -10°C in farming region, the water in heat storage pond can be alternative heat source in the cold winter. Given the days of ambient temperature below 0°C is no more than 7% in recent five years, ambient temperature is set to dry bulb temperature of 0°C and web bulb temperature of -1°C.

Table 1. Design conditions of the AWDSHPS

Water temperature of shrimp pond	Ambient temperature (DB/WB)	Water temperature of heat storage pond
20°C	0/-1°C	0°C

According to design requirements mentioned above and engineering practice, we developed the system simulation model in GREATLAB, which is a well-validated vapor-compression system modeling and analysis tool. Since this paper focused on the proposed AWDSHPS and its operating performance during full growing season, modeling methods are not described here. Detailed information can be found in the references [17, 18]. Fig. 7 is the system model of the novel AWDSHPS using GREATLAB, of which the operating principle is in accordance with that shown in Fig. 5.

Based on the design conditions (Table 1), component performance got from manufacturers and size limitations, we carried out the system optimum design with simulations. Specifications are listed in Table 2. On this basis, we can analyze system performance at design and off-design conditions in later section.

4. System performance analysis

In this section, system performance at design and off-design conditions were numerically analyzed. Ambient temperature varies in the range of -5°C to 15°C. For simplicity, water temperature of heat storage pond is always 5°C higher than the ambient. As shown in Fig. 8, with the increment of ambient temperature, system COP and heating capacity increase almost linearly as well. For the three heating modes, system in WSHM has the highest COP with an average of 3.7, followed by 5% decrease in AWSHM and 10% in ASHM. As to the heating capacity, system in all three modes can meet the desired value of 16kW when ambient temperature is above 2°C. Even at serious conditions that ambient temperature drops to -5°C, the WSHM and AWSHM can still satisfy this requirement.

Above comparison of COP and heating capacity in three modes partly demonstrates the advantages of additional heat source of water. That of evaporating temperature in Fig. 9 further reveals this. In comparison to very low ambient temperature at night or cold winter, water temperature of heat storage pond is about 5°C higher owing to its huge heat capacity. Therefore, taking heat from water or air and water together will lead to an increase in evaporating temperature. The system performance benefits from it. For example, the evaporating temperature increases from -7.7°C in ASHM to -3.2°C in AWSHM at ambient temperature of 0°C, resulting in 7% increase in energy efficiency and 27% increase in heating capacity. Furthermore, higher evaporating temperature mitigates the influence of frosting. The air-cooled fin-tube evaporator is easy to frost in winter due to relatively lower evaporating temperature and higher humidity ratio. For conventional air source heat pump system, frosting often occurs at the working condition that ambient temperature is below 7/6°C according to Chinese standard [19]. Under that working condition, the relative evaporating temperature in ASHM of this system is about -3°C. By comparison, the same evaporating temperature (-3°C)

in AWSHM of this system appears at ambient temperature of 0°C. That means frosting can only happen on the most severe days with proper heating mode switch, thus the heating capacity attenuation is much smaller than that of air source heat pump system. That's why the new system can be downsized, which lower both initial investment and operating costs.

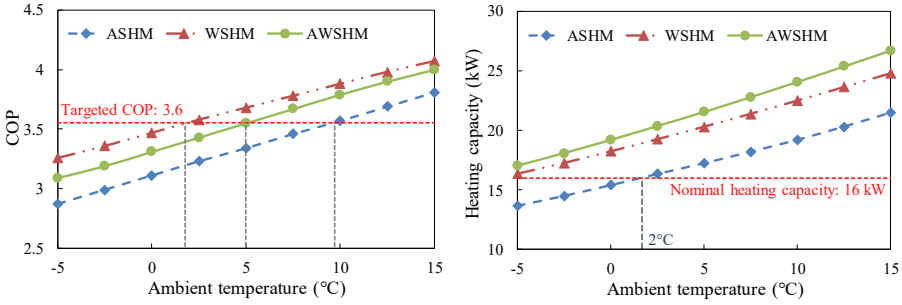

Fig. 8. System performance versus ambient temperature

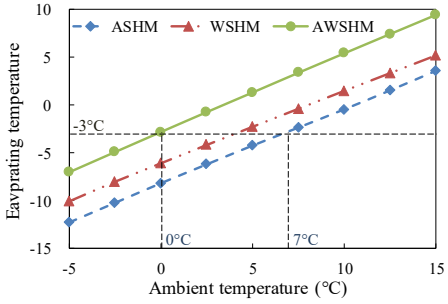

Fig. 9. Evaporating temperature versus ambient temperature

5. Operational strategy of full growing season in winter

The proposed AWDSHPS will be applied to heat shrimp pond for the whole growing season, nearly 3 months. To generate better operational strategy, two aspects should be considered. Firstly, timely heating mode switch. According to comparison and analysis in section 4, at severe conditions, system performance in ASHM is very poor. Although the other two modes perform better, they cannot always enable because the heat absorbed from heat storage pond is limited. Otherwise, excessive heat loss will lead to icing. Thus, WSHM or AWSHM should be adopted at severe conditions while ASHM at better ones. Secondly, proper on-off operation. In the early days when ambient temperature is above 15°C, system efficiency is high but additional heat input is unnecessary. With time going on, the ambient temperature gradually decreases, resulting in growing heating demand. Meanwhile, the energy performance gets worse and worse. However, shrimp pond water temperature can fluctuate in a large range of 20°C~32°C. Thus, a certain amount of heat can be stored. At the beginning of growing season, we can turn on heat pump unit to store oversupply of heat, keeping pond water temperature at a high level. So, shrimp pond requires less heat in cold winter when system is underperforming. More power is saved to compensate for early input.

Based on load model and system model, we optimized the operational strategy. Fig. 10 is the overall logic diagram. With historical meteorological data and strategy mode as input, AWDSHPS model calculates heat input to shrimp pond and heat absorbed from heat storage pond. The two outputs are then given to subsequent load models, from which water temperature of full growing season is finally obtained. According to this procedure, operational strategy is optimized with minimum power consumption as objective and water temperature as constraints.

For ease of application, we introduce a simple optimized operational strategy here. The principles are,

- If water temperature of shrimp pond is below 23°C, turn on machine. Select ASHM, WSHM or AWSHM at ambient temperature of greater than 10°C, 5~10°C, or less than 5°C, respectively.
- If water temperature of shrimp pond exceeds 23°C, turn off machine.

The following command of mode switch is shown in Fig. 11.

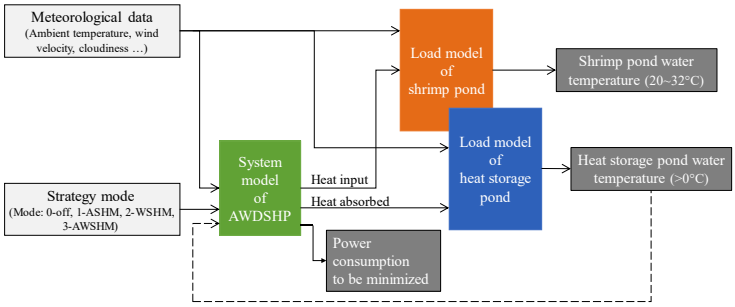

Fig. 10. Block diagram showing the optimization logic

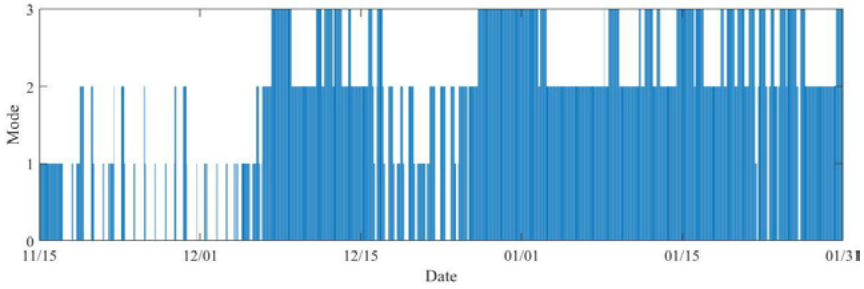

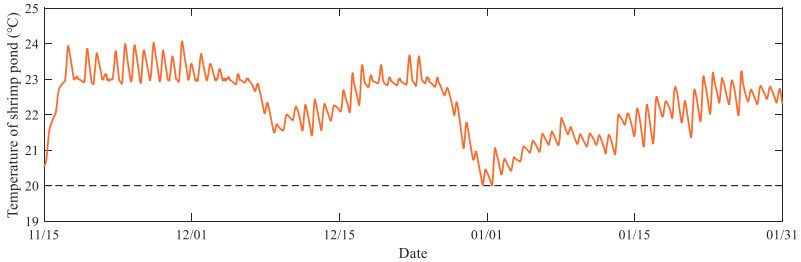

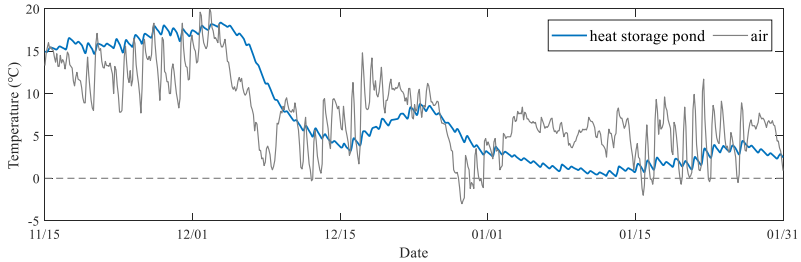

Fig. 11. Mode switch during full growing season (0-off, 1-ASHM, 2-WSHM, 3-AWSHM)

(*a*)

(*b*)

By substituting above strategy into the model, the results obtained are shown in Fig. 12. Water temperature of shrimp pond fluctuated from 20°C to 24°C, which is suitable for shrimp culture. That of heat storage pond always keeps above 0°C, which ensures the heat absorption in WSHM and AWSHM. Besides, the fluctuation of shrimp pond water temperature is less than that in Fig. 6, resulting in lower power consumption.

Consequently, we reduced the total power consumption to 8372kWh. Multiplied by local average electricity price of 0.55CNY per kWh, total operating costs were 4600CNY. The initial investment of our new AWDSHPS is approximately 16000CNY, of which heat storage pond is not included. Since all heat storage ponds have been excavated before. They are used for shrimp farming in summer but idle in winter. By comparison, coil-fired boiler with shrimp pond covered 1-layer film was common in the past. According to calculation by load model and on-site investigation, total coal consumption was about 11360kg and corresponding costs were 10220CNY. As a result, approximately 55% of energy costs can be saved with our new AWDSHPS.

6. Conclusions

In this study, a new AWDSHPS was proposed for shrimp culture. The load model of shrimp pond was built, experimentally validated, and then used for heating demand calculation. Furthermore, system design and modelling were fulfilled using GREATLAB and system energy performance was analyzed. At last, operational strategy of full growing season was optimized and a simple but effective one was adopted for practical use. All in all, main conclusions can be drawn as follows.

The proposed AWDSHPS is proven to have more stable energy performance, lower investment and operating costs than traditional heat pump systems. It is more suitable to replace original coil-fired boilers. This type of system can also be considered for other aquaculture applications, especially where two suitable heat sources are available.

With water in idle pond as additional heat source, the AWDSHPS has shorter defrost cycle and better energy performance. At ambient temperature of 0°C, for example, the evaporating temperature increases from -7.7°C to -3.2°C, resulting in 7% increase in energy efficiency and 27% increase in heating capacity.

For multiple heat source systems, the characteristics of different heat sources should be deeply understood. In this case, heat storage capacity of water source and performance attenuation of air source are comprehensively considered. With optimized operational strategy in full growing season, the total costs reduced by 55% relative to that of boiler heating. This value could be bigger by adopting better strategy, which is expected to be further discovered.

Abstract

Buildings consume approximately 40% of the primary energy used in the U.S. The energy-independence challenge is particularly acute for buildings in colder U.S. climates that have a longer heating season. Heating is by far the biggest consumer of energy, accounting for at least 30%, and in some cases as much as 60%, of total energy use. In addition, the gradually phase-down of current refrigerants requires further research to identify suitable low-global warming potential (GWP) replacements. Hydrocarbons represent a possible solution, but their flammability yields to a number of challenges towards the actual commercialization in the residential sector. In this paper, a packaged air-source heat pump with external flow reversible is proposed as a viable solution to safely utilizing flammable refrigerants, such as propane (R-290). The proposed system can also be adapted to serve as a cold-climate heat pump that provides heating, cooling, and domestic hot water. A detailed dynamic model has been developed to evaluate the performance benefits of the proposed system architecture. Moreover, the use of propane as the working fluid reduces the total charge required by the system, which yields to possible down-sizing of the equipment. To this end, a charge minimization study has been carried out to further investigate the trade-off between reduced charge inventory and performance.

1. Introduction

As the adverse environmental effects of using hydrofluoricarbon (HFC) refrigerants become more and more apparent, the efforts towards developing technology to efficiently utilize alternative refrigerants has grown significantly. Specifically, R-290 (propane) is being considered due to its negligible global warming potential (GWP) and ozone depletion potential (ODP). However, propane inside a residential heat pump needs to be combined with a secondary loop due to its flammability. Commonly, R-290 heat pumps are paired with Ethylene Glycol/water (EG) secondary loops that can travel through the home. Application of this technology in northern regions of the US presents several challenges, with the largest being the broad range of both heating and cooling ranges necessary in this region. The components selected need to strike a balance between efficiency and being able to meet requirements over large operating conditions. According to a 2014 Northeast/Mid-Atlantic Air-Source Heat Pump Marketing Strategies Report [1], the adoption of air-source heat pumps in homes that currently use electricity, oil, or Propane furnaces for heating in the Northeast/Mid-Atlantic region could result in an annual savings of $1.2 Billion and over 7 million metric tons of annual carbon emissions. Additionally, the report found that the average heat pump capacity in the Massachusets market is 2.3 tons. According to the Department of Energy [2], the minimum required seasonal performance for these

E-mail address: dziviani@purdue.edu.

heat pumps is an 8.2 heating seasonal performance factor (HSPF) and a 14 seasonal energy efficiency ratio (SEER).

Wang et al. [3] performed a comprehensive literature review on the advantages of using hydrocarbon refrigerants in secondary loop heat pumping systems. In addition to increased safety, lower charge levels, and potentially reduced operating costs, it was found that hydrocarbons saw an average of 9.6% improvement in performance over fluoronated refrigerants while in heat pumping applications. Palm [4] concluded that the Coefficient of Performance (COP) of systems using hydrocarbon refrigerants would be equal to or greater than those of systems using R-134a or R-22, and also found that the majority of components for HFC systems can be used in R-290 sytems. Some disadvantages listed by this paper are the smaller number of compressors available in high-capacity ranges, as well as the danger of flammability. Park and Jung [5] experimentally compared R-290 and other hydrocarbons in air conditioning application and found that R-290 achieved a 1.9% higher COP but had 11.5% smaller cooling capacity. However, the paper found that this result was achieved with less than 50% mass of charge. Fernando et al. [6] experimentally validated the temperature profile through an evaporator that legitimizes the decision to use glycol as a seondary loop fluid, as shown in Fig. 1. Additionally, Fernando found that small propane charges in heat pump applications both increase the safety of the system, and also still result in similar COP to HFC systems under similar operating conditions.

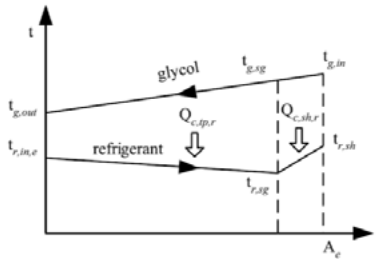

Fig. 1. Evaporator temperature profile [6].

A 50/50 combination of EG will reduce the freezing temperature of the secondary loop fluid to below -33℃, making it safe for use during the coldest temperatures measured in the Boston area, and is non-toxic. Ginies et al. [7] studied the effects of low-solubility oils in R-290 refrigeration systems in an effort to allow end users to utilize larger capacity units while staying within safety standards set by EN378, ISO5149, and the like. The study focused on Polyalkylene Glycol (PAG) and Polyolester (POE) oils, and found that when the correct oil is chosen for a 0.1 kg R-290/kW in a 60 kW system, the charge could be reduced by 18-30% without compromising capacity.

While many technologies aimed at increasing vapor compression cycle (VCC) have been investigated, there is often difficulty justifying increased completixty to obtain performance benefits. As such, generally only solutions that are both simple and efficient are widely accepted. One of these methods is known as economization, which comes in two forms. First, a flash tank can be placed in the expansion process to separate phases in a two-phase flow, allowing saturated liquid to enter the evaporator and bypassing the vapor to the compressor. This strategy has been proven to be controllable without compromising compressor suction superheat by Xu et al. [8]. The second form of economization is known as closed economization and achieved with an internal heat exchanger (IHX), which can be effectively controlled with an electronic expansion valve (EXV) [9]. Economization also allows vapor injection into the compressor at specific points, with increased precision on the superheat control. In theory, an infinite number of injection ports can be used to achieve saturated-vapor compession and can result in up to 51% COP improvement in an R-404A cycle. However, 75% of this performance benefit can be achieved with only three injection ports, which is considered to be the practical limit by Mathison et al. [10].

Multi-stage compression technology applied in a cold climate heat pump (CCHP) has been investigated via simulation by Caskey [11]. In this work, a gas heating system was compared to a two-stage heat pump in US Army barracks located in the central and northern US. The analysis resulted in a predicted CO_2 reduction by 33.5% while simultaneously reducing the heating cost by 25%. Gschwend et al. [12] further analyzed

possibilities to reduce power consumption of barrack buildings for the U.S. Army. The researchers concluded that the use of a two-stage heat pump lead to a seasonal COP of approximately 3.0, along with potential energy savings of 20% – 35% in the existing buildings.

This work presents the design and modeling of a packaged vapor-injected (VI) two-stage R-290 VCC featuring two EG/Water secondary loops and external flow reversal for hydronic heating and cooling of a residential home. The design focuses on cold climates, thus designating this work a CCHP. A 5-ton system design is proposed, annual data is analyzed for Boston, USA, and the system is assessed for performance in both weather datasets at two design temperatures. A dynamic and detailed model of the system has been developed and utilized to assess the impact of charge inventory.

2. System Design and Approach

2.1. System overview

The proposed R-290 – EG heat pump schematic is shown in Fig. 2. The VCC uses 2-stage compression with VI in the intermediate stage. An IHX is utilized to facilitate closed economization with the dual purpose of further sub-cooling the flow from the condenser outlet and superheating the economized vapor to be injected into the compressor. All three system heat exchangers will be plate heat exchangers (PHX). The IHX used for economization will be the smaller capacity heat exchanger (HX), while the condenser and evaporator will be larger PHXs that transfer heat between R-290 and the EG secondary loop. There is no 4-way valve associated with the VCC because the EG loop enters a multi-input multi-output (MIMO) valve which enables transition between heating and cooling modes to the home. Additional components in the VCC include an oil separator located at the second stage discharge that returns the oil to the suction of the first stage of compression, as well as a suction-line accumulator to ensure no 2-phase flow enters the compressor suction port. A filter-drier is located at the outlet of the condenser to remove potential contaminants from the R-290, and there is also a liquid receiver placed at the inlet to the sub-cooler for charge modulation.

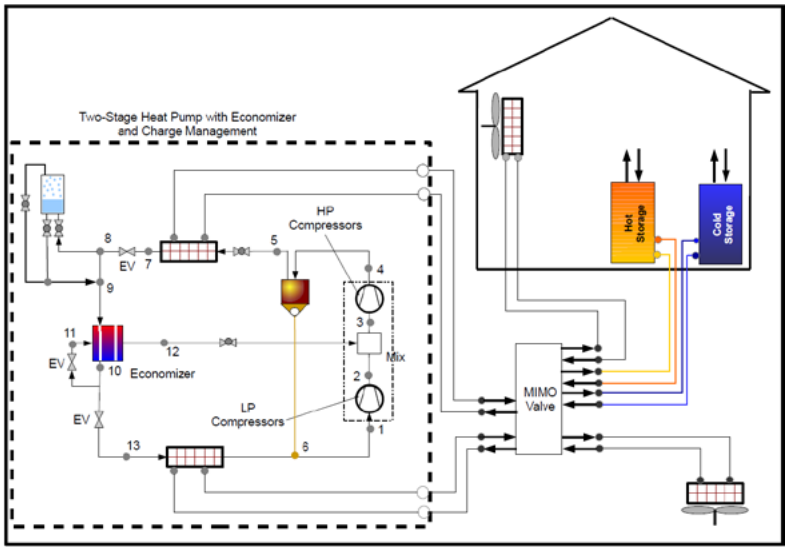

Fig. 2. Concept schematic of the packaged R-290 CCHP with secondary loops, external flow reversal, and possible coupling with cold and hot storage tanks.

The EG MIMO valve is used to direct flow into the home and has four sets of inputs and outputs. One set directs flow to an air-source heat exchanger exposed to the ambient to provide capacity modulation. The other three lead to the home, with one leading to an air-source heat exchanger to control the indoor environment and the other two leading to a hot and cold storage tank. This enables the system to utilize nearly 100% of the heat

pumped by the VCC, either at that moment or later on via thermal storage. This also enables grid-interaction with the system, as thermal storage can be used to eliminate the need to run the VCC during peak hours.

2.2. Seasonal weather and load calculations

The system design was based off of weather data from Typical Meteorological Year 3 (TMY3) [13], for the Boston Logan airport. This data contains, among other things, average dry bulb temperatures and relative humidity for every day in a typical year. This allowed the calculation of how many hours the heat pump system would need to run at the given operating conditions over the course of one year. Data from Boston is shown in **오류! 참조 원본을 찾을 수 없습니다.**. The design internal environment was 50% relative humidity with a dry bulb temperature of 21.1 ℃. Therefore, at 21.1 ℃ there was zero load, designating this temperature as the chosen balance point. A heat pump capacity of 5 tons was the design target, motivating a design capacity of 17.58 kW at -20 ℃. The target load profile is shown in Fig. 4. On the cooling side, a design temperature of 30 ℃ was chosen, and a sensible heat ratio (SHR) across the evaporator was assumed to be 0.7. This resulted in a design total cooling load of 7.3 kW after the consideration of occupants and other heat sources. It is assumed that each occupant creates 100 W of heat and that four occupants are in the home. Additionally, the lighting and appliance heat loads are assumed to be 750 W each. The complete cooling load calculation can be seen in Eqs. 1 through 5.

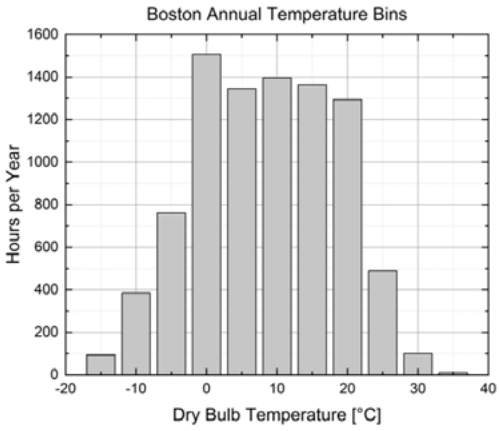

Fig. 3. Dry-bulb temperature bins for Boston over 1 year.

$$\dot{Q}_{\text{cool,sens}} = \frac{(T_{\text{amb,cooling}} - T_{\text{indoor}}) \cdot \dot{Q}_{\text{heat,design}}}{(T_{\text{indoor}} - T_{\text{amb,heat,design}})} \tag{1}$$

$$\dot{Q}_{\text{cool,sens}} = \dot{Q}_{\text{cool,base}} \cdot SHR \tag{2}$$

$$\dot{Q}_{\text{cool,base}} = \dot{Q}_{\text{cool,sens}} + \dot{Q}_{\text{cool,lat}} \tag{3}$$

$$\dot{Q}_{\text{int}} = \dot{Q}_{\text{occupant}} \cdot N_{\text{occupant}} + \dot{Q}_{\text{lighting}} + \dot{Q}_{\text{appliance}} \tag{4}$$

$$\dot{Q}_{\text{cool}} = \dot{Q}_{\text{cool,base}} + \dot{Q}_{\text{int}} \tag{5}$$

After these two capacities were specified along with the balance point, linearization was conducted for both heating and cooling mode to provide design capacities at individual ambient temperatures across the design range. These functions are shown in the load profile shown in Fig. 4.

When these loads are multiplied by the hours at which the heat pump needs to operate at these conditions (**오류! 참조 원본을 찾을 수 없습니다.**), the overall energy requirement for both heating and cooling can be calculated, in kWhr. These plots for heating are shown in Fig. 5, while cooling mode demand is shown in Fig. 6.

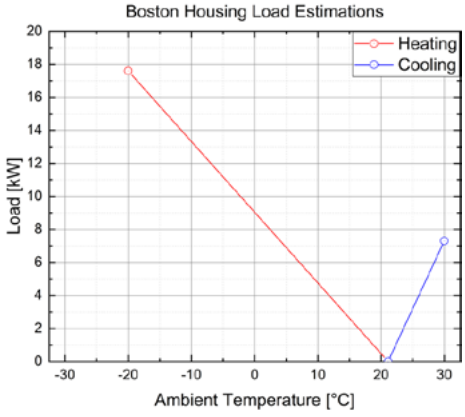

Fig. 4. Heat-pump design loads for Boston with balance point fixed at dry bulb temperature of 21.1 ℃ and 50% relative humidity.

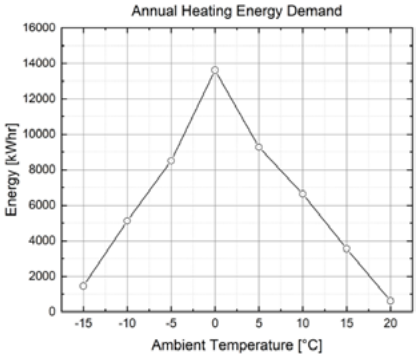

Fig. 5. Boston annual heating energy demand.

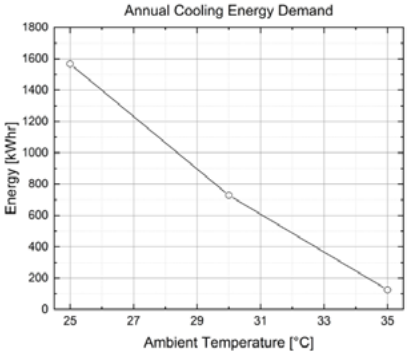

Fig. 6: Boston annual cooling energy demand.

2.3. Modeling overview

Once the loads are determined, a dynamic model was developed using the Modelica language [14] in a Dymola environment [15] utilizing the TIL Suite [16]. This form of modelling was chosen to enable both pseudo-steady state modelling, as will be conducted with the seasonal analysis herein, but also dynamic modelling for charge sensitivity and control strategy studies. The system within Dymola is shown in cooling mode in Fig. 7.

For a given operating condition, defined by the ambient temperature, indoor temperature, and required capacity, the primary method of performance quantification is the COP. The COP is the ratio of delivered capacity to power input, including only compressor power. The delivered capacity is defined as heat absorbed via the evaporator in cooling mode heat rejected via the condenser in heating mode and, shown in Eqs. 6 and 7, respectively.

$$COP_{\text{cool}} = \frac{\dot{Q}_{\text{evap}}}{\dot{W}_{\text{in}}} \tag{6}$$

$$COP_{\text{heat}} = \frac{\dot{Q}_{\text{cond}}}{\dot{W}_{\text{in}}} \tag{7}$$

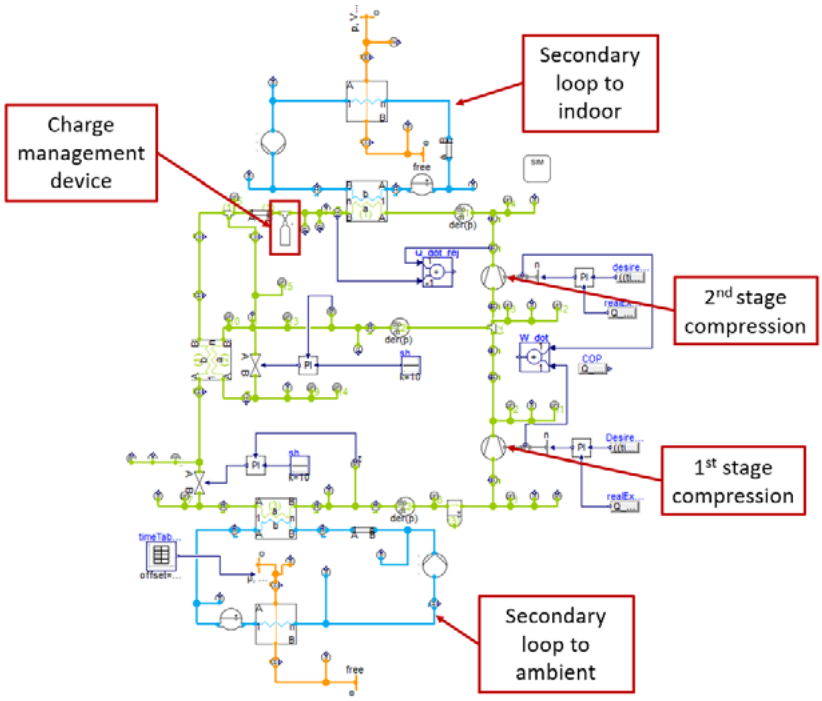

Fig. 7. View of the complete CCHP model within Dymola including secondary loops and charge management system.

Once the COP of the system is calculated it can be converted into two metrics that are more commonly used in industry for quantifying the performance of a system. These metrics are SEER and HSPF for cooling and heating modes, respectively. Both metrics are the ratio of desired heat transfer over the work input, which is the same as COP except for being seasonal averages. This means that each HSPF and SEER rating at an operating condition is weighted by how many hours the system operates at that condition, resulting in an assessment of seasonal performance. Additionally, COP takes both the numerator and denominator to have the same units, resulting in a dimensionless value. Both HSPF and SEER take the heating or cooling capacity in BTU, with the power input in Watt-hrs., resulting in a factor of 3.412 to convert from COP to the units for SEER and HSPF. The calculation of SEER and HSPF are shown in Eqs. 8 and 9.

$$SEER = \frac{\sum_{i=1}^{N} COP_i \cdot N_{\text{hours,i}}}{\text{Total Cooling Hours}} \tag{8}$$

$$HSPF = \frac{\sum_{i=1}^{N} COP_i \cdot N_{\text{hours,i}}}{\text{Total Heating Hours}} \tag{9}$$

The second shared component model is for the compressor, which follows a standard AHRI 10-Coefficient map that outputs mass flow rate as $\dot{m}_{\text{map}}$ and power consumption as $\dot{W}_{\text{in}}$ for a given condensation and evaporation temperature. The format for the map is shown in Eq. 10.

$$C_1 + C_2 \cdot T_{\text{evap}} + C_3 \cdot T_{\text{cond}} + C_4 \cdot T_{\text{evap}}^2 + C_5 \cdot T_{\text{evap}} \cdot T_{\text{cond}} + C_6 \cdot T_{\text{cond}}^2 + C_7 \cdot T_{\text{evap}}^3 + C_8 \cdot T_{\text{evap}}^2 \cdot T_{\text{cond}} + C_9 \cdot T_{\text{cond}}^2 \cdot T_{\text{evap}} + C_{10} \cdot T_{\text{cond}}^3 \quad (10)$$

The compressor is assumed to be variable speed, and the required speed is determined as a ratio of the mass flow rate given by the compressor map, $\dot{m}_{\text{map}}$, and the required flow rate across a given heat exchanger, $\dot{m}_{\text{Req'd}}$, determined from the simplified system model. As the authors were unable to obtain an experimental map for a variable speed R-290 compressor of this capacity, a map for a smaller variable speed R-290 scroll compressor was utilized and scaled up via speed as well as by the number of compressors in tandem for both the first and second stages to provide the desired capacity. This ratio is shown by Eq. 11, and the operation frequency is calculated by Eq. 12 for 60 Hz operation. The overall isentropic efficiency of the compressor is then calculated by Eq. 13.

$$Frac_{\text{speed}} = \frac{\dot{m}_{\text{req'd}}}{\dot{m}_{\text{map}}} \quad (11)$$

$$f_{60} = \text{Frac}_{\text{speed}} \cdot 60 \quad (12)$$

$$\eta_{\text{is,o}} = \frac{Frac_{\text{Speed}} \cdot \dot{m} \cdot (h_{2,\text{s}} - h_1)}{\dot{W}_{\text{in}}} \quad (13)$$

where

$$h_{2\text{s}} = f(p_2, s_1) \quad (14)$$

and

$$\dot{W}_{\text{in}} = Frac_{\text{Speed}} \cdot (h_2 - h_1) + \dot{Q}_{\text{comp}} \quad (15)$$

where

$$\dot{Q}_{\text{comp}} = 0.05 \cdot \dot{W}_{\text{in}} \quad (16)$$

Because the compressor map from Eq. 10 was calculated with a fixed suction superheat of 10 K, superheat correction was added to ensure an accurate prediction of compressor performance. Mass flow rate with a correction factor F of 0.75 and power consumption are corrected using Eqs. 17 and 18, respectively.

$$\frac{\dot{m}_{new}}{\dot{m}_{data}} = 1 + F \cdot \left(\frac{\rho_{suc,new}}{\rho_{suc,data}} - 1 \right) \quad (17)$$

$$\frac{\dot{W}_{new}}{\dot{W}_{data}} = \frac{\dot{m}_{new}}{\dot{m}_{data}} \cdot \frac{\Delta h_{s,new}}{\Delta h_{s,data}} \quad (18)$$

Table 1. Heat exchanger pressure drop and heat transfer correlations.

Fin-and-Tube, R-290 Side	Gnielinski [18]; Dittus, and Boelter [19]	Konakov for Smooth Pipes [20]
Fin-and-Tube, Air Side	Haaf [21], constant η [22] (Assumed to be 0.9)	Haaf [21]
Plate IHX	Evaporation: Shah [23] Chen [24] / Condensation: Shah [25] / 1-Phase: Gnielinski [18], Dittus, and Boelter [19]	Konakov for Smooth Pipes [20]
Plate HX, R-290 Side	Evaporation: Longo [26] Condensation: Longo [27]/ Gnielinski, Dittus, and Boelter	Quadratic Mass Flow Dependent [28]
Plate HX, EG Side	VDI Plate Alpha [29]	VDI Single-Phase [29]

This CCHP utilizes two types of heat exchangers, and both models assumed homoegenous equilibrium flow. The EG to air are fin-and-tube heat exchangers, while the R-290 to EG transfer utilizes plate heat exchangers.

The dimension of these heat exchangers were obtained through a separate modeling effort using a tool from Bell et al. [17] known as ACHP. Additionally, to conservatively estimate secondary loop losses, an extra 20% load was placed on the R-290 side of the cycle. A summary of heat transfer and pressure drop correlations utilized is provided in Table 1.

3. Results and Discussion

A full piping and instrumentation diagram (P&ID) is provided in Fig. 8 to offer a detailed schematic of the VCC aspect of this work. To simulate the TMY3 data, both ambient temperature and the required capacity for that temperature needed to be actively called into the model. This was completed by utilizing an externally-defined table that drove conditions assessed in the model. Fig. 9 shows the ability of the model to import TMY data as an air-temperature inlet value over the course of a year, and Fig. 10 shows the P-h diagram ability of the model, following the nomenclature from Fig. 8. Capacity modulation is to be achieved through control of the compressor speeds along with active modulation of the EXVs via proportional-integral (PI) control.

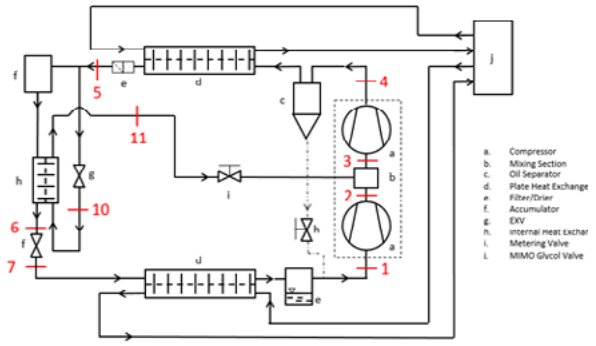

Fig. 8. P&ID of the proposed VCC.

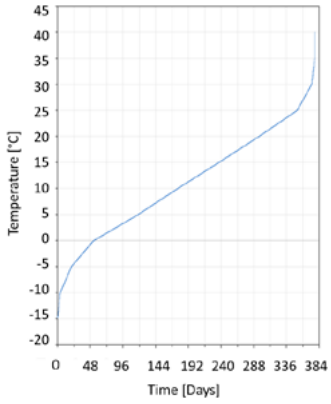

Fig. 9. 1 Year of TMY data for Boston in Dymola.

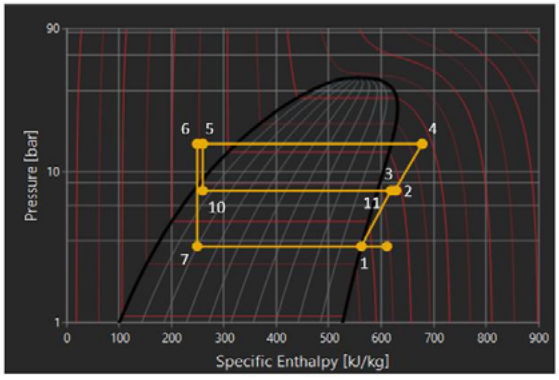

Fig. 10. P-h diagram of R-290 system in Dymola.

Preliminary results were achieved with a steady-state model of similar fidelity, which are presented in this section. These results include supplementary electrical heating to achieve the desired heating capacity. To identify the amount of supplementary capacity, the sources of heating capacity is differentiated between compressors and supplementary electric heating in Fig. 11. COP calculation with supplementary resistive heating is calculated using Eq. 19, where the COP of the electric heating is assumed to be the ideal value of 1.

$$COP_{\text{weighted}} = \frac{COP_{\text{VCC}} \cdot \dot{Q}_{\text{VCC}} + (1) \cdot \dot{Q}_{\text{elec}}}{\dot{Q}_{\text{total}}} \quad (19)$$

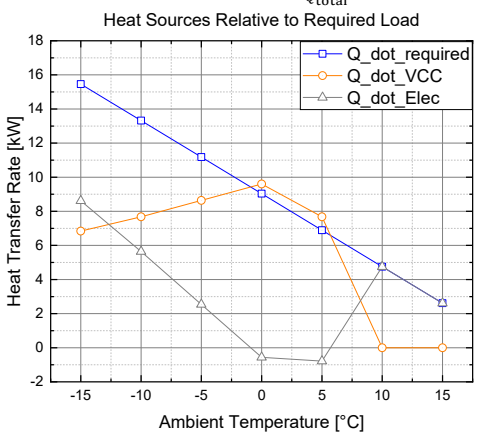

Fig. 11. Heat source variation with ambient temperature and associated load.

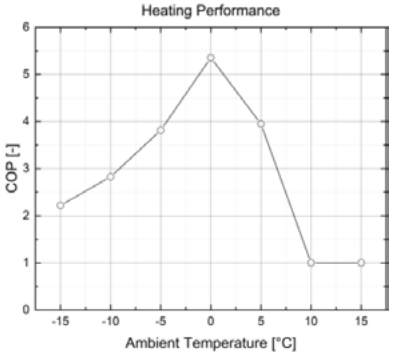

Fig. 12. Seasonal COP in heating mode.

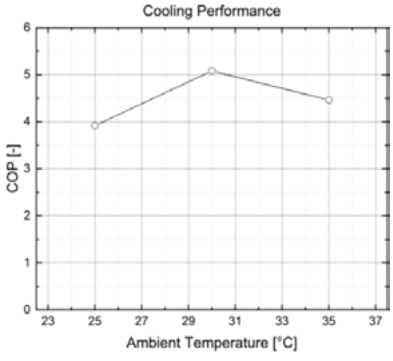

Fig. 13. Seasonal COP in cooling mode.

Tandem compressors were utilized, and variable speed inputs were used to simulate engaging and disengaging compressors to provide as much capacity as possible. This system achieved a SEER rating of 14.1 and an HSPF of 10.1. Seasonal COP results from the model are provided for heating and cooling modes in Fig. 12 and Fig. 13, respectively.

Being R-290 an A3 refrigerant, charge minimization while guaranteeing system performance throughout the season is a very important aspect to be investigated. The dynamic model was utilized to simulate performance of the system in heating mode, including dependence of the charge of the system. This was accomplished through a parametric study which used time dependent ambient and heating load conditions across a range of imposed system charges. The charge modulation has been accomplished by including a charge filling station on liquid line after the condenser, as shown in Fig.7. These conditions are embodied in Fig. 14 for the ambient condition in dependence of time during the dynamic simulation.

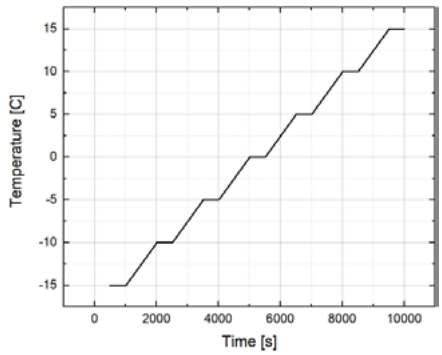

Fig. 14 Simulated heating season across a range of -15 ℃ to 15 ℃

The periods of steady temperature are taken from Fig. 4 in increments of 5 ℃. These were simulated across a range from -15 ℃ to 15 ℃ via a time dependent table interpolation. A curve fit of the heating load data from Fig. 4 allowed the calculation of the heating load at each point in time according to the ambient temperature. Finally, a total charge was imposed upon the system across each simulated heating season to find an optimal minimal charge that ensures system performance across the heating season while minimizing hazards of excessive charge inside the system. This study was conducted across a range of system charge from 0.1 kg to 0.6 kg.

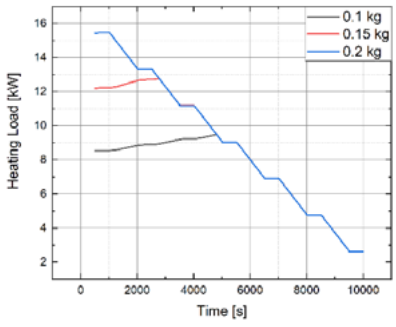

Fig. 15 Simulated heating performance in dependence of total system charge

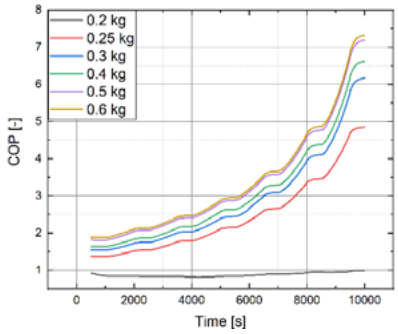

Fig. 16 Simulated heating COP in dependence of total system charge

The first criteria for the minimum charge required was to achieve the heating load determined by the ambient condition. As seen in **오류! 참조 원본을 찾을 수 없습니다.**, the system began to meet the heating demand at a system charge of 0.2 kg. This was taken as an absolute minimum charge, but the system COP, as shown in **오류! 참조 원본을 찾을 수 없습니다.**, indicated poor system performance at this charge amount. As expected, the system COP increased with increasing charge until diminishing returns were observed at higher amounts of system charge, serving as a maximum realistic amount of charge within the system. A system charge between 0.4 kg and 0.5 kg is clearly indicated as the optimal charge in the system, as an increase to 0.6 kg provided little benefit in system performance.

4. Conclusions and Recommendations

A multi-stage VI CCHP architecture using R-290 as the refrigerant has been proposed and was coupled to a novel EG secondary loop connected to a residential home. The target environment is the northern US, so TMY3 data from Boston, USA was utilized, and dry bulb temperature bins were developed for one year. A target heating capacity of 5 tons (17.58 kW) at -20 ℃ was chosen with a suggested balance point of 21.1 ℃

and 50% relative humidity indoor condition to provide a seasonal load profile. A dynamic modeling structure was developed and described, and the TMY temperatures were input. However, COP calculations using seasonal loads and temperatures were performed using a steady-state model with similar assumptions. These calculations were then used to provide both seasonal performance calculations for the proposed architecture as well as a reference parameters and results for further dynamic modeling development. The proposed cycle was able to achieve a SEER value of 14.1 and an HSPF of 10.1. Finally, charge minimization was performed with respect to system performance in terms of heating load demand and system COP to ensure both the performance and safety of the system to be constructed. A preliminary charge estimation of 0.45 kg to meet heating demand and moderate system COP was calculated. Future work is to repeat the seasonal calculations with the proposed dynamic model and further assess control algorithms and active charge management to leverage the dynamic modeling abilities. Furthermore, a potential prototype system is being developed for experimental validation.

Abstract

Power-to-heat-to-power systems are an interesting approach to deal with the intermittent power generation from renewable energy sources. However, storing heat requires large storage volume and associated heat losses decrease the system performance. High Temperature Heat Pump (HTHP) systems can operate during surplus power generation periods storing heat in a latent heat storage and discharge it to drive a heat engine for electricity generation. The presented work has been performed under the frame of the EU funded CHESTER project (www.chester-project.eu) in which the performance of this technology is assessed. This paper presents the experimental study of a HTHP which will be integrated into a Compressed Heat Energy STorage (CHEST) system. A Low Global Warming Potential (GWP) working fluid is implemented and the configuration cycle is selected to optimize the charging conditions of a latent heat storage. The operating temperatures of the HTHP are set from 72°C to 105°C in the heat source side. The heat sink temperature is set at 133°C that corresponds to the melting point of the phase change material.

1. Introduction

The amount of electricity produced by renewable energy systems in the EU reached 30% of the total gross electricity consumption in 2016. Hydro and wind power play a key role in the renewable power market contributing with 36.9% and 31.8% respectively of the total renewable power consumed [1]. However, the intermittent nature of renewable energy sources poses a challenge to overcome the successful coverage of the electricity network. Electricity storage systems are expensive and the existing technologies cannot satisfy the demand requirements of the grid at an affordable cost [2].

Other concepts of large-scale power storage systems are pumped hydro storage (PHS), compressed air energy storage (CAES), and pumped thermal electricity storage (PTES). PHS dominates the electricity storage market with 96% of the total stored capacity worldwide. It requires large water reservoirs and high height of elevation between the reservoirs. CAES is also depending on geographical characteristics of the area since it requires underground reservoirs [3]. PTES systems have been implemented in solar power systems being the second larger electricity storage technology [4]. Thermal storage presents lower cost than electricity storage systems and with an attractive life expectancy that can reach 10,000 cycles of operation [5].

E-mail address: Miguel.ramirez@tecnalia.com

PTES systems can present different configurations and various combination of systems have been proposed in the literature. A combination of heat pump, thermal storage and organic Rankine cycle (ORC) can results in high roundtrip efficiency when the heat source temperature of the heat pump is higher than the condensing temperature of the ORC. Roundtrip efficiencies can reach values equivalent to 1.3 for heat source temperatures from 80° to 110°C and using R-1233zd(E) as working fluid [6]. Another similar concept the called Compressed Heat Energy STorage (CHEST) system has presented power ratio values of 1.25 operating with 100°C heat source temperature and 15°C of heat sink in the ORC side [7].

2. The CHESTER project

The CHEST system of this study is a combination of Rankine cycles and a latent heat storage unit that can use either water or organic media as working fluid [5]. The system is activated via high temperature heat generated from low temperature heat via a thermal cycle (heat pump). The high temperature heat generated charges the latent heat thermal energy storage (LH-TES). Sensible heat could be also stored in a sensible heat thermal energy storage (SH-TES) to optimize the cycle. Then during power demand periods heat from both the LH-TES and SH-TES storages is discharged to drive a heat engine cycle, in this case is an organic Rankine cycle (ORC), to generate electricity. This is an attractive concept to operate when cheap electricity and low temperature heat is available to cover power demand during high demand periods.

The aim of the CHESTER project is to develop and validate via a small-scale CHEST system of 10kWe the possibility to store power in heat and to deliver it as power minimizing losses. This system is destinated to store excess power from the generation of RES into thermal storage systems and to deliver it as electricity when demanded. The four main sub-systems developed for the CHEST system are the HTHP, the LH-TES along with the SH-TES, the ORC, and an isobaric expansion engine that will minimize the power consumption of the ORC system. The schematic diagram presented in Fig. 1 shows the basic configuration of the system and heat and power flows.

The heat source temperature of the CHEST prototype ranges from 60 to 100°C and the LH-TES charging temperature is in the range of 133-145°C. Therefore, these temperatures are considered as the heat source and heat sink of the HTHP, respectively. For these high temperature operating conditions, specialized components must be implemented such as compressor, refrigerant, lubricant, expansion device and others.

On the ORC side the heat source temperature is designed to be 133-145°C. In the in the dissipation side the temperature of the sink is in the range between 10 to 40°C. The operation of the ORC cycle is not analyzed in this study.

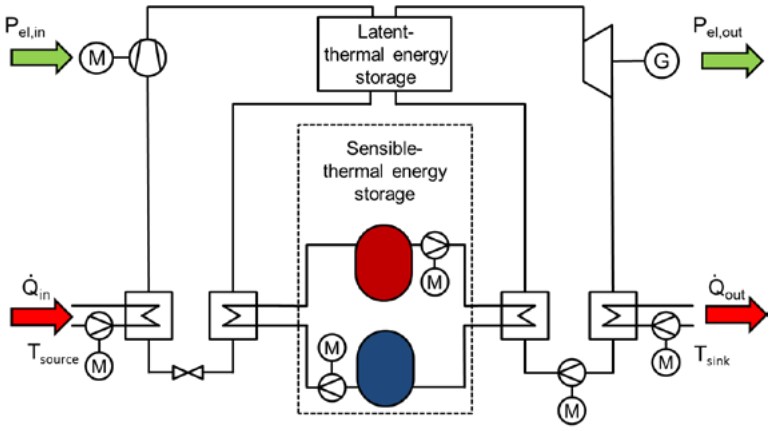

Fig. 1. Schematic diagram representing the CHEST system concept [8].

3. Testing method

For this study a water-to-water heat pump has been considered. Water flow temperatures can be controlled to simulate the operating conditions of the Chester project prototype. The water temperature is controlled in the source and both sink sides, the latent and the sensible.

The testing conditions and periods are selected according to the objectives of this study and the very high operating temperatures. Heat source water temperatures from 70° to 105°C are selected to obtain the performance curves at different temperature conditions of the source. In the sink side the water outlet temperature is maintained steady at approximately the melting point of the phase change material (133°C) and with the minimum experimentally possible temperature difference between inlet and outlet. In this way it is possible to simulate the operation of the HTHP during the charging of the LH-TES. In the subcooler the ΔT between the fluid inlet and outlet is maintained between 50 to 70 K by controlling the water inlet temperature. All water flow rates in the secondary circuits were maintained stable during each test.

During charging of the LH-TES the heat transfer coefficient will drop decreasing the capacity needed at the condensing. To match the heat pump´s heating capacity with the charging capacity of the LH-TES partial load can be applied. This is achieved via a speed drive (inverter) which controls the compressor speed and can drop the heating capacity of the heat pump. To measure the compressor capacity at part load conditions three compressor speeds were chosen for the testing campaign between 1000 to 1500 rpm.

It is also considered that the maximum operating temperature of some components in the liquid line is 80°C. Therefore, a secondary function of the subcooler was to cool the liquid leaving the condenser to protect the components in the liquid line. The subcooled water inlet temperature was controlled and set according to the subcooler refrigerant outlet temperature. The range of operating conditions are presented in Table 1.

Table 1. List of main components of the HTHP.

Parameters	Setpoint values
Compressor speed	1000, 1230, 1500rpm
Heat source inlet temperature	72, 82, 92, 105°C
Heat sink temperature	133-135°C
Superheating degree setpoint	8-10 K
ΔT Subcooler	50–70 K

4. Experimental setup

The characterization of the HTHP for the Chester project system has been performed in a water-to-water heat pump testing rig in TECNALIA's thermal energy laboratory facilities. This testing rig is used to test heat pump components for high temperature applications (up to 160°C) and heating capacities up to 300kW. The prototype has been manufactured according to safety regulations 2014/68/EU, EN 16084:2011 and EN 378:2016.

The HTHP prototype mainly comprises a compressor, a condenser, a subcooler, an expansion device, and a rack of evaporators. Additional auxiliary components are included in the refrigerant circuit in order to protect the main components and to operate the heat pump safely.

In the suction line, a suction separator is installed to ensure only refrigerant in vapor state is entering the compressor. At the discharge line, a muffler is installed to minimize pressure pulsations. After the condenser a liquid receiver is positioned to accumulate the liquid refrigerant during partial load operation. In the liquid line, a filter/drier is used to protect the expansion device from debris and to maintain the fluid dry. A solenoid valve is mounted to stop liquid migration into the evaporator during off-cycles. Finally, sight glasses are installed in both the suction and liquid lines to control visually the state of the fluid.

The working fluid charged in the circuit is the R-1233zd(E) which is a low GWP fluid and its critical temperature is 165.6°C [9], [10]. A compressor able to operate at very high temperatures has been selected. The compressor is the HBC511 model, manufactured by Viking Heat Engines and can operate at temperatures up to 215°C [11]. There is available study in the literature about the performance of the HBC511 compressor operating with other fluids such as HFO-1336mzz(Z) and R-245fa [12], but none with HCFO-1233zd(E).

Part of the pipelines of the refrigeration cycle and the heat exchangers were kept uninsulated or with removable insulation for visual control, thermography and material monitoring. This causes drop of the global performance of the system, however, the equipment and personnel safety are prioritized.

The list of the main components including the model and manufacturer is presented in Table 2 and the configuration of the proposed HTHP is presented in Fig. 3.

Table 2. List of main components of the HTHP.

Component	Manufacturer	Model
Compressor	Viking Heat Engine	HBC511
Inverter	Siemens	G120
Lubricant	Fuchs	SEZ320
Evaporator #1	SWEP	B80Hx30
Evaporator #2	SWEP	B120Tx30
Condenser	SWEP	B25THx50
Subcooler	SWEP	B86Hx57
Expansion device	Danfoss	ETS12.5
Liquid receiver	Bitzer	FS152
Suction accumulator	Emerson	A17
Discharge muffler	ESK	GDX
Filter/dryer	SANHUA	DTG/L

The secondary fluid circuits consist of four different closed water loops, for the condenser, the subcooler, the evaporators and for the compressor cooling system. The water loop of the condenser is connected to the laboratory cooling system which consists of a buffer tank of 1 m^3 volume, a water cooler, a three-way valve and a water pump driven by an inverter. The subcooler is connected to the medium temperature water loop of the laboratory which is cooled by a geothermal system. The water to the evaporators is heated by a gas boiler and the control is achieved via a secondary loop and a three-way valve. The water loop of the compressor cooling circuit is pumped via a small water pump of 35 W and the water is cooled in a copper pipe coil.

4.1. Monitoring and data logging

Temperature, pressure and flow rates values are measured by sensors in the refrigerant circuit and the four water loops. All data is logged every 1 second by the acquisition system of the laboratory and recorded in a

computer. The datalogging period is considered when the temperature, pressure and flow rate values have been in steady state for a minimum period of time of 10 minutes. The data stored in these periods is averaged and used for the data analysis.

The temperature values in the refrigerant circuit are measured with 4-wire RTD PT100 1/3 DIN sensors custom made by TC-direct. The sensors are positioned in stainless steel thermowells in a counter-current position at the inlet and outlet of each of the main components. Pressure is measured with pressure transducers SPKT*D made by Carel. Two different measure ranges are used depending on the location of measurement whether to be in low- or high-pressure side. Refrigerant mass flow rate is monitored by the Coriolis meter SITRANS FC410 made by SIEMENS.

The temperature in the water loop is measured by six 4-wire PT100 class 1/10 DIN sensors. They are inserted in thermowells at the water inlet and outlet lines of the heat exchangers. Flow rate of the water in the evaporator, condenser and subcooler is measured via three electromagnetic flow meters Sitrans MAG3100 sensors made by SIEMENS. The range of measurements of the sensors and their uncertainties are presented in Table 2.

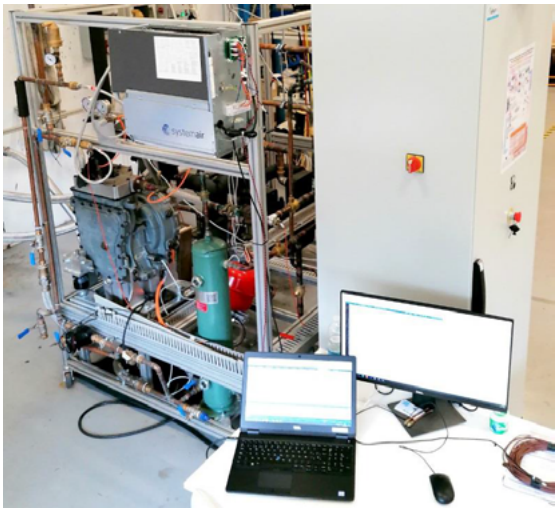

Fig. 2. View of the HTHP testing rig, control panel and datalogging equipment.

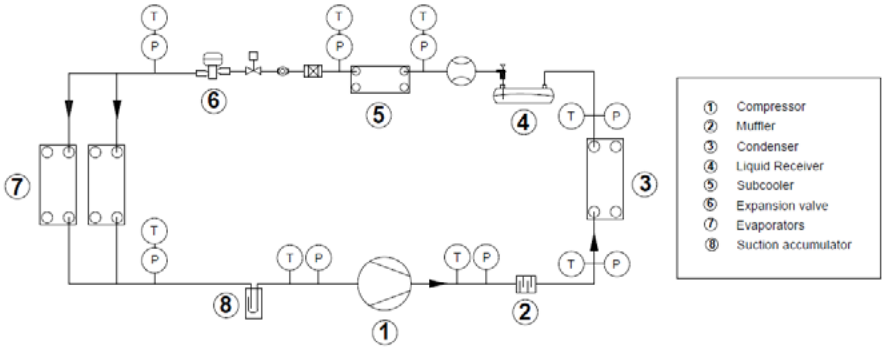

Fig. 3. Schematic diagram of the refrigerant cycle of the HTHP test bench.

Table 2. List of measurement ranges and uncertainties of the monitoring devices.

Measurement	Type	Range	Uncertainty
Temperature - water	PT100, 1/10 DIN	-50 +200°C	±(0.03 °C+0.5%)
Temperature - refrigerant	PT100, Class A	-50 +200°C	±(0.15 °C+0.2%)
Pressure	Transducer	-0.5 to 7 bar / 0 to 30 bar	±0.24% FS
Mass flow – water	Electromagnetic	5-100 l/min	±1.5% FS
Mass flow - refrigerant	Coriolis	20 to 6400 kg/h	0.1% FS
Power	Analyzer	10 to 520 VAC / 40 to 70 Hz	±1% FS

5. Experimental results

The results of the testing campaign are used to study the performance of the HTHP under the Chester system operating conditions and to evaluate the compressor´s performance. The obtained results are considered for the optimization of the HTHP prototype for its integration with the LH-TES and the SH-TES in a CHEST system.

The cooling capacity of the HTHP was calculated for both evaporators considering a single water inlet and outlet. The capacity of both in-parallel connected evaporators ranged from 27.5 to 68.6 kW. The superheating degree was set through the controlled at 8 K and the actual value measured ranged from 7.5 to 8.7 K. Water inlet and outlet temperatures in the evaporator ranged from 72 to 105°C and from 66 to 95°C respectively.

The function of the condenser in the CHEST system will be delivered by the phase change material within the LH-TES. The heating capacities values calculated in this study are used for the sizing of the storage systems. The heating capacity delivered to the condenser´s water loop was calculated between 12.1 kW and 42.3 kW. Water temperatures ranged from 123 to 128°C and 130 to 133.5 °C in the condenser inlet and outlet respectively. The average water temperature difference was approximately 5.5 K. The water pumps used limited the further drop of the temperature difference, therefore they will be substituted for the next testing campaign. In the refrigerant side the condenser inlet and outlet temperatures were measured between 143 to 133 °C and 135 to 132 °C, respectively. The subcooling at the condenser was calculated from 1 to 1.6 K.

The heat transferred to the water in the subcooler ranged from 10.8 to 29.2 kW at water outlet temperatures from 75.8 to 114.6 °C. The subcooling degree measured in the subcooler ranged from 50 to 68 K. The liquid refrigerant leaving the subcooler was maintained below 80 °C due to components' temperature limitations.

Water flow rate and pressure were maintained steady in all loops at 1.32, 0.93, and 0.19 kg/s in the evaporator, condenser and subcooler, respectively. The pressure in the water loops was maintained above 3 bar-g.

The evaporating temperatures and pressures for all tests ranged from 64.1 to 93.6 °C and 4.4 to 9.1 bar-a, respectively. Since the condensing temperature was fixed above 133 °C, the condensing pressure was very stable at approximately 20.4 bar-a.

It should be mentioned that the heat losses in the refrigeration cycle were very high due to poor insulation at the main sections of the piping, specially in the high-pressure side. The existing insulation material in the test bench had to be removed because it presented some irregularities due to high temperature operation such as outgassing and hardening. Furthermore, the vibrations coming from the compressor caused failure in the soldering and some parts of the pipeline were maintained uncovered for material monitoring purposes. This have caused considerable heat losses which are calculated to be between 10 to 26% of the heat produced. The heat transferred to the cooling water of the compressor crankcase is also included in the mentioned percentage and it has to be further evaluated.

In Fig. 4 the COP of the HTHP and power consumption are presented over the temperature lift which is the difference between the condensing and evaporating temperature. As expected, the highest COP value of 7.2 is seen during 1000 rpm speed and at low temperature lift. For 1230 and 1500 rpm the maximum values resulted in 6 and 5.4, respectively, under temperature lifts of approximately 30 K. The lowest COP values for the three compressor speeds were between 3.8 and 4.1 and are observed at temperature lift of 60 K, approximately.

According to the Chester prototype site requirements the compressor must operate consuming below 15 kWe of power (W_{in}). The results presented in Fig. 4 show that the power consumption of the HTHP, which consists of the compressor and inverter consumption, ranged from 5.5 to 13.2 kW. Therefore, the HTHP can run at any speed up to 1500rpm when integrated to the CHEST system.

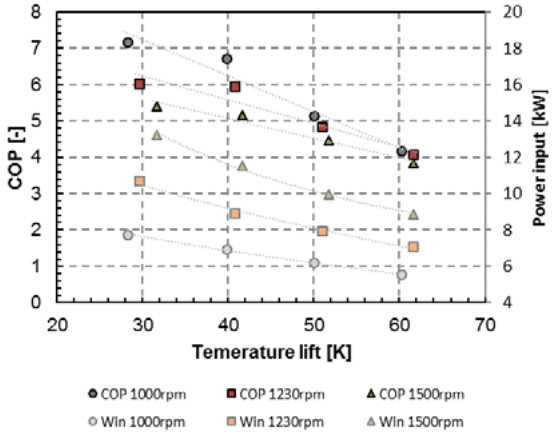

Fig. 4. Performance of the heat pump (COP) and the power consumed (W_{in}) by the compressor and inverter versus the temperature lift.

5.1. Compressor performance

The compressor suction and discharge temperatures ranged from 71.2 to 101.2 °C, and from 136.6 to 149.4 °C, respectively. The suction and discharge pressures ranged from 4.2 to 8.7 bar-a, and 20 to 21.9 bar-a, respectively. Fig. 5 presents the measured mass flow rates for each compressor speed over the evaporating temperature. The lowest mass flow rate was 0.14kg/s, which was measured at compressor speed of 1000 rpm. The mass flow rate increased with the compressor speed to 0.17 and 0.19 kg/s for 1230 and 1500 rpm, respectively. For speed of 1230 rpm the mass flow rate ranged from 0.17 to 0.36 kg/s and for compressor speeds of 1500 rpm the mass flow rate ranged from 0.19 to 0.40 kg/s.

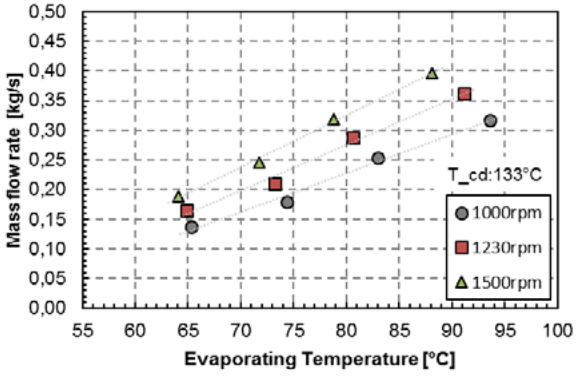

Fig. 5. Refrigerant mass flow rate values at condensing temperature 133°C.

The lowest pressure ratio was calculated at compressor speed of 1000 rpm and heat source of 72 °C. The maximum pressure ratio recorded was 4.9 at 1500 rpm and heat source temperature of 105 °C. The performance of the compressor is further evaluated through the isentropic and volumetric efficiencies. In Fig. 6 both the isentropic and volumetric efficiencies are presented over the pressure ratio. The isentropic efficiency was calculated by Equation 4. The highest value of the isentropic efficiency was 82.4% which corresponds to compressor speed of 1000 rpm and pressure ratio of 4.5. The lowest value is calculated for operation at 1500 rpm speed and pressure ratio of 2.9.

The volumetric efficiency was calculated by Equation 5 and the results ranged from 70.9 to 85.4%. The calculated points show a pattern that splits the values depending on the evaporating temperature and therefore on the mass flow rate.

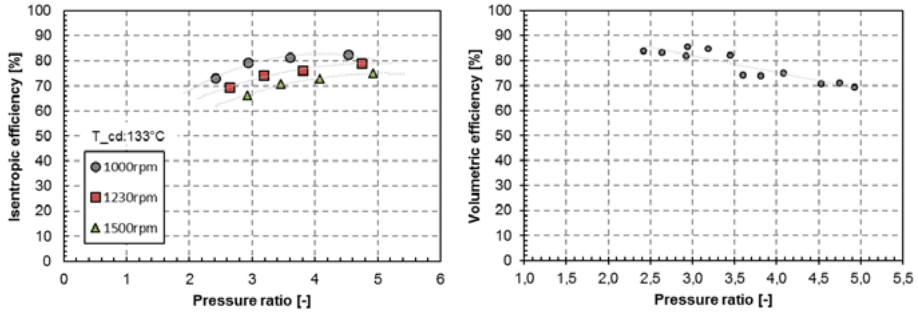

Fig. 6. The isentropic efficiency of the compression phase at different compression speeds (left); and the volumetric efficiency of the compressor (right).

In this study the main objective is to evaluate the performance of the compressor working with R-1233zd(E) to facilitate the selection of the main components of the CHEST system's HTHP. The COP of the HTHP was calculated using Equation 3 but the results are not used for characterization purposes of the testing bench due to the low quality of insulation used. Moreover, the evaporators have not been sized for this specific compressor, therefore, are not optimum for this configuration. However, the results of performance are promising, and they can be used for comparison purposes with future tests.

6. Data reduction and simulations

The presented results have been calculated using equations and calculation software packages such as Microsoft Excel and REFPROP [13]. Both the cooling and heating capacities of the HTHP were calculated using the Equations 1 and 2 described below.

$$Q_w = m_w \cdot c_{p,w} \cdot \Delta T_w \quad (1)$$

$$Q_r = m_r \cdot \Delta h_r \quad (2)$$

Where the heating/cooling capacity of the heat pump (Q_w) is the result of the water mass flow rate (m_w) by the specific heat capacity ($c_{p,w}$) by the temperature difference between the water inlet and outlet of the heat exchanger (ΔT_w). The heating/cooling capacity in the refrigerant side (Q_r) is the refrigerant mass flow rate (m_r) by the enthalpic difference (Δh_r) of the fluid between the inlet and outlet of the refrigerant in the heat exchangers.

The COP is calculated from the ratio of the sum of heating capacities in the condenser and subcooler (Q_{out}) over the power consumed (W_{in}). by both the compressor and the inverter (Equation 3)

$$COP = \frac{Q_{out}}{W_{in}} \quad (3)$$

The isentropic efficiency is calculated from the ratio of the enthalpy difference in the compression process assuming an isentropic compression to the experimental enthalpy difference of the compression stage as presented in Equation 4. The isentropic compression enthalpy is calculated from the difference between the isentropic enthalpy at the discharge ($h_{dis,is}$) and the enthalpy at the suction (h_{su}). The actual compression enthalpy is calculated by the difference between the actual enthalpy at the discharge (h_{dis}) and the enthalpy at the suction of the compressor.

$$\eta_{is} = \frac{h_{dis,is} - h_{su}}{h_{dis} - h_{su}} \quad (4)$$

The volumetric efficiency is calculated by Equation 5, and is the ratio of the refrigerant mass flow rate (m_r) by the specific volume at the suction (V_{su}), over the theoretical volume of gas displaced by the piston (V_{displ}) multiplied by the frequency per second and by the number of pistons (n). The volumetric displacement of the single piston compressor considered for this study is 511cm^3. The specific volume of the gas at the suction line is calculated using REFPROP [13].

$$\eta_{vol} = \frac{m_r . V_{su}}{V_{displ} \cdot (f/60) \cdot n} \quad (5)$$

7. Conclusions

The performance of a HTHP working with a low-GWP working fluid has been investigated. The HTHP is designed to be part of a CHEST system where its function is to charge a LH-TES at temperatures above 133°C. Additional sensible heat from the subcooler charges a SH-TES system resulting in a subcooling degree between 50-68 K.

Water was used as secondary fluid and the mass flow rates were maintained steady during the testing campaign. The water inlet temperatures set for the testing campaign ranged from 72°C to 105°C, and the condenser water outlet temperature ranged from 133 to 135°C. For each testing condition three compressor speeds were tested, 1000, 1230, and 1500rpm.

The capacity of both evaporators in parallel configuration was measured as a sum and ranged from 27.5 to 68.6 kW. The heating capacity delivered to the water in the condenser was estimated from 12.1 to 42.3 kW. The subcooler's heating capacity was calculated from 10.8 to 29.2 kW with a temperature difference in the water-side from 13 to 35 K.

Evaporating and condensing temperatures ranged from 64 to 94°C and 133 to 125.8 °C, respectively. The compressor suction temperatures ranged from 71.2 to 101.2 °C, and the discharge temperatures from 136.6 to 149.4 °C, respectively. The suction pressures ranged from 4.2 to 8.7 bar-a and the discharge pressures remained stable as expected between 20 to 21.9 bar-a. The superheating degree value resulted from 7.5 to 8.7 K and the total subcooling degree achieved in both the condenser and subcooler resulted from 50.7 to 69.4 K. Using the subcooler was crucial to protect the components in the liquid line and maintain them below their maximum operating temperatures (80°C).

The operating pressure ratios of the compressor were calculated from 2.4 to 4.9. The lowest compressor speed presented higher isentropic efficiency ranging from 73 to 82%. While for 1500 rpm, the isentropic efficiency ranged from 66 to 75%. The highest volumetric efficiency was 85% and was recorded under the 1000 rpm compressor speed at high pressure ratio conditions. However, the volumetric efficiency was weakly influenced by the compressor speed since the difference between the volumetric efficiency values resulted from 0.5-1.4% at each operating condition.

The COP of the HTHP tested resulted in values from 3.8 to 7.2. The maximum values were recorded as expected at the lower compressor speeds, 1000 rpm and 105 °C heat source temperature. The lowest performance values resulted under heat source temperature of 72 °C and temperature lift of 60 K.

Power consumption of the HTHP that consisted of the consumption of the compressor and the inverter was measured in the range of 5.5 to 13.2 kW. Since the power supply in the Chester prototype site is limited to 15kWe the results show that there is no limitation for any of the compressor speeds tested.

Finally, actualization of the control algorithm is necessary to control the operation range of the HTHP coupled to the CHEST system. Different operating modes will be implemented into the control and will be tested individually. In addition, further optimization of the thermal insulation of the refrigerant pipeline must be conducted to increase the efficiency of the cycle.

Abstract

Thermal storage systems use for district heating can improve their efficiency by decreasing their storage temperature and therefore minimizing heat losses and cost. A high temperature heat pump (HTHP) operating with heat source temperature between 30 °C to 50 °C can further optimize the performance of the system and deliver hot water above 70 °C at demand. In this study a HTHP that uses thermal energy produced by a solar thermal system and stored in a seasonal thermal storage has been developed, installed and experimentally investigated under real conditions. An additional challenge of the present work was to build the heat pump using off-the shelf components without further modifications. During two years of operation the water source temperatures measured were from 31 °C to 40 °C and the heating capacity resulted from 35 kW to 43.7 kW. The COP calculated resulted in values from 5.3 to 6 for pressure ratios between 2.3 to 2.8. The results demonstrated that HTHPs are an attractive approach to use low grade heat sources specially when produced by renewable energy sources.

1. Introduction

Seasonal thermal energy storage systems charged by solar thermal energy present a potential to provide heating for domestic applications. Large solar collector surfaces and large volume of storage accumulators can balance the seasonal mismatch during the year [1]. For thermal storage specially during the season, low temperature storage is preferable to minimize the heat losses during the year. Heat pumps are systems that can use low temperature heat source to produce high temperature water for space heating applications. In addition, heat pumps help the stratification of the storage tank by returning the source water colder [2]. In previous studies on heat pumps combined with seasonal thermal storage and gas boilers, results showed that heat pumps can provide between 49 to 67 % of the heating demand, while the direct discharge of the storage can cover between 33 to 39 % [3].

The performance of a heat pump as part of a combination of heating systems is maximized when is correctly integrated considering the thermal behavior of the system. The correct integration of the heat pump in the system has a greater impact on its performance than the COP of the heat pump itself [4]. Systems such as seasonal thermal storage charged by a solar thermal system present high temperature fluctuations during the year. For high fluctuation profiles between heat source and heat demand temperatures the capacity of the heat pump is recommended to be 60 % of the maximum hourly peak demand [5].

2. Description of the site

The heat pump prototype of this study is part of a seasonal thermal storage demonstration plant installed in Warsaw, Poland. The installation consists of a solar thermal collector field, a seasonal thermal energy storage tank (STES), a gas boiler, the heat pump and the heating load (building) as presented in Fig. 1. The solar thermal collector field's total area is 151 m^2 of flat plate collectors positioned on the ground. The thermal storage tank consists of a heavily insulated water tank with a total internal volume of 800 m^3. The building is part of a hospital with a total surface area of 793 m^2 in two-floors. The building´s heating system consists of a gas boiler of 92 kW heating capacity. Finally, the high temperature heat pump (HTHP) is a prototype that has been developed for this specific application. It is designed for nominal operating conditions of 30 °C evaporation and 75 °C condensing temperatures and a maximum heating capacity of 63 kW.

The solar collectors' field is located near the storage tank and heat is transferred using glycol as a medium. The HTHP is located in the underground floor of the building to heat. Heat from the STES tank is transferred to the building via underground insulated water pipes.

The operation of the system starts when the STES is charged with thermal energy via the solar collectors during high solar radiation periods. Thermal energy can then be stored in the seasonal thermal energy storage for long periods during the year, in order to be used to heat the building during the heating period (April – September).

In the heating season heat from the storage tank is directed to the building heating system by demand. Hot water from the storage tank is directed to the building via the underground piping and heat is transferred to the building´s heating water loop via heat exchangers. When the temperature of the hot water coming from the STES is below the temperature set by the heating system the water is directed to the heat pump. If the supply water temperature is below 45 °C then the HTHP is activated. The hot water produced by the heat pump is driven into a 1m^3 buffer to moderate its cycle periods. When the hot water temperature coming from the storage tank is not high enough for space heating neither for the heat pump operation (< 30 °C), then the gas boiler is activated to cover the heating demand.

The heating water supply temperature and flow conditions are set by the control algorithm of the building´s heating system and gas boiler. The mass flow rate in the sink side is set at 1.08 lt/s, which is the maximum flow rate that the gas boiler can operate. The building heating requirements is 82.8 kW with a maximum supply and return water temperatures of 75 °C and 56 °C.

The operation of the heat pump prototype during the testing campaign is fully dependent on the environmental conditions, the heat stored in the storage tank and the heating demand. The water supply temperature is defined by the control algorithm of the building´s heating system. Therefore, the ON/OFF cycles of the heat pump are conditioned to the heating capacity stored into the buffer tank and the heating demand.

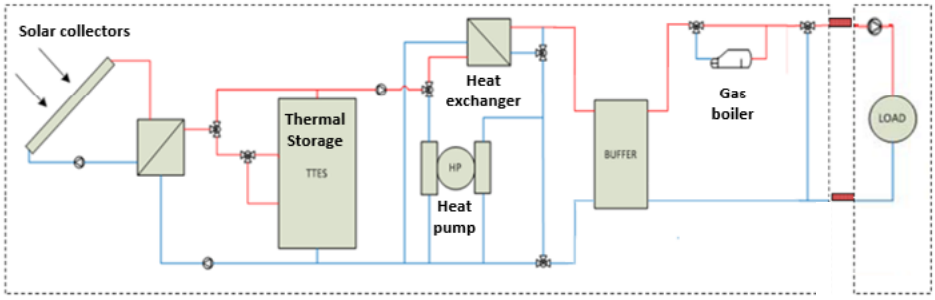

Fig. 1. Schematic diagram of the demo site in which the HTHP is installed, showing the configuration between the solar thermal field, the STES, the HTHP, the buffer tank, the gas boiler and the load.

3. Heat pump description

The HTHP prototype is a single loop water-to-water heat pump equipped a reciprocating compressor. The main components of the refrigeration cycle consist of the compressor, the condenser, a liquid receiver, the expansion device, and the evaporator as shown in Fig. 2. The safety equipment and auxiliary components consists of a suction accumulator, an oil separator, a filter/drier, two sight-glasses and block valves. The suction accumulator and the oil separator are positioned in the suction and discharge line respectively. The liquid receiver is installed between the condenser and the expansion device.

The compressor used in this prototype is the semi-hermetic reciprocating compressor 6MU-40X made by Copeland. It is a six cylinders compressor with bore 80.6mm, stroke 57.5 mm and 153 m^3/h volumetric displacement. The maximum suction and discharge pressures are 22.5 bar-g and 32.5 bar-g. The compressor is charged with 3.3 lt of POE ISO46 lubricant. The expansion device installed is an electronic expansion valve (EEV) ETS25 made by Danfoss. It is equipped with a stepper motor of 160 steps and it is controlled via an electronic control (EKD316). The evaporator is the brazed plate heat exchanger B120Tx90 made by SWEP and it has a heat transfer surface area of 6.19 m^2. The condenser is the V200Tx50 also a brazed plate heat exchanger made by SWEP with a surface area of 11.6 m^2.

The working fluid used in this prototype is the 1,1,1,3,3-pentafluoropropane (R-245fa). This fluid is a non-flammable HFC normally used for organic Rankine cycle applications. It has a boiling point of 15.3 °C and critical point of 153,8 °C [6]. It belongs to B1 category of ASHRAE 34-2013 [7]. It has a global warming potential (GWP) of 1030. [8]

3.1. Methodology and data monitoring

The data collected and used for this work belongs to a period of 12 months of operation. During the datalogging period the HTHP operated for a total of 9934 minutes which consisted in 209 operation cycles. The duration of the cycles ranged from 13 minutes to 10 hours and 40 minutes of continuous operation. All monitored values are measured and recorded every 30 seconds for 24 hours per day.

For the data analysis the data logged is filtered and only operation cycles with steady source and supply water temperatures are considered. Data belonging to the start-up period of approximately 5 minutes and the last 1 minute of every cycle is not considered in this analysis. In addition, cycles lower than 20 minutes of duration are not considered in this study due to their unstable performance. Average values of temperature, pressure, power and flow measurements are calculated and analyzed.

Fig. 2 shows the location of the sensors in both the refrigerant and water cycles. Temperature in both the refrigerant and water circuits are measured using 4-wire PT100 type “A” sensors. The temperature sensors in the water side are intrusive type inserted within the water pipes at the inlet and outlet ports of the heat exchangers. The temperature sensors of the refrigerant cycle are mounted on the surface of the copper pipeline at the inlet and outlet of the main components. The refrigerant pressure is measured by pressure transducers mounted at the inlet and outlet of the main components via Schrader access ports. The sensors output signal is 4-20 mA and require a supply voltage of 24 Vdc. There are two models of sensors mounted on the circuit of

different measurement range, the PT5-07 and PT5-18 both made by ALCO Emerson, both have a measurement error of ≤±1 % FS.

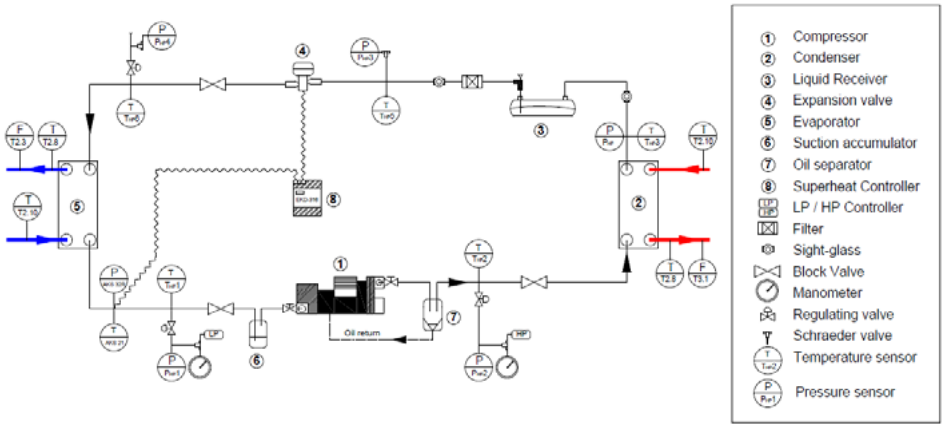

Fig. 2. Schematic diagram of the heat pump prototype presenting the configuration, the main components and the data measuring points.

The water flow rate in both the heat source and heat sink is measured by two electromagnetic ENDRESS HAUSER flow meters. The output signal is 4-20 mA and the maximum operating temperature is 225 °C with an accuracy of ±0.5 % of reading. The energy consumed by the compressor is measured by an energy meter connected to the power supply within the electrical power box. In addition, voltage and current of the compressor power supply are also measured in all three phases.

4. Experimental results

During the 12 months of monitoring the seasonal storage tank temperature ranged from 60 °C at the beginning of September to 25 °C in January. From January to April the temperature of the water in the tank remained low and was not used. After April the solar radiation increased and the charging of the storage tank continued.

In Fig. 1 are presented the water source and sink temperatures during the heat pump operation. The water source temperature variated between 31.2 °C to 39.9 °C and the water outlet in the condenser from 46.2 °C to 54.5 °C. The temperature difference between the water inlet and outlet of the evaporator and condenser was calculated from 5.2 K to 7.1 K and 5.4 K to 6.8 K respectively. Both water pumps in the evaporator and condenser loop were maintained at steady speed. However, the flow rate fluctuated slightly during the monitoring period, from 1.25 to 1.33 kg/s in the evaporator and from 1.52 to 1.56 kg/s in the condenser.

The cooling and heating capacity were calculated from the measurements of mass flow rate and temperature in the water cycles as presented in Equation 1.

$$Q_w = m_w \cdot c_{p,w} \cdot \Delta T_w \quad (1)$$

In the evaporator the capacity transferred from the storage tank water to the refrigerant ranged between 29 up to 37.1 kW as presented in Fig 3. On the condenser side the minimum and maximum heating capacity was calculated 34.9 and 43.7 kW respectively.

The variation of the water source and sink side temperatures was approximately between 8.3-8.7 K, which resulted in a small range of operation conditions. Three points were selected to present the lowest and highest performance values. In Table 1 are presented three operating cycles that correspond to minimum and maximum source temperatures recorded (31.2 and 39.9 °C). The data from the operation during the maximum temperature lift (31.3 K) is also presented, which is calculated from the difference between the condensing and evaporating temperature.

Table 1. Experimental results from selected operating cycles.

			Tw,ev,i		ΔT_lift
			Min	Max	Max
Evaporator	Water inlet	°C	31,24	39,93	36,03
	Water outlet	°C	26,02	32,81	30,12
	Water flow	kg/s	1,33	1,25	1,31
	Evaporating temp.	°C	18,94	25,82	22,07
	Evaporating press.	bar-a	1,18	1,53	1,33
Condenser	Water outlet	°C	47,60	54,53	52,39
	Water inlet	°C	42,24	47,75	46,42
	Water flow	Kg/s	1,56	1,54	1,52
	Condensing temp.	°C	48,6	55,64	54,44
	Condensing press.	bar-a	3,19	3,9	3,7
Temperature lift		K	29,7	29,9	31,4

The refrigerant evaporating and condensing temperatures were calculated via REFPROP software [9] using as input values the low and high side pressures. The evaporating temperature and pressure ranged from 18.9 °C to 25.8 °C and 1.18 bar-a to 1.53 bar-a respectively. The condensing temperature and pressure resulted from 47.3 °C to 55.64 °C and 3.05 bar-a to 3.9 bar-a respectively. The pressure ratio calculated from the ratio of the absolute evaporating and condensing pressures resulted between 2.3 to 2.8.

The superheating degree at the suction line was controlled by the superheat controller of the EEV. It was set at higher value than in conventional systems due to the risk of saturation in the compressor´s suction port. The superheating and subcooling degree values ranged from 7.7 to 13 K and 7 to 9 K respectively.

Figure 4, shows the pressure enthalpy diagram of the cycles presented in Table 1. The green and red lines correspond to the operation during minimum and maximum source temperature. The blue line corresponds to the highest temperature lift recorded.

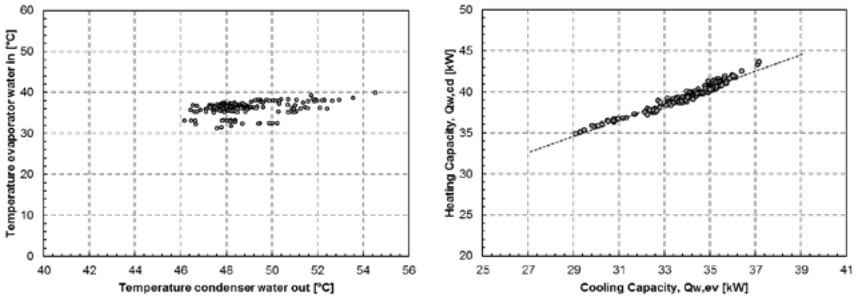

Fig. 3. Graphs of the temperatures of heat source and heat sink (left) and the heating capacity over the cooling capacity (right).

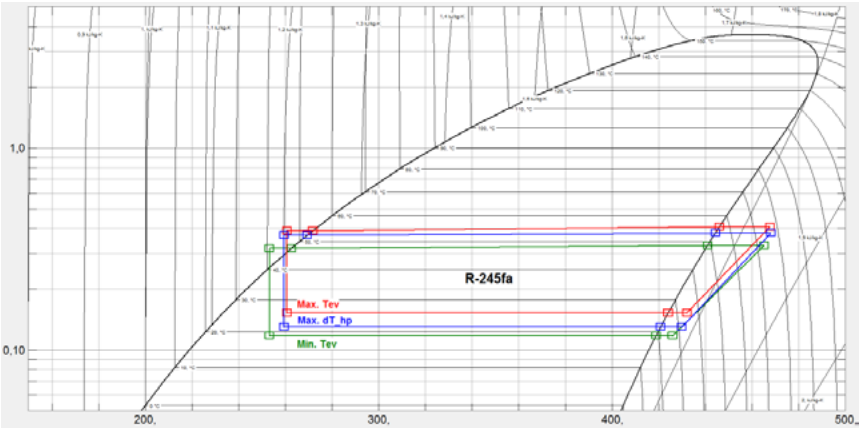

Fig. 4. Pressure and enthalpy diagram of R-245fa showing the operation of the HTHP under the conditions presented in Table 1.

During the monitoring campaign the speed of the compressor was maintained steady at 1500 rpm. The minimum and maximum suction and discharge temperatures recorded ranged from 26.8 °C and 35.3 °C to 72.2 °C to 77.3 °C respectively. The suction and discharge pressure ranged from 1.2 bar-a to 1.5 bar-a and 3.2 bar-a to 4.1 bar-a respectively. The power consumed by the compressor was measured in the range from 6.3 kW to 7.8 kW.

To evaluate the compressor performance the isentropic and volumetric efficiencies were calculated using Equations 1 and 2. The isentropic efficiency presents the ireversibilities during compression. The volumetric efficiency is the ratio of the volumetric flow rate over the volumetric displacement of the compressor. The volume in the suction (V_{su}) is calculated by REFPROP. The mass flow rate (m_r) is calculated from the ratio of the heating capacity at the condenser over the enthalpy difference between the refrigerant inlet and outlet in the condenser (Equation 3). The volumetric displacement (V_{displ}) is provided by the compressor manufacturer, the frequency (f) is 1500 rpm and the number of pistons (n) is six.

The minimum and maximum isentropic efficiency resulted from 45 % to 51 %. The volumetric efficiency was almost stable and ranged from 56 % to 58 % as shown in Figure 4 (left) in which are presented both efficiencies over the pressure ratio.

$$\eta_{is} = \frac{h_{dis,is} - h_{su}}{h_{dis} - h_{su}} \quad (1)$$

$$\eta_{vol} = \frac{m_r . V_{su}}{V_{displ} \cdot (f/60) \cdot n} \quad (2)$$

$$\dot{m}_r = \frac{Q_{w,cd}}{\Delta h_{cd}} \quad (3)$$

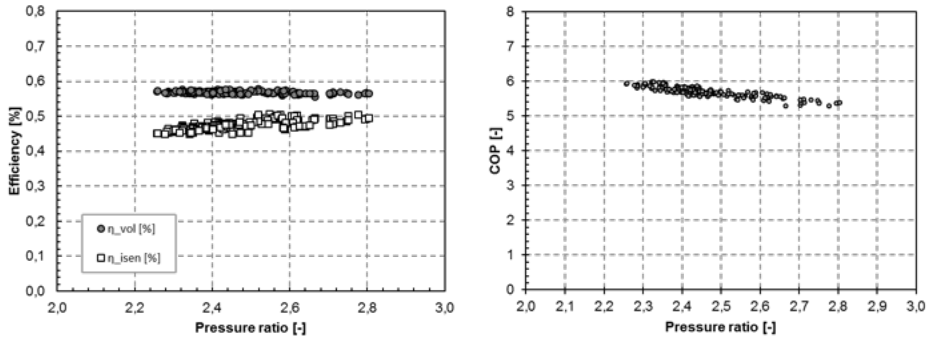

Fig. 4. Diagram of the isentropic and volumetric efficiencies over the pressure ratio (left) and the COP values of the HTHP over the pressure ratio (right).

The low isentropic efficiency values show that ireversibilities and losses are considerable under these operating conditions. Low temperature lift and overheating of the compressor could also be the causes of this inefficiencies. It is also observed that the volumetric efficiency is low. The low evaporating temperature and pressure conditions reduce the density of the fluid, reducing also the volumetric flow rate.

The COP of the heat pump was calculated by the ratio of the heating capacity by the power consumed by the heat pump (Equation 4). The results present a short range of values due to the also small range of operating conditions. The minimum and maximum calculated COP values resulted in 5.3 and 6 respectively. The power consumed by the compressor resulted from 6.3 kW to 7.8 kW. In Figure 4 (right) are presented the COP values over the pressure ratio of the heat pump.

$$COP = \frac{Heating\ Cap}{Power\ input} = \frac{Q_{out}}{W_{in}} \quad (4)$$

The total amount of energy stored in the seasonal storage during the datalogging period was 55.44MWh from which 34 % were lost through heat losses. The total amount of thermal energy delivered from the storage to the HTHP was 18.23 MWh and to the building 18.46 MWh. The total amount of energy consumed by the building for heating was 112.32 MWh in one year, from which 16.4 % was covered by the heat directly supplied from the seasonal thermal storage, 19 % was covered by the HTHP and 64.6 % was produced by the gas boiler. The total amount of electricity consumed by the compressor resulted in 3.73 MWh.

From the ratio of the total energy supplied to the building to the total energy consumption the Seasonal Energy Efficiency Ratio (SEER) was calculated 5.73.

According to the European Environment Agency from data of 2016, the emissions related to electricity generation are equivalent to 0.773 grams of CO_2eq per kWh [10]. The heat pump´s electricity consumption is equivalent to 2.88 tonnes CO_2eq per year. The emissions that have been saved by the heat pump considering a gas boiler instead would be 4.3 tCO_2eq per year. Therefore, total emissions of 1.42 tCO_2eq are saved by the HTHP during the year of operation. On the other hand, the emissions that saved from the heat provided by the seasonal thermal storage to the building are 3.72 tCO_2eq considering that gas boiler would be the heat source. In total the saved emissions of the full installation are 5.14 tCO_2eq in one year of operation.

5. Conclusions

The experimental data of one year of operation of a water-to-water high temperature heat pump which used heat from a STES tank to provide heat to a hospital has been presented. The HTHP was designed and manufactured using off-the-shelf components. The design operating temperatures are between 30-45 °C in the heat source side and up to 75 °C in the sink side. The working fluid used is R-245fa and the secondary fluid in both loops, the evaporator and condenser is water. The hot water produced by the heat pump is directed to a buffer tank of 1 m^3 internal volume and then delivered to the heating water grid.

Data was collected for a period of 12 months of the system´s operation. During this period the heat pump operated for a total of 9934 minutes which consisted in 209 operation cycles. The monitored values were measured and recorded every 30 seconds for 24 hours per day.

The water source temperature variated between 31.2°C to 39.9°C and the water outlet in the condenser from 46.2°C to 54.5°C. Both water pumps in the evaporator and condenser loop were maintained at steady speed and presented flow rates between 1.25 to 1.33 kg/s in the evaporator and from 1.52 to 1.56 kg/s in the condenser. The heating capacity of the heat pump variated between 34.9 kW and 43.7 kW.

The evaporating temperature and pressure ranged from 18.9°C to 25.8°C and 1.18 bar-a to 1.53 bar-a respectively. The condensing temperature and pressure resulted from 47.3°C to 55.64°C and 3.05 bar-a to 3.9 bar-a respectively. The pressure ratio calculated variated between 2.3 to 2.8.

The compressor´s isentropic efficiency resulted in values between 45 % and 51 %. The volumetric efficiency presented stable values that ranged from 56 % to 58 %. The compressor presented low performance due to the losses related to the high temperature operation. In addition, the fluid conditions at the suction line present low density which could be improved by increasing the evaporation temperature. The power consumption of he compressor resulted from 6.3 to 7.8 kW and the COP of the heat pump variated between 5.3 and 6.

In terms of the demo system, the total amount of energy stored in the seasonal storage during resulted in 55.44 MWh from which 34 % were lost through heat losses. The heat delivered by the seasonal thermal storage to the building corresponded to the 50.3 % and to the heat pump the 49.7 % of the total heat delivered. The total heat demand of the building was 112.32 MWh in one year, from which 16.4 % was covered by the heat directly supplied from the seasonal thermal storage, 19 % by the HTHP and 64.6 % was delivered by the gas boiler.

The total saved emissions from the heat pump operation comparing to a gas boiler operation in Poland are 1.42 tCO_2eq. The combined emissions saved from the heat delivered by both the heat pump and the thermal storage are 5.14 tCO_2eq in one year.

It is concluded that improvements on the control algorithm will certainly increase the seasonal performance of the heat pump and of the installation. During the operation cycles the heating water outlet temperature was controlled by the building´s control algorithm. The temperature of the buffer tank could not exceed the temperature set by the control causing short cycling of the heat pump.

The experimental results have demonstrated that HTHP systems are an attractive approach to use when low temperature heat source is available. In cases where the heat source is produced by renewable energy sources it could further improve the efficiency and the carbon footprint of the system.

Abstract

One of the most common factors affecting the performance of brazed plate heat exchangers (BPHE) is the not uniform distribution of the refrigerant. This problem is especially important in the evaporator as the refrigerant enters in it in two phase flow and usually the distribution of liquid and vapor is not uniform over all the channels. This problem is very well known in the literature, and manufacturers have implemented some technical solutions like introducing distributors in the inlet port in order to minimize this effect. Nevertheless, the applied solutions usually are developed only for nominal conditions and the deviations in other conditions are normally not known. In this contribution, an experimental analysis of the refrigerant distribution in an evaporator BPHE as a function of the inlet and outlet conditions will be presented. BPHE has been tested and evaluated working at several inlet conditions (quality) and outlet conditions, the refrigerant distribution inside the BPHE has been registered using thermography. From this analysis an estimation of the influence of the refrigerant maldistribution in the system performance has been obtained.

1. Introduction

The use of braze plate heat exchangers (BPHEs) for two-phase flow boiling was increasingly investigated within the last 10-15 years with the intention of using the high compactness and efficiency. Maldistribution was quickly observed as higher demands and bigger heat exchangers were needed. In that sense, BPHE evaporators are very sensitive to uneven distribution of the refrigerant among the different plates because of the fact of having two phase flow in their inlet port. As a consequence of that, the heat transfer can be highly degraded affecting significantly to the global system performance.

The precise determination of the real refrigerant mass flow in each plate is difficult but some research has been done in the qualitative estimation of it based on infrared thermography. This technic can be applied because of the fact that the refrigerant/water temperature in each plate would have a different profile depending on the vapor/liquid refrigerant distribution in each channel.

From the early literature on the plates arrangements on flow distribution is presented by boasiouny et al [1, 2] where results indicate that manifold diameter and number of channels have great influence in maldistribution. Maldistribution causes higher or lower thermal performance degradation depending on if it is a U-type or Z-type heat exchanger. Z-type plate arrangement have more tendency to suffer maldistribution, see Tonon et al. [3].

The quality distribution in heat exchanger manifolds were investigated by Vist et al. [4] and thermal performance can be reduced due to liquid/vapor maldistribution. From their observations, vapor is taken out

in the first channels when the inlet quality was low (x=0.11) but distributes evenly in the first channels when quality increased. However, no mention about the superheat in the evaporator is made.

Mass flow, flow pattern and inlet quality are variables to take into account to have mass flow evenly distributed within the channels. For high mass flow and low inlet quality, better distribution is mentioned by many researchers [5,6]. However, depending on the flow pattern better or less distribution is observed. Flow visualization before entering the evaporator recognized two patterns: churn and separated flow. Churn flow is recommended as liquid and vapor phase are homogeneously mixed whereas in separated flow, the different layers of vapor and liquid, according to Zou et al., are perfectly separated [7].

For microchannel heat exchangers, Elbel et al. [8] proposed an improvement for achieving better refrigerant distribution. The solution consisted in remove flash gas; vapor phase is separated from liquid phase after the expansion valve. In this way, only liquid is flowing within the microchannel heat exchanger while the vapor phase is being bypassed. Thermography pictures showed clear more uniformly distributed superheat with this flash gas removal system. Furthermore, better system performance was observed when using the separation device. Although quality maldistribution can be reduced in some cases introducing some modifications in the inlet, Tou et al. [9] reported that the outlet header pressure drop can have an influence in the mass flow rate maldistribution from tube to tube.

As mentioned before, infrared thermography has been used in order to study this phenomenon. It has the advantadge of being non-intrusive and non-contacting, which makes this technic easy to apply. In the works of Bowers et al, or Longo [10, 11] used thermography in microchannel heat exchangers to visualize the two-phase flow region for different outlet vapour qualities and superheats of 5 and 10 K and to outline a methodology to quantify both refrigerant maldistribution and effective usage of the heat exchanger respectively.

Regarding BPHE, although the problem is known [6] and some solutions has been adopted by the main manufacturers in order to achieve a better refrigerant distribution, see for instance [12] where a system that feeds homogenously with refrigerant all channels has been developed or the introduction of what is call equalancer distributor in order to improve the refrigerant distribution [13], from the practical point of view, there is not a final totally satisfactory solution for this problem. In fact, the intrinsic design characteristics of this type heat exchanger made that the analysis of the refrigerant distribution more difficult to carry on and the detailed examination of the maldistribution from the experimental point of view is challenging. This has made that the amount of information in the open literature of this kind of phenomena for this type of heat exchanger is significantly less than for other heat exchangers like tube and fin or microchannel heat exchangers.

In this paper, the refrigerant maldistribution problem in BPHEs is going to be analyzed as a function of different operation parameters like evaporator inlet quality, evaporator superheat and water temperature difference. The analysis has included a wide test campaign in which the refrigerant distribution in the evaporator has been characterized at different working conditions using infrared thermography. Later on the influence of the refrigerant maldistribution in the system performance has been evaluated in such a way that the influence of this type of problem can be quantified.

2. Experimental Set-up

The test bench for the characterization of water to water heat pumps was used. The test bench was able to control the water mass flow through the evaporator and the condenser in such a way that it allows maintaining a constant water temperature difference at a constant inlet water temperature in both heat exchangers. In this test bench a heat pump able to control its operational subcooling and superheat has been installed. The scheme of the heat pump is shown in figure 1. Between the condenser and the liquid receiver there is throttling valve, this valve allows the control of the subcooling at the outlet of the condenser. Its operation principle is shown in figure 1b, in steady state conditions, the liquid receiver must be in saturated conditions, this fact produces that changing the pressure drop introduced by the throttling valve, the system is able to control the amount of refrigerant inside the liquid receiver and the heat pump subcooling. In order to measure the subcooling, it was made measuring the temperature and the pressure at the outlet of the condenser. Between the liquid receiver and the evaporator there is an electronic expansion valve which allow the control of superheat. In a similar way the determination of superheat was done measuring the temperature and the pressure at the compressor inlet, it was assumed that the pipe from the evaporator to the compressor was short enough in order to assume that these conditions would be the conditions at the evaporator outlet. This experimental set up allows the stable control of the vapor quality at the evaporator inlet (subcooling at a condensing temperature) and the superheat at the evaporator outlet.

The system topology shown in figure 1 only allows working in stable conditions at superheats higher than 5K. In order to work in saturated conditions, the heat pump shown in Figure 1 has been modified.

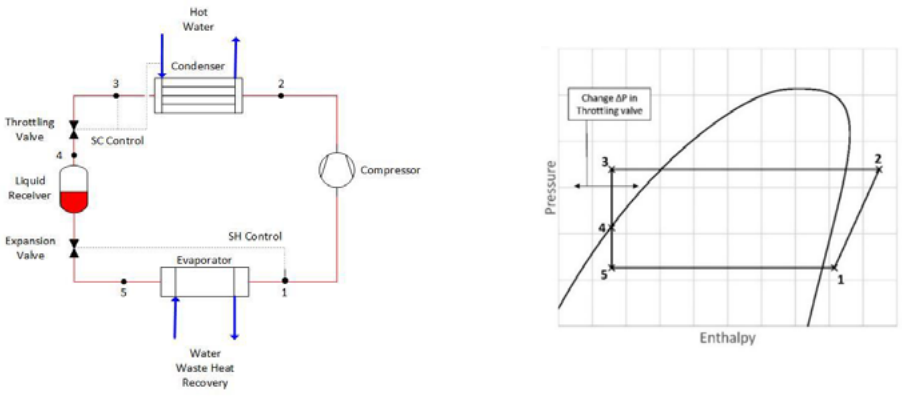

Figure 1. Mode 1 configuration system lay-out and refrigerant cycle

Figure 2 shows the other working alternative which allows working with 0 K superheat. In this configuration, a by pass system has been installed in the heat pump in such a way that the liquid receiver is placed at the outlet of the evaporator

the expansion valve is dedicated to control the subcooling at the expense of losing the superheat control which is fixed to 0 K. In this sense, the liquid receiver is placed at the outlet of the evaporator (point 5) ensuring saturated vapor conditions at compressor inlet (zero superheat). The expansion valve is removed from the system and therefore the superheat will be not controlled and the only heat pump control is related to the subcooling.

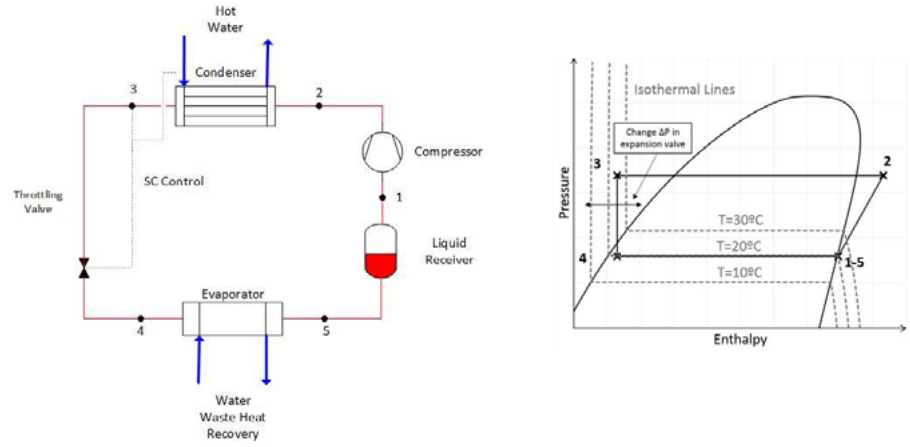

Figure 2. Mode 2 configuration: system lay-out and refrigerant cycle

Figure 3 shows a scheme of the test unit with all the instrumentation used. The green box corresponds to the BHPE evaporator. The main characteristic of it are 120 plates, capacity of 40 kW capacity at the nominal point, a horizontal port distance and vertical port distance of 50 mm and 466 mm respectively resulting a 6 m^2 heat transfer area.

There is a water loop in the condenser and in the evaporator, each water loop has a temperature sensor at the inlet and outler of the water side and have a Coriolis mass flow meter to measure the water mass flow rate. The water pumps of each circuit are equipped with an inverter which adjusts the water mass flowrate in such a way that the water temperature difference can be maintained as constant. These two water loops are connected to a third one which allows to control the water temperature inlet in both heat exchangers. More detailed information about this system can be found in [14].

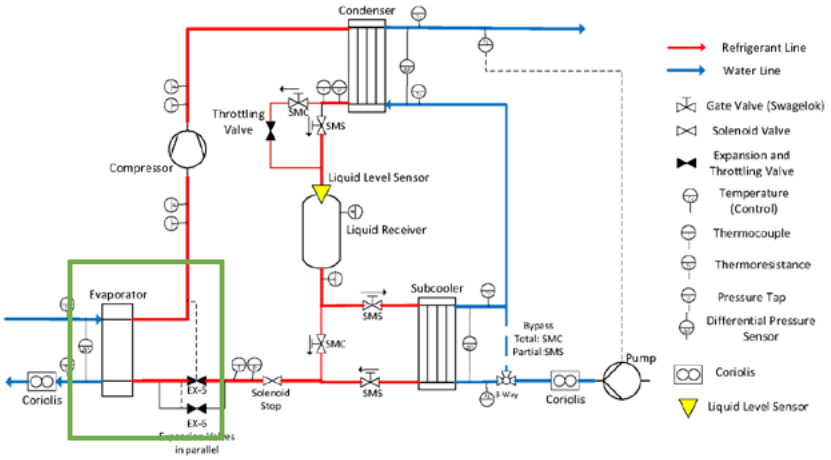

Figure 3. Propane Water-to-water heat pump in which the refrigerant distribution in the evaporator has been tested.

Regarding the refrigerant circuit, two temperature sensors are placed in each inlet and outlet of both heat exchangers. Three Rosemount sensors are installed in the refrigerant side, at the compressor inlet and outlet and in the liquid receiver. The last pressure sensor constitutes a way to verify the subcooling value. The mass flow rate in the refrigerant side is determined by means of a heat balance between the water side and the refrigerant side. In order to monitor and measure the parameters on the BHPE, all the sensors were connected to a data acquisition system "Agilent 34970A", where all parameters were monitored. The relative and absolute accuracy of each device are shown table 1.

Table 1. Instrumentation used in the test rig

	Model	Relative accuracy	Absolute accuracy
Pressure	P 1151 Smart GP7 Rosemount	0.12 % of Span	0.03
	P 1151 Smart GP8 Rosemount	0.15 % of Span	0.08
	P 3051 TG3 Rosemount	0.14 % of Span	0.04
Temperature	RTD Class 1/10 DIN		0.06
Mass Flow	Coriolis SITRANS F C MASS 2100	0.3 % of Reading	
Thermography Cam	FLIR P640	0.3%	2ºC

To register the refrigerant distribution, the surface of the evaporator is been photographed using the camera FLIR P640 infrared camera. The accuracy of the camera is shown in table 1, it should be also commented that although the estimation of the exact temperature has a higher error than an RTD, the sensibility of the camera is of 30mK, therefore although quantitative test could present significative deviations from the reality, under the proper, the camera would be able to supply a qualitative representation of the heat transfer process in the BPHE. The IR camera was set to a measuring range of -40 to 120ºC.

Figure 3 shows a transversal picture of the evaporator installed in the system and a frontal view with the location of the refrigerant and water inlet/outlet ports. As it can be seen in the picture, the transversal side of the evaporator was covered with a non-reflective painting in order avoid any possible dispersion derived from undesired environmental radiation reflections.

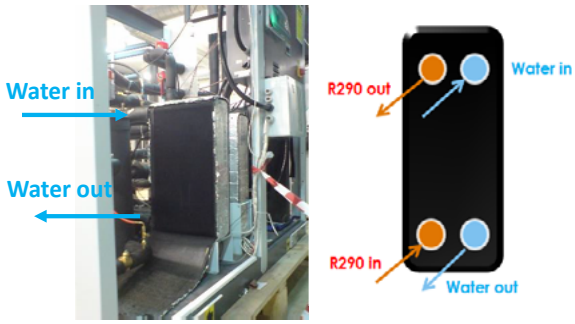

Figure 3. Picture of a frontal view of the evaporator and a transversal view with the location of the inlet/outlet ports

With this experimental setup and after the pre-evaluation and literature research on the relevant aspects that could affect the refrigerant distribution in the evaporator, the points represented in the test matrix shown in figure 4 where measured. The refrigerant distribution in the evaporator was evaluated for evaporator outlet superheat (SH) from 0 K to 15 K and the evaporator inlet quality (x) for a water temperature difference in the evaporator of dT_water=5 K and dT_water=13 K with a water inlet temperature of 20ºC.

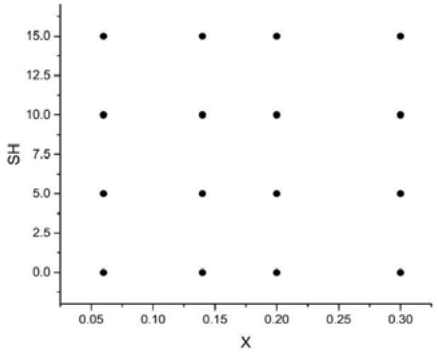

Figure 4. Experimental measures points for dTwater= 5 K and dTwater= 13 K

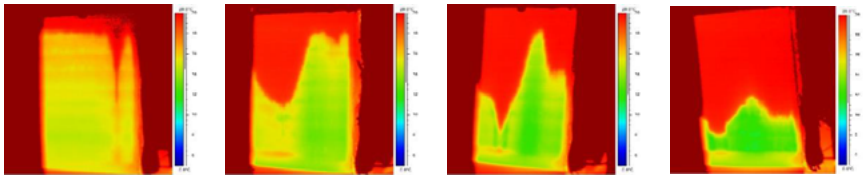
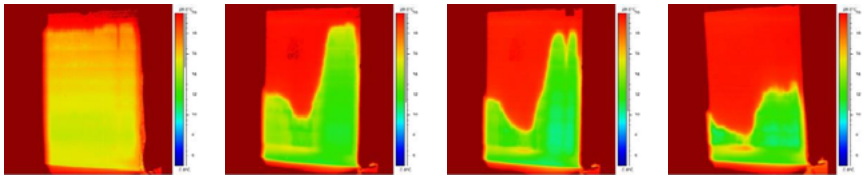
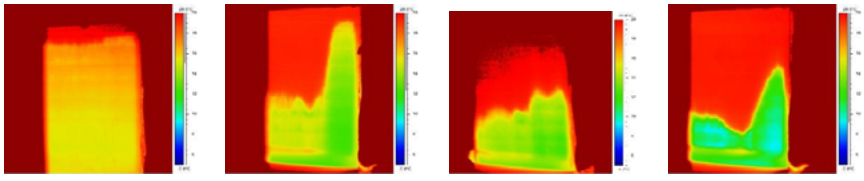
3. Obtained Results

Table 2 and table 3 shows the corresponding IR thermographies for a water temperature difference of 5 K and 15 K respectively. They are given in tables in the corresponding order of superheats. The minimum temperature of the scale is set to -6ºC and the maximum to 20ºC. The same scale is maintained for both sets of data in order to be able to stablish comparisons among them.

The values shown in the different columns represents different superheats and the values represented in the different files represents different evaporator inlet qualities.







In order to evaluate the maldistribution influence in the system performance, the evaporation temperature (T_evap) has been selected as the basic indicator parameter.

The points can be observed in the thermography pictures presented in table 2 and table 3:

- The two-phase flow region can be identified by a sharp change in color from yellow/green to red.
- The minimum temperature in table 3 are smaller than in table 2.

- The measured evaporation temperature is approximately 2 K lower than the minimum surface temperature registered by the camera.
- In the points with superheat, the two-phase flow region is not even distributed, indicating a maldistribution of the refrigerant mass flow. The right or the central part of the heat exchanger has a a larger fraction of the heat exchanger at lower temperature. This indicates a larger amount of liquid refrigerant in passing through this part of the heat exchanger.
- The points with 0 K superheat show a quite similar evaporation temperature independently of the refrigerant inlet quality.
- The inlet quality influences the distribution in a complex way. For qualities close to 0 and qualities about 0.3 the degradation of the system performance with the superheat is smaller than for the quality values the between them. The possible explanation could be related to the distribution system, which probably is optimized for vapor qualities of 0.3, then as we go further from these values the refrigerant distribution will be worst. The improvement at low vapor qualities could be related to the fact that at these conditions all the refrigerant is almost in liquid phase. In fact, in these conditions the observed pattern is different to the rest.
- For higher superheats the two-phase flow area is smaller than for lower superheats.
- Comparing both tables, the degradation of the BPHE performance is higher at higher water temperature differences.

Table 2. Thermographies for dT_{water}= 5 K with variation of inlet quality and superheat

	SH=0	SH=5	SH=10	SH=15

x=0,30	Tevap= 6.04 ºC 	Tevap= 4.81 ºC 	Tevap= 3.67 ºC 	Tevap= -0.46 ºC 

Figure 5 represents the evaporation temperature as a function of the vapor quality and superheat for both sets of experiments. In that figure 5 (left) can be observed that evaporation temperature is almost independent of vapor quality except when superheat have a value comparable or lower than the water temperature difference. If the maldistribution of the refrigerant depends on the refrigerant quality at the evaporator inlet and it is

independent of the water side, the information obtained from figure 5 (left) points to the fact that, although there is a maldistribution it do not have a direct influence on the heat exchanger performance as the evaporating temperature do not change significantly. In figure 5 (right) the results are not so clear, but it can be stated that the obtained results depend in all the working map on the superheat and on the vapor quality.

A possible explanation could be related to the fact that in figure 5 (right) water temperature lift is similar or higher than the superheat in all the cases. Based on that hypothesis, the performance of the heat exchanger will be affected by the maldistribution problem when water temperature lift is higher than superheat, and in these cases the vapor quality at the inlet will have influence on the heat exchanger performance.

Based on that explanation for the obtained results, it can be determined that refrigerant maldistribution could increase its effects in the degradation of the heat exchanger performance in applications where the temperature difference in the secondary fluid side could be high like when the heat pump evaporator is used in heat recovery applications with a finite source of low temperature heat in order to produce heat at high temperature.

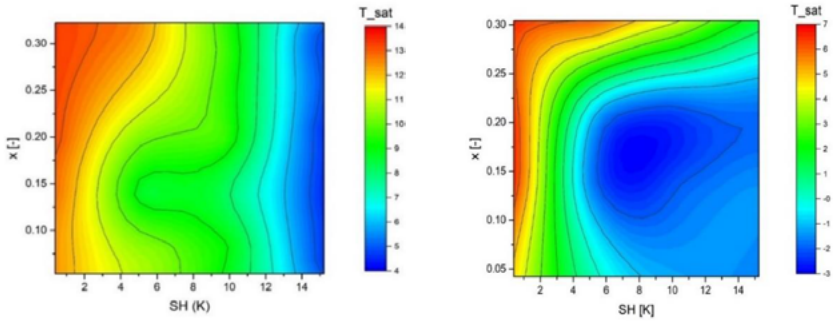

Figure 5. Saturation temperature for dT_{water}= 5 K (left). Saturation temperature for dT_{water}= 13 K (right)

4. Conclusions

Maldistribution in a brazed plate heat exchanger has been experimentally observed with infrared thermography. When maldistribution occurs, evaporator surface temperature is distributed unevenly and can be registered with thermography as it is non-intrusive and non-contacting, having no influence in the evaporator. Inlet quality and superheat has been changed during the tests for a given water temperature difference to observe this phenomenon.

As observed in the thermography pictures (figures 2 and 3), inlet quality has an influence in maldistribution at first sight. For high inlet quality, better refrigerant distribution is observed. However, superheat is observed to have a minor effect. The higher the superheat, better distribution is shown in the thermography for a 5 K water temperature difference Most homogeneous temperature map distribution is achieved when no superheat is performed.

Evaporation temperature has a great impact in system efficiency. Were the evaporator forced to work with a high level of superheat, less area is available for evaporation thus, evaporation temperature decreases. As expected, higher evaporation temperature is achieved when both low superheat and high inlet quality refrigerant is flowing. Although maldistribution is observed in thermography, underperformance is not inherited to all the cases. Related to that it is crucial to be able to determine how the maldistribution influence the performance of a BPHE as in some applications it could be higher than expected. In fact maldistribution have a higher influence in system performance when water temperature differences are equal or higher than superheat. This could be a relevant factor to take into account in applications where there is a high temperature difference on the secondary fluid like heat pumps used for energy recovery applications based on waste heat sources of finite availability.

Abstract

Heat pumps are becoming more and more desirable around the world as an efficient mean of space conditioning for both cooling and heating requirements. Heat exchangers (HXs) are the key components in these devices and pose some unique design challenges because the same HX has to operate as an evaporator in one mode and as a condenser in the other. Studies have proved that by optimizing the refrigerant circuitry, the performance of HXs can be significantly improved. In a reversible heat pump application, the optimal circuitry obtained under the air conditioning (AC) mode cannot guarantee optimal performance if it is used in the heat pump (HP) mode. Our study shows that the single objective optimal design obtained under AC mode yields 11.4% capacity degradation when it is used in HP mode. This paper presents a multi-objective refrigerant circuitry optimization approach to achieve robust heat exchanger performance in both cooling and heating modes. This work builds on a newly developed Integer Permutation based Genetic Algorithm (IPGA), which can guarantee good manufacturability of optimal circuitry designs. The enhanced IPGA extends the capabilities to generate designs with splitting and merging circuits, thus exploring the design space thoroughly. Two multi-objective problem formulation is proposed. One formulation aims at minimizing refrigerant charge, and the other formulation aims at maximizing HX capacity. The optimal HX designs are analyzed at the system level as a part of a reversible heat pump simulation. A case study using an A-type indoor unit shows that the optimal design obtained using the formulation to minimize charge can yield charge reduction by 19.2% under AC mode and 21.6% under HP mode. The optimal design using the formulation to maximize capacity improves the cooling capacity by 2.3% and system COP by 2.5% under AC mode and meanwhile, improves the heating capacity by 3.0% and system COP by 2.8% under HP mode. Considering the performance degradation of the single objective optimal, the effective capacity improvement of the bi-objective optimal is 14.4%.

1. Introduction

Tube-fin heat exchangers (TFHXs) are prominent components in air conditioning and heat pump systems. This type of heat exchanger consists of a bundle of tubes with fin sheets. The performance of TFHXs is greatly affected by a large number of structural parameters (tube diameter, tube length, fin type, fin thickness, etc.) and therefore, conducting optimization on such parameters can significantly improve its performance [1]. In addition to those parameters, the configuration of tube connections, i.e. refrigerant circuitry, determines the refrigerant flow path, and also significantly impacts the heat exchanger performance [2-8]. For an existing

E-mail address: vikrant@umd.edu

TFHX design with a given geometry, performing optimization on refrigerant circuitry is more convenient and cost effective than varying other structural parameters. For example, changing the circuitry is a matter of changing U-bend length and locations, whereas changing tube-spacing can require new fin dies, which is costly and has much longer lead time.

Researchers have tried to use different tube-fin HX circuitry optimization approaches to obtain the best circuitry under a specific operating condition. Domanski et al. [2] developed an optimization tool called ISHED (Intelligent System of Heat Exchanger Design). This optimization scheme switches between Evolutionary learning and Symbolic learning. They performed comprehensive studies to optimize circuitry of TFHXs as evaporators or condensers [9-11]. Their maximum reported HX capacity improvement from optimization runs and experimental validations are 13% from CO_2 gas cooler [12] and 2.2% from a R410A evaporator [13], respectively. Wu et al. [14; 15] developed another optimization approach, which switches between knowledge-based GA and Simulated Annealing. Moreover, the group created effective operators (greedy crossover and greedy mutation) to improve the convergence. They performed circuitry optimization on 3 evaporators and 1 condenser, and the maximum predicted capacity improvement in their study is 7.4%. Ploskas et al. [16] represented circuitry using an adjacency matrix and constrained the hairpins to be on one side of the HX. By comparing five different derivative-free optimization algorithms, they concluded that TOMLAB/glcDirect and TOMLAB/glcSolve can efficiently find optimal or near-optimal circuitries. In their study, the TFHXs are also optimized under specific operating conditions either as an evaporator or as a condenser.

For a reversible heat pump system, the same TFHX operates as a condenser in one mode and as an evaporator in the other mode. In literature [17], various performance metrics have been used as objectives for the TFHX circuitry optimization studies, however, all reported circuitry optimization are performed under specific refrigerant operating condition. Taking an indoor unit as an example, the optimal circuitry obtained by optimizing the HX as an evaporator in air conditioning mode does not necessarily guarantee desirable performance when the refrigerant flow is reversed, and it operates as a condenser under heat pump mode. It is thus clear that circuitry optimization for HX in reversible heat pump application has not been explored. This paper aims at tackling this challenge.

The remainder of the paper is organized as follows. Section 2 details an enhanced heat exchanger circuitry optimization algorithm. Section 3 presents two multi-objective problem formulations to achieve robust heat exchanger performance in a reversible heat pump. Section 4 presents a case study to demonstrates the efficacy of the proposed circuitry optimization algorithm and compare the bi-objective problem formulations with a single objective problem formulation. Section 5 analyses the optimization results and presents system level simulation results. Section 6 presents the conclusions of this study.

2. Enhanced Integer Permutation based Genetic Algorithm

2.1. Chromosome representation

To conduct optimization using Genetic Algorithm, the first step is to find a mathematical representation of the circuitry. A good individual representation (chromosome) can not only reduce the searching space, but can also simulate the nature of the problem [18]. In our previous research, an Integer Permutation based Genetic Algorithm (IPGA) [17] was developed to obtain the optimal circuitry designs. IPGA represents tubes as a sequence of integers (i.e. integer permutation). For an integer permutation, each integer (i.e., tube number) appears exactly once, thus, any chromosome generated by the Genetic Algorithm can be mapped to a valid circuitry and the size of the search space is dramatically reduced by the elimination of redundant designs. Li and Aute [19] have shown that IPGA demonstrates superior capability to obtain better refrigerant circuitries with lower computational cost than the other methods in literature. Readers are referred to the original paper [19] for more details of the IPGA developed in our previous research.

However, the previous IPGA cannot generate designs with splitting and merging of circuits. In order to remedy this limitation, a new chromosome representation called ‘Split Branch Chromosome’ (Fig. 1(a)) is developed and implemented in the enhanced IPGA. The new chromosome representation uses the concept of jagged arrays, with each element of this array representing a branch of tubes. Each branch contains 3 parts. The 1st part of the branch represents the tube sequence. The 2nd part of the branch represents the upstream tube. The 3rd part of the branch represents the downstream tube. Dummy tube number ‘0’ is used as the place holder in the 2nd part, if the 1st tube of the branch is an inlet tube of a circuit. And dummy tube number ‘-1’ is used as the place holder in the 3rd part, if the last tube of the branch is an outlet tube of a circuit.

Fig. 1(b) shows the chromosome representation of the 24-tube heat exchanger in Fig. 1(a). This sample heat exchanger has one splitting tube (tube # 3) and one merging tube (tube #20). With the ‘Split Branch

Chromosome', number of circuits is flexible, i.e., the optimal number of circuits is also an output from optimization and it can represent circuitry designs with splitting and merging circuits.

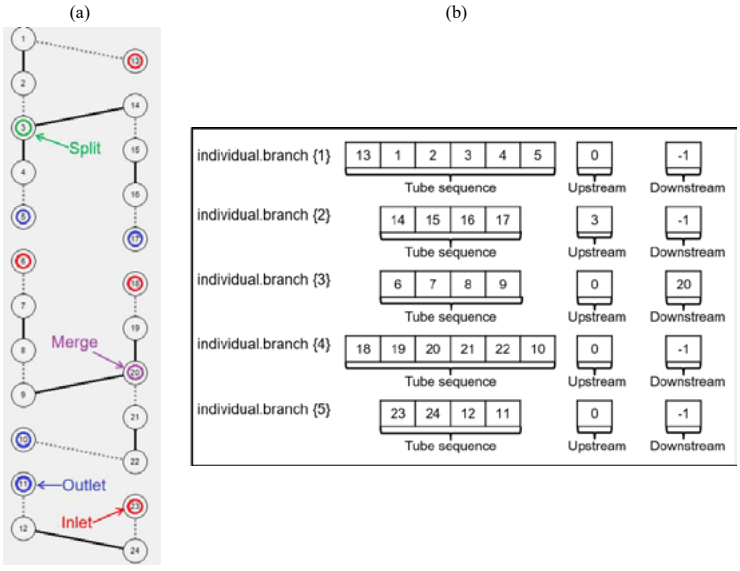

Fig. 1. Chromosome Representation: (a) 24-tube heat exchanger sample; (b) Split branch chromosome

2.2. GA Operators

In Genetic Algorithm, the creation of new individuals relies on the genetic operators. By transforming the selected individual to a new individual with potentially better fitness, the genetic operators direct the search and drive the optimization process.

To adapt the new chromosome representation and extend IPGA's capability to generate designs with splitting and merging circuits, the enhanced IPGA requires new genetic operators. Therefore, two novel genetic operators (Fig. 2) are developed. In order to generate circuit splitting, the split operator in Fig. 2 (a) randomly determine one tube as the splitting tube and make a sub-section of tubes to form a new branch, thus creates a split. Oppositely, the merge operator in Fig. 2 (b) randomly determines one tube as the merging tube and makes a sub-section of tubes to form a new branch, thus creates a merging of circuits.

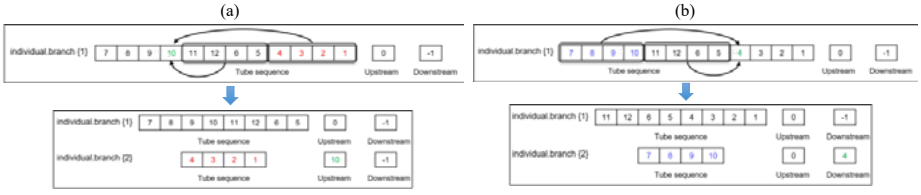

Fig. 2. (a) Split operator; (b) Merge operator

In order to adapt to the change of the chromosome representation, the six GA operators from previous IPGA [17] are modified to form six new GA operators (Fig. 3). The 'gene sequence inversion' operator in Fig. 3(a) chooses a random subsection of a branch and inverts the order of the tubes. The 'gene insertion' operator in Fig. 3(b) puts a randomly selected tube into a random position. The 'in-branch transposition' operator in Fig. 3(c) reverses two randomly chosen tubes inside a single branch, while the 'cross-branch transposition' operator in Fig. 3(d) reverses two randomly selected tubes between different branches. The 'branch detachment' operator in Fig. 3(e) splits a randomly selected branch into two branches. The 'branch union' operator in Fig. 3(f) chooses two branches and unites them into one branch. With the 'branch union' and 'branch detachment' operators, the number of circuits can be varied and optimized in a generic fashion.

Fig. 3. GA Operators: (a) Gene sequence inversion; (b) Gene insertion; (c) In-branch transposition; (d) Cross-branch transposition; (e) Branch detachment; (f) Branch union

3. Problem Formulations

To achieve stable heat exchanger performance in reversible heat pump, two problem formulations are explored. The 1st formulation in Equation (1) aims at maximizing the heat exchanger capacity under different operating conditions. One of the objectives is to maximize the HX capacity when it is operated as an evaporator under cooling mode, and the other objective is to maximize the capacity when it is operated as a condenser under heating mode. The 2nd formulation in Equation (2) aims at minimizing refrigerant charge. One objective is to minimize charge under cooling mode and the other objective is to minimize charge under heating mode. It should be noted that real heat pump systems may use a charge reservoir (e.g., accumulator or receiver) to store charge, but such reservoir is not considered here as the focus is to minimize the charge in the heat exchangers only.

Both problem formulations implement 8 constraints. The first 5 operating constraints limit capacity, refrigerant pressure drop, refrigerant charge, outlet refrigerant saturation ΔT and sensible heat ratio in acceptable ranges as compared with the baseline. The remaining 3 constraints are manufacturability constraints. Specifically, the 6th constraint ensures the inlet and the outlet tubes on the same side of HX. The 7th constraint avoids long U-bends spanning over 2 tube rows. The last constraint avoids partially overlapped U-bends crossing. The manufacturability constraints and the constraint handling scheme are detailed in Li et al. [17].

It is worthwhile to mention that in order to evaluate the performance of the HX under both operating modes, the HX performance under AC mode is first evaluated, then the refrigerant flow direction is reversed (i.e. the inlets and outlets tubes are swapped), and the HX performance under HP mode is evaluated. In addition to the reversion of refrigerant flow direction, the air and refrigerant inlet conditions and the empirical correlations to predict in-tube heat transfer coefficient and pressure drop are also changed to accommodate the switch between AC mode and HP mode.

4. Case Studies

An evaporator from an A-type indoor unit (Fig. 4(a)) is used as the baseline for circuitry optimization, because it is experimentally validated in our laboratory. Table 1 shows the structural parameters for the baseline indoor coil. Table 2 shows the operating conditions for the baseline coil working in cooling mode and heating mode. The air side conditions are adopted from ASHRAE Test Standard [20]. The air velocity flow maldistribution at the frontal face of the A-type indoor unit is simulated using an OpenFOAM® based CFD model (Fig. 4(b)), and the air maldistribution profile is imposed on the air side to improve the HX performance prediction. Table 3 lists the empirical correlations used for local heat transfer and pressure drop calculations during the performance evaluation of the HX as an evaporator or a condenser.

Table 1: Structural Parameters and Operating Conditions of Baseline Evaporator

Structural Parameters	Unit	Value
Tube Outer Diameter	mm	9.5
Fins Per Inch	FPI	15
Fin Type	-	Wavy Louver
Tube Length	m	0.503 m
Vertical Spacing	mm	20.0 mm
Horizontal Spacing	mm	25.0 mm
Number of Tube Banks		4
Number of Tubes Per Bank		22

Table 2: Operating Conditions of Baseline Working as an Evaporator and a Condenser

Operating Parameters	Unit	Baseline as Evaporator	Baseline as Condenser
Refrigerant	-	R410A	R410A
Pressure	kPa	1154.55	2432.44
Temperature	◦C	12.03	65.07
Refrigerant Quality	-	0.22	-
Refrigerant Mass Flow Rate	kg/s	0.0312	0.0275
Air Volume Flow Rate	ft^3/min	600	617
Air Pressure	kPa	101.325	101.325
Air Temperature	◦C	26.42	21.23
Air Relative Humidity	%	50.97	58.80

Table 3: Correlations Adopted in HX Simulation

Operating Mode	Heat Transfer Correlations	Pressure Drop Correlations
Refrigerant - Liquid Phase	Dittus and Boelter [21]	Blasius [22]
Refrigerant - Two Phase Boiling (Evaporator)	Jung *et al.* [23]	Jung and Radermacher [24]
Refrigerant - Two Phase Condensation (Condenser)	Cavallini et al. [25]	Lockhart and Martinelli [26]
Refrigerant - Vapor Phase	Dittus and Boelter [21]	Blasius [22]
Air	Wang *et al.* [27]	Wang *et al.* [27]

At the fitness evaluation stage, a finite volume heat exchanger model [28] is used to simulate the performance of the heat exchanger with different circuitries. The model can account for the refrigerant flow maldistribution among different circuits by iterating on the pressure residual at the outlet of each circuit. This

HX model was validated with measured data [29] for the same baseline HX under AC and HP modes, and the deviation between simulations and experiments are below 5% as shown Fig. 4(c).

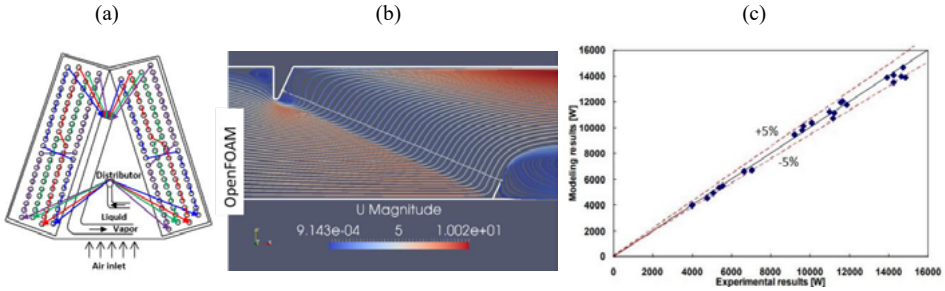

Fig. 4. (a) Baseline Circuitry; (b) Air Maldistribution in A-type Unit Simulated by CFD Model; (c) Experiment Tests vs Simulations

5. Results

5.1. Bi-objective optimization result

In this case study, the GA population size is set to 200, the number of generations is set to 500 and the population replacement ratio is 20% (i.e. the elitism reservation ratio is 80%). Fig. 5(a) shows the Pareto front for Formulation (1) plotted in the objective space. The Pareto front consists of 23 optimal designs. Fig. 5(b) shows the Pareto front using Formulation (2). The X-axis and Y-axis are the refrigerant charge under AC and HP mode. This Pareto front consists 36 optimal designs. Among the optimal designs in two Pareto fronts, the designs whose capacity/charge ranks at the median of the all designs in the Pareto front are sampled for further analysis, since it is expected to exhibit balanced performance under AC and HP modes.

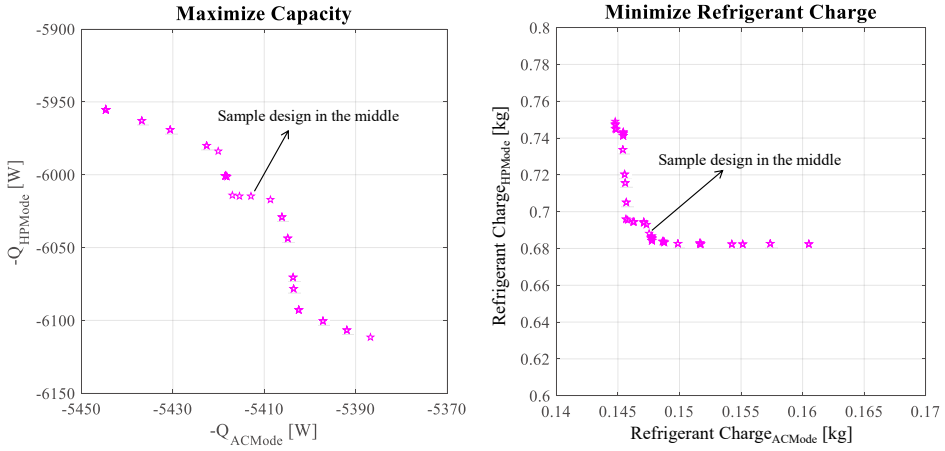

Fig. 5. (a) Pareto Front for Maximizing Capacity; (b) Pareto Front for Minimizing Refrigerant Charge

5.2. Single objective optimization result

To emphasize the necessity to use the multi-objective problem formulation to optimize heat exchangers in reversible heat pumps, the same baseline heat exchanger is optimized solely under air-conditioning mode using a single objective problem formulation. The only objective is to maximize the evaporator cooling capacity under AC mode. The operating constraints and the manufacturability constraints are kept the same as those in Section 3. And the GA settings (the population size, the number of generations and population replacement ratio) are also the same as in the previous practice. Fig. 6(a) shows the GA evolution progress of the single objective optimization. The single objective optimal yields 2.4% capacity improvement under AC mode.

Fig. 6(b) shows the performance comparison between the single objective optimal with the bi-objective optimal to maximize capacity under both AC and HP modes. The bi-objective optimal yields 2.3% capacity increase under AC mode, which is a little less than the improvement of the single objective optimal under AC mode (2.4%). However, if the single objective optimal is used as a condenser in a reversible heat pump, the capacity degrades from 5845 W to 5177 W by 11.4% compared to the baseline. In contrast, the bi-objective optimal still improves condenser capacity by 3.0% under HP mode, it indicates that the effective capacity improvement of bi-objective optimal under HP mode is 14.4% (i.e., 11.4%+3.0%) considering the performance degradation of the single objective optimal under HP mode.

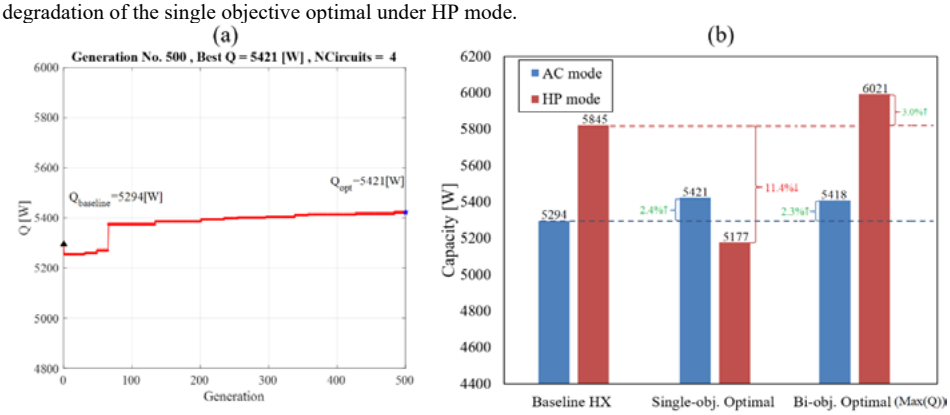

Fig. 6. (a) Single objective optimization GA progress; (b) Comparison of single-obj. with bi-obj. optimal

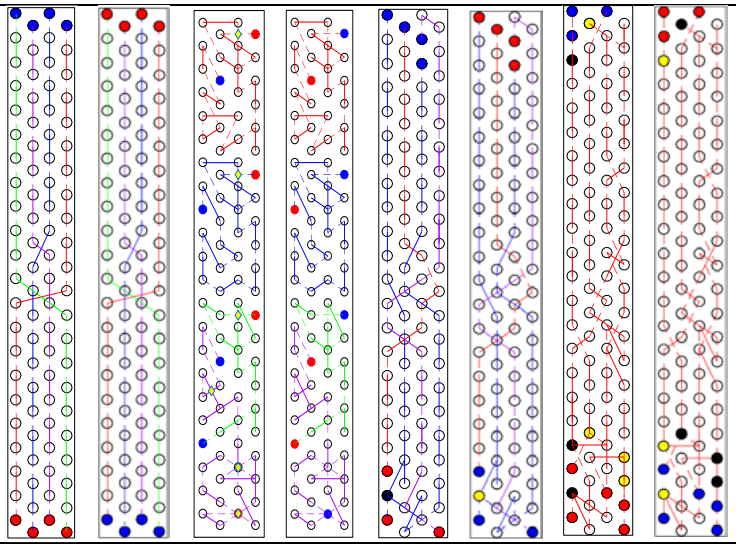
Table 4 presents the detailed performance of the baseline, the single objective optimal and the bi-objective optimal designs sampled from above Pareto fronts. Compared with the baseline, the optimal design from bi-objective Formulation (1) yields a capacity increase of 2.3% when it is used as an evaporator under AC mode and it yields the capacity increase of 3.0% when it is used as a condenser under HP mode. This indicates that its circuitry design is resilient to variation in operating conditions. Both refrigerant charge and the pressure drop are less than or equal to the baseline under the corresponding modes.



As a result of optimization using Formulation (2), the optimal design by minimizing refrigerant charge yields a charge reduction of 19.2% under AC mode and the charge reduction by 21.6% under HP mode. Meanwhile its capacity is slightly higher than the baseline under the corresponding operating modes.

Table 4: Summary of Optimization Results

Case	**Baseline**		**Single-obj. Optimal (Maximize Q)**		**Bi-objective Optimal (Maximize Q)**		**Bi-objective Optimal (Minimize Charge)**	
Mode	AC	HP	AC	HP	AC	HP	AC	HP
Capacity [W]	5294	5845	5421 (2.4%↑)	5177 (11.4%↓)	5418 (2.3%↑)	6021 (3.0%↑)	5305 (0.2%↑)	5918 (1.2%↓)
Ref. DP [kPa]	11.9	7.3	11.7 (1.7%↓)	7.3 (-)	11.9 (-)	6.5 (11.0%↓)	11.7 (1.6%↓)	6.6 (9.6%↓)
Sensible Heat Ratio	79.9%	100%	80.6%	100%	79.8%	100%	79.5%	100%
Outlet Saturation ΔT [K] (+ superheat, - subcooling)	+8.4	-9.48	+9.4	-8.5	+8.7	-10.13	+8.85	-10.02
Refrigerant Charge [g]	182.5	877.8	168.9 (7.5%↓)	828.5 (5.6%↓)	161.0 (11.8%↓)	877.8 (-)	147.5 (19.2%↓)	688.3 (21.6%↓)

Table 5 presents the circuitry of the baseline, the single objective optimal design and the bi-objective optimal designs from problem Formulation (1) and Formulation (2). In the circuitry plots, a solid line represents a U-bend on the near end of the heat exchanger, while a dotted line represents a U-bend on the far end. The red tubes are the inlets, while the blue ones are outlets. Merging tubes and splitting tubes are represented by yellow and black circles, respectively. In terms of manufacturability, the baseline has 2 long U-bends spanning over 3 tube rows, while all U-bends from the optimal designs are shorter than 3 tube rows.

Table 5: Circuitry of Baseline and Optimal Designs

Case	Baseline		Single-obj. Optimal (Maximize Q)		Bi-objective Optimal (Maximize Q)		Bi-objective Optimal (Minimize Charge)	
Mode	AC	HP	AC	HP	AC	HP	AC	HP
Circuitry								
U-bends (Length ≤ 2 tube rows)	82	82	84	84	85	85	87	87
U-bends (Length > 2 tube rows)	2	2	0	0	0	0	0	0

5.3. System level result

In order to test the system performance of the optimal designs and the baseline, a component-based vapor compression simulation tool [30] is used to simulate a realistic reversible heat pump cycle which is experimentally validated [29] using the baseline HX as the indoor coil. Fig. 7(a) and Fig. 7(b) show the schematic of the reversible heat pump system under cooling mode and heating mode, respectively. The information of other components (outdoor HX, compressor, expansion device) is detailed in the original paper [29]. The test condition is the ANSI/AHRI Standard 210/240 A cooling and heating conditions [31].

In Fig. 7(a) and Fig. 7(b), the air flow maldistribution profile simulated using an OpenFOAM® based CFD model ([32]) can be observed at the frontal face of A-type indoor unit. The air velocity at the apex is largest and the air velocity decreases from top to bottom of the coil.

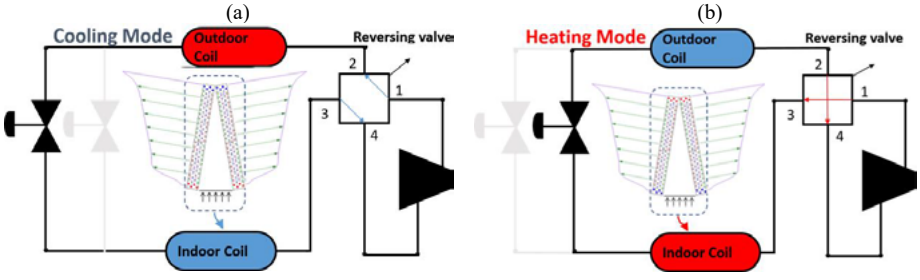


Fig. 7. Schematic of Reversible Heat Pump System: (a) Cooling (i.e. AC) Mode Operation; (b) Heating (i.e. HP) Mode Operation

Fig. 8 shows the system performance of the reversible heat pump system using the baseline or the optimal circuitry designs as indoor coil. Under cooling mode (Fig. 8(a)), the optimal design by maximizing capacity gains COP improvement from 3.54 to 3.63 by 2.5%, but the optimal design by minimizing refrigerant charge

only leads to COP improvement from 3.54 to 3.55 by 0.3%. Meanwhile, under heating mode (Fig. 8(b)), the optimal design by maximizing capacity gains COP improvement from 4.61 to 4.74 by 2.8%, but the optimal design by minimizing refrigerant charge only leads to COP improvement from 4.61 to 4.65 by 0.8%.

From the P-h diagrams, when the optimal design by maximizing capacity (red line in Fig. 8) operates as an evaporator in AC mode, it induces higher evaporating temperature. When it operates as a condenser in HP mode, it induces lower condensing temperature. Thus, the system efficiency is improved.

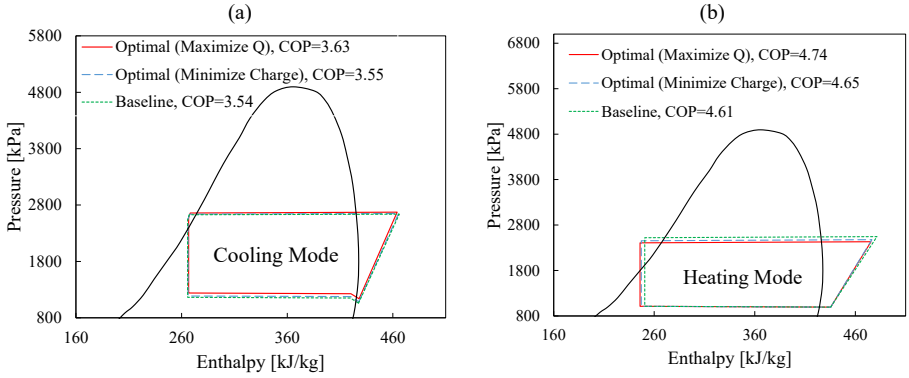

Fig. 8. R410A P-h diagram using Different Circuitry Designs in Indoor Unit: (a) Cooling mode; (b) Heating mode

6. Conclusion

This paper presents a newly developed tube-fin heat exchanger circuitry optimization algorithm. A new chromosome representation and eight GA operators are developed to extend the capability of Integer Permutation based Genetic Algorithm. In order to obtain optimal circuitries with improved performance under both air conditioning and heat pump modes for reversible heat pump system, two multi-objective problem formulations are explored. Case studies using an A-type indoor unit from a reversible heat pump system shows that the optimal design using the formulation with the objective to maximize heat exchanger capacity leads to 2.3% (AC mode) and 3.0% (HP mode) capacity improvement. In addition, it yields COP improvement by 2.5% (AC mode) and 2.8% (HP mode). Considering the single-objective optimal design obtained under solely AC mode induces 11.4% capacity degradation if it is used in HP mode, the effective capacity improvement of the bi-objective optimal is 14.4%. The optimal design obtained using the formulation with the objective to minimize refrigerant charge effectively reduce heat exchanger refrigerant charge by 19.2% (AC mode) and 21.6% (HP mode), meanwhile maintaining the heat exchanger capacity and COP to be the similar amount as the baseline. Use of the proposed circuitry optimization approach in early design stages can help assure a certain minimum robust performance of heat exchangers in heat pumps during both cooling and heating mode usage as well as assist in redesign of existing heat exchangers for new lower-GWP refrigerants.

Abstract

Heat pump manufacturers gradually adopt microchannel heat exchangers (MCHX) as the outdoor coils due to the compactness and lower cost. The relatively small hydraulic diameter of MCHX also enhances the heat transfer compared to traditional tube and fin coils. However, such benefits may turn to a challenge when heat pumps operate under the frost condition. Air flow is easily blocked when frost builds up in the smaller flow channels formed by the fins and microchannel tubes. To study the MCHX performance under frost condition, we developed a Modelica-based dynamic model that accounts for the performance degradation under frost conditions. The MCHX is modeled using the finite volume method and the sensible and latent heat transfer between refrigerant and moist air is solved using both heat and mass conservation equations. Regarding the frost accumulation, the model considers both the frost densification and thickness growth which will reduce the conductivity of the tube surface and the minimum free flow area, leading to poor air-side heat transfer. The model can also be applied on a heat pump system along with other in-house developed Modelica component models to assist the understanding of heat pump COP degradation during frost.

1. Introduction

In winter, heat pump systems are typically more energy efficient in providing heating than electric heaters or gas fired furnaces. Following the principle of the Carnot Cycle, heat pumps can transform the low-grade ambient heat to higher-grade space heat, making the cycle Coefficient of Performance (COP) higher than one. The popularity of heat pumps in many places of the world has been motivating researchers and engineers to further improve the system efficiency and reduce the cost. To that end, microchannel heat exchangers (MCHX) gain momentum in heat pump installations. MCHX, being widely used in the automotive AC industry, has a typical hydraulic diameter of 1 mm which is much smaller than the ones of tube-and-fin heat exchangers (TFHX). The small hydraulic diameter leads to compactness since the increase of heat transfer area-to-volume ratio is accompanied by the decrease of hydraulic diameter. Khan and Fartaj [1] conducted a literature review on MCHX in which the MCHX's compactness was corroborated by the example that a state-of-the-art multi-port flat tube heat exchanger registered a capacity per volume in the range of 2-3 MW/m^3. Although, it goes without saying that using MCHX in heat pumps is advantageous, there are still challenges faced by the traditional TFHXs, that MCHXs cannot address better. One such challenge is the frost-induced performance degradation during winter operations. As the outdoor unit becomes evaporator during a heat pump operation, its surface temperature may be lower than both the freezing point and the dewpoint of ambient air. Frost can therefore accumulate on the evaporator and as a result, the thermal resistance of the evaporator increases, eventually deteriorating the heat pump efficiency.

Email: jiazhen@umd.edu

To mitigate the frost built-up and its negative impact on cycle performance, we need to understand how frost first appears and distributes on the evaporator; how the increased thermal resistance due to frost built-up alters the operation of vapor compression cycle; lastly how the altered VCC operation reciprocates on the frost accumulation. Those questions can be answered either through experimental or numerical studies. Henry Barrow [2] was among the first to register his concern over frost accumulation in heat pumps. Through his fin model, he concluded the increased thermal resistance due to frost were majorly caused by air flow blockage, and the impact from lower thermal conductivity of frost was secondary. Moallem et al. [3] experimentally measured both the frost thickness and weight accumulated over two evaporators used in air source heat pumps. They used a digital scale to measure the frost weight and a CCD camera to capture the frost thickness growth over time. They concluded the frost onset was highly dependent on local fin temperature and the frost grew faster when the water vapor content of incoming air is higher. The same group of researchers [4] later developed a semi-empirical model that predicts non-uniform frost growth on heat exchangers. The model adopts a quasi-steady state, heat and mass balance-based segment-by-segment approach.

This paper introduces a Modelica-based full dynamic microchannel heat exchanger model with frost prediction capability, as opposed to a quasi-steady state approach, and further applies the model on a vapor compression cycle model, so that the impact from frost accumulation on cycle operation can be quantified. As suggested in the above literature, a comprehensive frost model should consider both the frost densification process which impacts the fin surface thermal conductivity and the frost thickness growth which blocks air passage through the heat exchanger. By exercising the model, we would like to demonstrate that it is a helpful tool when conducting research on: how frost first appears and distributes on the evaporator? How the increased thermal resistance due to frost built-up alters the operation of vapor compression cycle?

2. Modeling Methodology

The modeling methodology includes two main pieces: a segment-by-segment based microchannel model and a frost model that serves as an add-on to the first one. The microchannel model further includes three control volumes: the air-side control volume, the refrigerant-side control volume and the fin and flat-tube wall control volume. The frost model is applied to air-side control volume only so that the frost simulation will not be constrained to particular geometries of the MCHX as well as the refrigerant flowing inside the MCHX flat tube.

2.1 Segment-by-segment based microchannel heat exchanger model

The above-mentioned control volumes are better visualized in Figure 1. In the direction of flat tubes, the heat exchanger is divided into a number of segments which comprise the three control volumes. The structure of the control volumes enables the reusability of each control volume for other types of heat exchangers. The green ports and red ports are Fluidports and Heatports, respectively. They both act as connectors and by connecting those ports to each other, a set of conservation equations are established (Eq. 1 – 4). Eqn. 2 and 3 also carry the information of flow direction through the positive and negative signs.

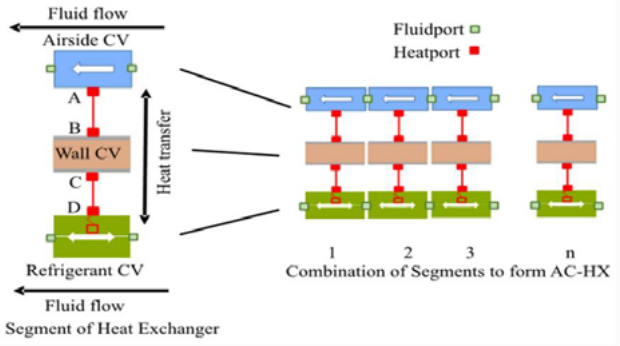

Figure 1 Subcomponent structure for MCHX model

Fluidports: $P_1 = P_2$ (1)

$$\dot{m}_1 + \dot{m}_2 = 0 \quad (2)$$

$$\dot{m}_1 h_1 + \dot{m}_2 h_2 = 0 \quad (3)$$

Heatports: $\dot{q}_1 + \dot{q}_2 = 0$ (4)

The refrigerant-side control volume is a lumped model which merges the multiple MCHX ports into a single tube (see Figure). The implicit assumptions here are that the refrigerant maldistribution among the ports are neglected and consequently there is a single temperature along the width of the tube (width here means length along the airflow direction). According to Li et al. [5], such an assumption tends to neglect the refrigerant maldistribution in each port which could lead to a heat exchanger level capacity degradation of 3.6%.

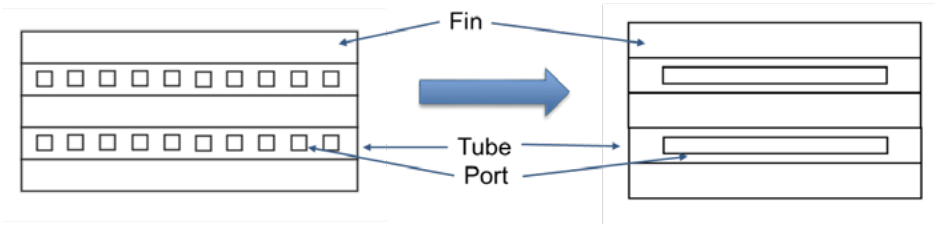

Figure 2: Refrigerant-side port-level simplification for MCHX model

The tube temperature for the lumped port profile of the model MCHX is evaluated as discussed below. The thickness δ_t is evaluated from Equation 5, using the tube height (H_t) and port height (H_p). The tube mass (m_t) is obtained from Equation 6, where n_t is number of tubes and ρ_t is the tube material density. The fin mass (m_f) of MCHX is evaluated from Eqn. 7, where A_s is surface area, t_f is fin thickness and ρ_f is fin material density. Weighted averages of specific heat capacity (c) and mass (m) from Equations 8 and 9 are used in the energy equation for the tube control volume to evaluate the dynamic temperature profile in Equation 10. Q_a and Q_r are heat flows to air-side and refrigerant-side respectively.

$$\delta_t = \frac{H_t - H_p}{2} \quad (5)$$

$$m_t = n_t \rho_t L_t (H_t W_t - A_c) \quad (6)$$

$$m_f = \frac{A_s}{2} t_f \rho_f \quad (7)$$

$$c = \frac{m_t c_t + m_f c_f}{m_t + m_f} \quad (8)$$

$$m = m_t + m_f \quad (9)$$

$$mc \frac{dT}{dt} = \dot{Q}_a + Q_r \quad (10)$$

The Q_a term is evaluated in the airside control volume. Fin efficiency η is used to combine primary and secondary heat transfer areas into a single effective heat transfer area (Eqn. 11). The primary and secondary areas for heat transfer are evaluated from Eqns. 12 and 13. The number of fins per unit length (called fin density) is represented by ξ. Pt is the tube pitch (distance between consecutive tubes).

$$A_e = A_p + \eta A_f \quad (11)$$

$$A_p = 2L_t(W_t + H_t - \xi t_f W_t) \quad (12)$$

$$A_s = 2L_t \xi \left[W_t (P_t - H_t) + P_t (W_f - W_t) \right] \quad (13)$$

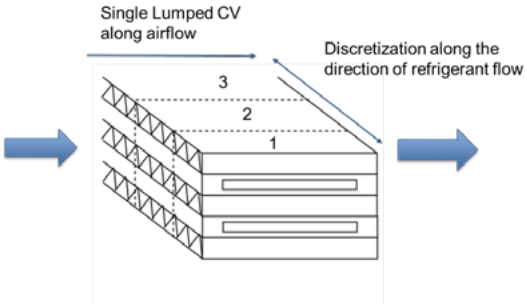

Figure 3: Discretization of airside control volume

The heat transfer coefficient for airside is critical for accurate evaluation for heat transfers. A linear correlation developed from experimental data is fed into the model for improved accuracy. The face area (A_f) is evaluated from geometrical parameters by Eqn. 14.

$$A_f = (n_t - 1)P_t + L_t \tag{14}$$

$$u = \frac{\dot{V}}{A_f} \tag{15}$$

$$\alpha = min\left(\left(\frac{\tilde{\alpha}}{\tilde{u}}\right)u, \alpha_0\right) \tag{16}$$

Face velocity (u) is obtained from volume flow rate ($\dot{V}$) using Eqn. 15 and is used as independent parameter for heat transfer coefficient (α) evaluation from the empirical Eqn. 16, obtained from manufacturing data. To model natural convection at zero flow rate, a condition happens during cycle shut down or mode switch, a minimal volume flow rate can be provided to get non-zero heat transfer coefficient values for zero flow case. The correlating terms $\tilde{\alpha}$and $\tilde{u}$are obtained from the linear trend line passing through origin. Epsilon-NTU method is used to evaluate air outlet temperature and airside heat transfer capacity (Q_a) can be now evaluated using the values of total heat transfer area, heat transfer coefficient and air temperatures.

The refrigerant-side control volume contains dynamic mass and energy conservation equations. Pressure and enthalpy are the state variables used for evaluating other thermo-physical quantities and for the progress in time. Homogenous model of void fraction is used in the model for faster simulation time because the refrigerant charge distribution is not critical parameter for evaluation.

2.2 Frost model

As discussed earlier, a complete frost model should consider both the frost thickness and the frost densification. Figure 4 describes the modeling approach that captures basic frost phenomenon [6].

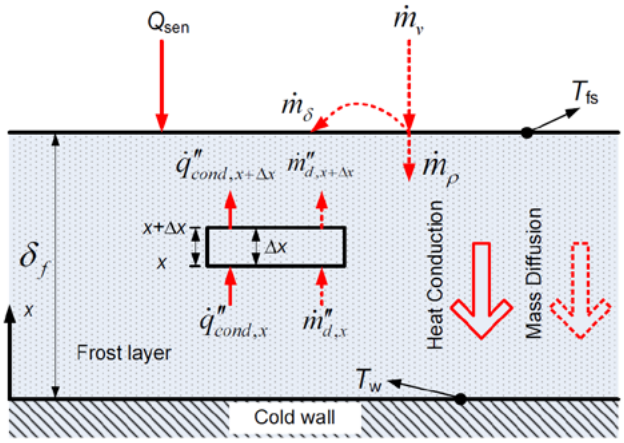

Figure 4: Schematic for frost modeling [6]

In Figure 4, the MCHX fin surface is generalized as a cold surface and the dotted shades represent the frost layer. The x direction points to the frost growth direction. As cold and moist air flows on the top of the cold surface at T_w, moisture deposits on the surface at a rate of $\dot{m}_v$, and turns to frost. The air stream rejects both sensible heat, Q_{sen}, and latent heat, in the condensate rate of $\dot{m}_v$, to the MCHX surface covered by frost. The condensate, $\dot{m}_v$, may either deposit on top of the fresh frost or, through the gap of topmost frost, deposit in the middle of the frost layer, resulting both the frost thickness growth, in the rate of $\dot{m}_\delta$, and the frost densification, in the rate of $\dot{m}_\rho$, respectively. As a result, the frost thickness, δ_f, and the frost density increases, the latter of which further affects the frost layer thermal conductivity. The basic frost accumulation phenomenon embodies a heat and mass transfer process, so the governing equations applied to the control volume are shown in Eqns. 17 and 18.

Mass Balance:

$$\dot{m}''_{d,x} - \dot{m}''_{d,x+\Delta x} = -\frac{\partial \dot{m}''_{d,x}}{\partial x}\Delta x = \frac{\partial}{\partial t}(\rho_f \Delta x) \tag{17}$$

Energy Balance:

$$\Delta x\left[-\frac{\partial q''_{cond,x}}{\partial x} - \frac{\partial}{\partial x}\left(\dot{m}''_d h_v\right)\right] = \frac{\partial}{\partial t}(\rho_f h_f \Delta x) \tag{18}$$

For the sake of simplicity, the paper omits the detailed mathematical deduction which can be found in [6] and only presents the solutions to the above governing equations. In addition, an empirical equation is used to connect the frost densification to the change of frost thermal conductivity.

Water vapor absorbed by the frost layer:

$$\dot{m}''_\rho = \frac{\zeta p_{v,sat}(T_w)}{R_v T_w \varphi}\sinh(\varphi \delta_f) \tag{19}$$

Where

$$\zeta = D_{eff}\{\frac{1}{\delta_f}cosh^{-1}[\frac{T_w}{T_{fs}}\frac{p_{v,sat}(T_{fs})}{p_{v,sat}(T_w)}]\}^2 \tag{20}$$

$$\varphi = \sqrt{\frac{\zeta}{D_{eff}}} \tag{21}$$

The average density of frost for the next time step:

$$\bar{\rho}_{f,t+\Delta t} = \bar{\rho}_{f,t} + \frac{\dot{m}_{\rho}^{"}}{\delta_f}\Delta t \tag{22}$$

The frost thickness for the next time step:

$$\delta_{f,t+\Delta t} = \delta_{f,t} + \frac{\dot{m}_{v}^{"} - \dot{m}_{\rho}^{"}}{\bar{\rho}_{f,t}}\Delta t \tag{23}$$

The thermal conductivity of the frost layer [7]:

$$k_f = 0.132 + 3.13 \times 10^{-4}\bar{\rho}_f + 1.6 \times 10^{-6}{\bar{\rho}_f}^2 (50 < \bar{\rho}_f < 400 \frac{kg}{m^3}) \tag{24}$$

3. Case study: Frost accumulation prediction on MCHX in a heat pump

With the help of the model described above, we can now analyze the frost accumulation by reviewing the air-side control volume of each segment. In the scope of this paper, the focus is to explore the frost thickness growth, the increase of frost density as well as the related frost thermal conductivity change on different locations of a MCHX. Furthermore, we want to compare the heat pump frost performance over two MCHX pass configurations: one pass and two-pass.

3.1 Heat pump system

The details of the system, a 3-ton R410A heat pump using a scroll compressor and thermal expansion valve (TXV), are described in [8] with only one replacement to the outdoor unit. A microchannel HX replaced the original tube-and-fin heat exchanger. Table 1 shows the dimensions of the microchannel heat exchanger.

Table 1: The one pass MCHX parameters

Refrigerant pass configuration	1 pass
Total number of flat tubes	48
Tube length (mm)	50
Tube pitch (mm)	2.54
Number of ports in a tube	10
Port height/width (mm/mm)	1/1
Fin type	Flat fin
Fins per inch	12

The operating condition of the heat pump follows the frost accumulation condition pursuant to ASHRAE Standard 116 (1995) [9]: the outdoor air condition is 1.7°C/0.7°C (dry bulb/wet bulb) and the indoor air condition is 21.1°C/13.2°C (dry bulb/wet bulb).

3.2 Prediction of frost growth, densification of MCHX

Since dynamic simulations require initial values to determine the solutions for the future time steps, the surface temperature, as shown in Figure 5, of MCHX is assumed to be 3K warmer than the incoming air at time 0. As vapor compression cycle starts, the refrigerant flowing inside the evaporator gradually cools the fin surface and in about 80 seconds, the fin surface temperature drops below the freezing point. It has to be noted that the system uses TXV to regulate the outlet superheat and thus, there will be an initial time region in which refrigerant temperature fluctuates, responding to the superheat adjustment by the TXV. This fluctuation is reflected on the surface temperature profile which rises and drops shortly after reaching sub-freezing temperature region. The surface temperature eventually stabilizes, and the last two segments are in superheated region. It needs to be noted that we only showed four out of ten segments' results for all plots in this section. This is because all simulation results show Segments 1 through 6, and Segments 7 and 8 have very similar predicted values. So, to clearly show the results and avoid putting a line on top of each other, we only reported the four segments that can best represent the trend of frost distribution. Figure 6 shows the frost growth in each MCHX segment. Segment 1 is the section closest to the inlet and Segment 10 is the section closest to the outlet, and the other segments fall in places in between. The frost starts to grow at about 80 seconds which coincides with the time at which surface temperature of the heat exchanger falls below the freezing point. The frost growth rate is very close to linear and its slope is determined by the frost surface temperature, and it is intuitive that the superheat region of the heat exchanger has the least amount of frost covered.

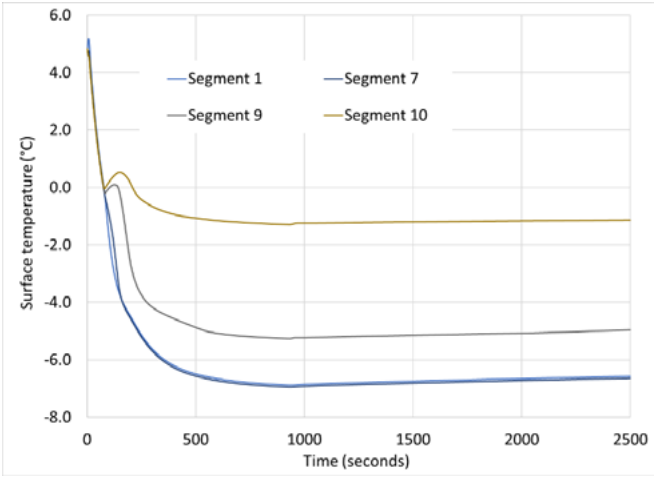

Figure 5: The surface temperature distribution over MCHX

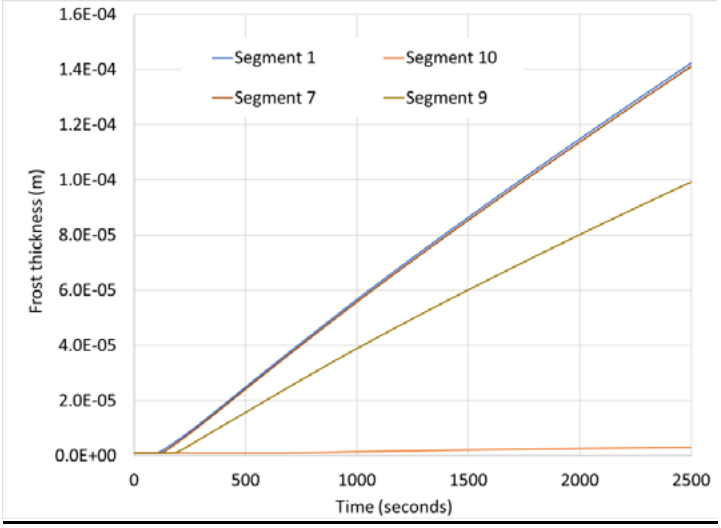

Figure 6: The frost thickness distribution over MCHX

Regarding the second aspect of frost accumulation, we use Figure 7 to examine the frost density distribution over the MCHX. To avoid any singularities, the initial frost density is assumed to be 30 kg/m^3 or 0.03 g/cm^3 [6,10]. Unlike the frost thickness growth, the frost densification process is non-linear and those segments closer to the evaporator outlet have slightly denser frost which are caused by the significantly smaller frost thickness. As shown in Figure 7, the densification of frost increases the frost thermal conductivity but such a level of increase is shadowed by the growth of frost thickness and, as as a result, the change of overall thermal resistance is dominant by the frost thickness growth.

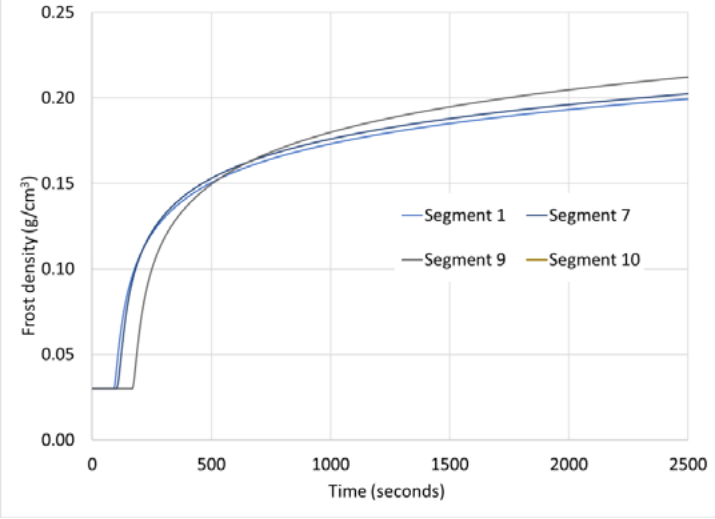

Figure 7: The frost density distribution over MCHX

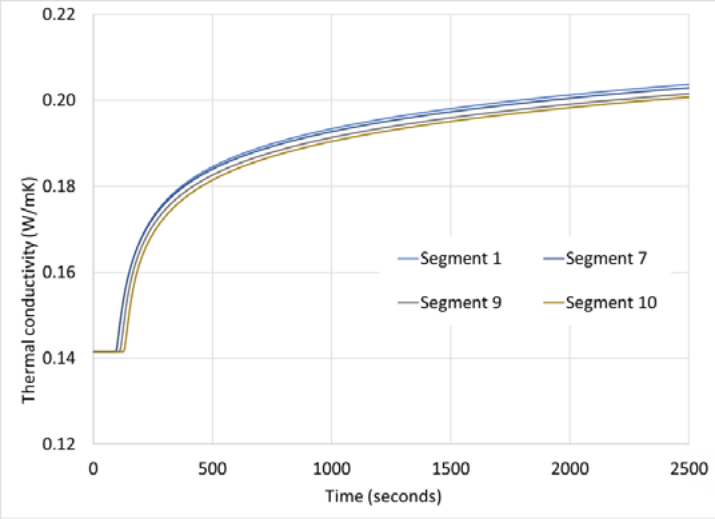

Figure 8: The frost thermal conductivity distribution over MCHX

To summarize, the increase in frost thickness will increase the thermal resistance between air and the refrigerant. The change in thermal conductivity due to frost densification plays a minor role in the change of thermal resistance. This can be observed by the fact that the change of thermal conductivity in Figure 8 is on relatively a smaller scale compared to the frost thickness growth. The net impact from both, the increase of frost thickness and frost density, is the increase of thermal resistance that impedes the heat transfer of air to refrigerant in the outdoor unit. The reduction of thermal conductive resistance is not the only reason for the cycle performance deterioration under frost conditions. As pointed out by Henry Barrow, there is yet another important factor contributing to the heat pump frost operation: air flow blockage. As frost grows among tubes and fins, the effective air flow passage becomes smaller, increasing the air-side pressure drop. Figure 8 depicts such a phenomenon. The air-side pressure drop doubles the amount than the non-frost value when assuming the air flow through the evaporator maintains constant. This also doubles the power of the fan in order to overcome the flow resistance. It has to be pointed out that in reality, the fan power usually remains constant and as a result, the air flow rate will decrease due to the increase of air side pressure drop. This further impairs the cycle capacity and COP. In the future, the current model will be improved by considering the air flow reduction during frost accumulation.

3.3 MCHX flow pass configuration to heat pump operation under frost condition

MCHXs are typically one or more passes as shown in Figure 9 [11]. By using a buffer (separator), refrigerant is restricted to flow into part of the tubes comprising the first pass, as opposed to flow into all tubes in the case of one pass. The refrigerant then turns 180° and flows into the rest of tubes comprised of the second pass. For an evaporator, the two-pass design expands the refrigerant as it turns into vapor, causing higher mass flux in tubes which may lead to better heat transfer and potentially higher pressure drop. However, since the air-side heat transfer remains dominant and such dominance is further amplified in the frost condition, the benefits of using two-pass over one-pass in heat transfer could be further depreciated. To make a closer examination, we established a two-pass MCHX that maintains all specifications of the one-pass design with the only modification that the flat tubes are divided into two passes: 8 tubes in the first pass and 40 tubes in the second pass.

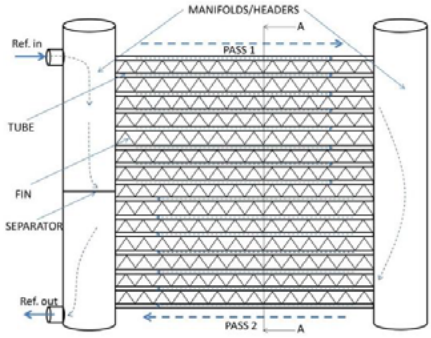

Figure 9: A sample view of Mircochannel Heat Exchanger

Figure 10 compares the pressure levels of the same heat pump system using one pass MCHX and two-pass MCHX. The two systems show almost identical pressure levels and only to compare the second digit after the decimal, one concluded that one-pass MCHX leads to both higher evaporating and condensing pressure levels. If we further compare the heat pump COP, which is demonstrated in Figure 11, we notice the COP is also similar and we have to compare the third digit after the decimal to conclude the two-pass MCHX leads a slightly larger heat pump performance. Such a close result is anticipated because the air-side condition is identical to the two evaporators and frost intensifies the air-side heat resistance dominance, meanwhile reduces the impact of better refrigerant-side heat transfer. In fact, at time when frost is yet to accumulate (t <80 seconds), we can notice the two pass MCHX cycle has a clearer edge in COP which disappears as frost builds up.

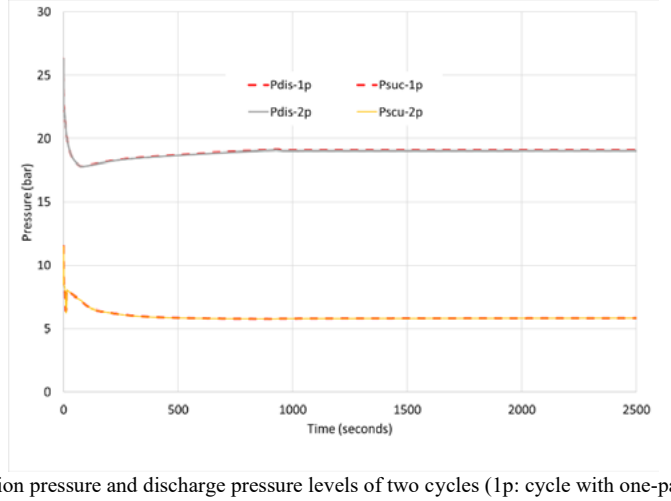

Figure 10: Suction pressure and discharge pressure levels of two cycles (1p: cycle with one-pass MCHX; 2p: cycle with two-pass MCHX)

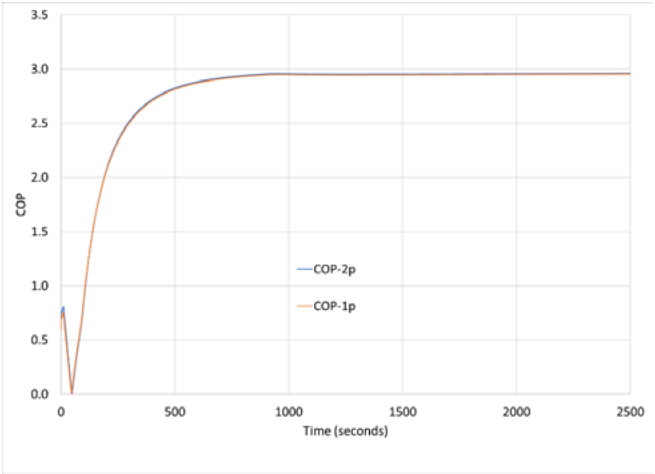

Figure 11: Coefficient of Performance (COP) of two cycles (1p: cycle with one-pass MCHX; 2p: cycle with two-pass MCHX)

4. Conclusions

The paper presents a numerical study on the operation of heat pump system with microchannel heat exchanger during frost accumulation. We modeled the microchannel heat exchanger using a segment-by-segment approach and lumped the multiple ports in the flat tube into one flow channel. The frost model is applied to the air-side control volume of the heat exchanger model so that it can be extended to other types of heat exchanger. We modeled the basic frost phenomena including frost densification and thickness growth. Through a set of case studies, we determined the frost growth on a heat exchanger depended mostly on the heat exchanger surface temperature. Regarding the heat transfer resistance due to frost accumulation, the thermal conductivity change due to the frost densification is apparently a secondary factor shadowed by the frost thickness growth. On a cycle-level comparison, we did not find significant performance enhancement by using a two-pass microchannel heat exchanger. We believe the dominance of air-side heat transfer resistance is further intensified by frost accumulation and as a result, the COP improvement from the two-pass MCHX is very much limited.

Abstract

Concerns about global climate change and potential legislation that may impact the use of refrigerants with high global warming potential (GWP) have accelerated the development of new refrigerants with reduced impact on climate change. Along with the Kigali amendment to the Montreal Protocol to phase down use of HFCs, there are regulations around the world with specific GWP limits for air conditioning and heat pump applications. The most common refrigerant used globally in residential and light commercial air conditioning systems and heat pumps is R410A, with a GWP of 2088. Regulations are already in place to limit the GWP to below 750 in many regions globally, and there may be further reductions needed in the future. This paper discusses alternative fluids that have been developed to most nearly meet the most often cited requirements for environmental, physical, and performance properties for air conditioning and heat pump applications. R454B, with a GWP of 466 and both performance and properties similar to R410A, is a potential alternative to meet these requirements while maintaining compatibility with systems similar to those of existing R410A designs to enable an orderly transition to lower GWP. Performance will be evaluated in a light commercial air conditioning and heat pump system and compared with R410A at both standard air conditioning and heating operating conditions. These refrigerants are shown to provide useful options to help maintain the quality of life and health benefits from air conditioning and refrigeration, but in an energy efficient, cost-effective, and environmentally sustainable manner.

1. Introduction

The current generation refrigerant for residential air conditioning and heat pumps, R410A, has a global warming potential (GWP) of 2088 [1] and is subject to regulations in many regions globally. R-410A is a

* Hughes, Joshua Tel.: +1-302-683-8275; fax: +1-302-683-8255.
E-mail address: joshua.hughes@chemours.com

non-flammable mixture of 50 wt% R32 and 50 wt% R125. R32 has been proposed for many years as an alternative refrigerant which has about 70% lower GWP than R410A and high cooling capacity. Therefore, many manufacturers have optimized some air conditioning products for the adoption of R32, with millions of air conditioning units using R32 as a refrigerant sold throughout Asia, New Zealand, Australia, US and Europe. However due to the Kigali amendment and F-gas regulation, as shown in Fig. 1, CO_2 emissions would need to be reduced significantly over time from previous baseline emissions. Therefore, R32 is likely not an ultimate solution to meet regulations for the future.

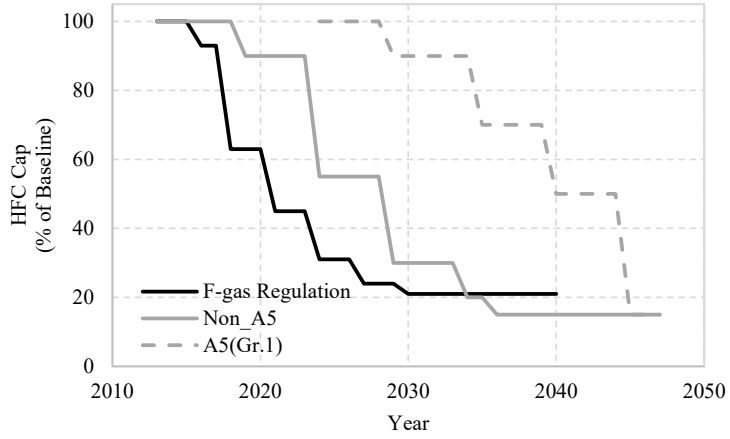

Fig. 1. HFC Phase-Down Steps of EU and Kigali Amendment (2016)

The HVAC&R industry has been searching for alternative refrigerants to help meet these new and anticipated future regulations. R454B, also known as DR-5A or XL41, is a low GWP replacement for R410A which provides similar capacity and energy efficiency to R410A. R454B is a mixture containing 68.9 wt% R32 and 31.1 wt% of HFO-1234yf. As shown in Table 1, R454B has a 100-year GWP (AR4) of 466 which could allow it to become a longer term solution to meet CO_2 reduction targets than other higher GWP candidates. Pressure of R454B is slightly lower than that of R410A and R32 at the same operating temperatures. Also, its lower liquid density contributes to the mass of refrigerant charge of R454B in an equivalent air conditioning or heat pump system that would be lower than that of R410A.

R454B is a mildly flammable refrigerant and has a received a safety classification of A2L under ASHRAE SSPC 34 [2]. The specific heat ratio is slightly higher for R454B compared to R410A, contributing to compressor discharge temperature of R454B that is slightly higher than that of R410A but well below the discharge temperatures of R32. Therefore, R454B is a potential alternative to meet environmental, physical and performance requirements while maintaining compatibility with systems similar to existing R410A designs.

Previous research of R454B has shown that R454B is a design-compatible replacement candidate for R410A. Schultz et al. [3] performed tests on a 4 RT (14 kW) rooftop heat pump to evaluate the performance of lower GWP refrigerants as alternatives to R410A in unitary air-conditioning and heat pump equipment. Minamida et al. [4] evaluated the system performance using R454B for VRF and mini-split air conditioner and observed R454B to have better COP than R410A. Also, previous testing by Hughes et al. [5] in a unitary ducted split air conditioning and heat pump system designed for R-410A has shown has similar cooling capacity and energy efficiency to R-410A.

Table 1. Property and performance comparison of refrigerants (ASHRAE-T condition, isentropic efficiency = 0.75)

Refrigerant	R410A	R32	R454B
GWP(AR4)	2088	675	466
Safety classification	A1	A2L	A2L
Condensing pressure [kPa]	3393	3473	3204
Evaporating pressure [kPa]	998	1018	913
Latent heat [kJ/kg]	159 (100%)	242 (152%)	194 (122%)
Volumetric capacity [kJ/m^3]	5646 (100%)	6236 (110%)	5378 (95%)
Discharge temperature [°C]	94	115	102
Cp/Cv (specific heat ratio)	1.412	1.514	1.414
Density suction [kg/m^3]	35.5	25.7	27.7
Density condenser [kg/m^3]	870.8 (100%)	812.2 (93%)	830.5 (95%)
Displacement volume [cm^3/rev]	31.6	31.6	31.6
Mass flow rate [kg/s]	0.065 (100%)	0.047 (72%)	0.050 (78%)
Cooling capacity [kW]	10.26 (100%)	11.33 (110%)	9.77 (95%)
Work [kW]	3.09 (100%)	3.33 (108%)	2.96 (96%)
EER [W/W]	3.32 (100%)	3.40 (102%)	3.30 (100%

2. Details of test setup

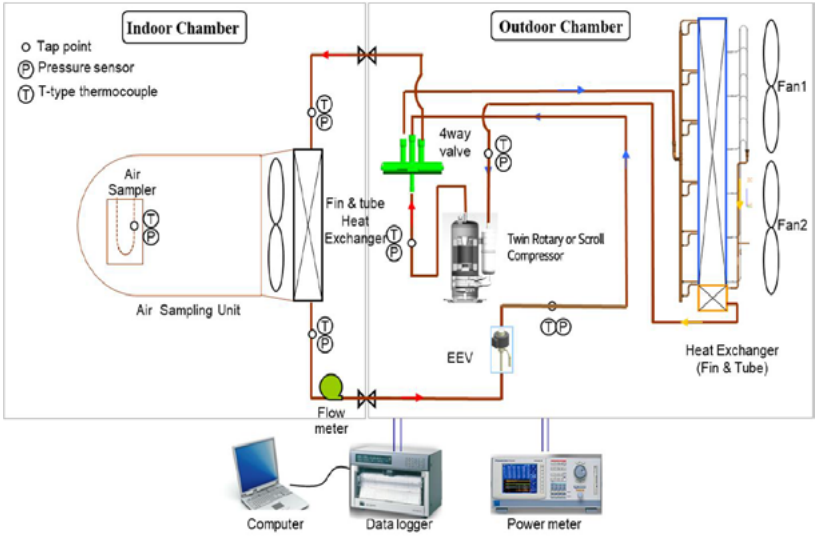

Fig. 2. Calorimeter layout for ceiling-mounted system (arrows show direction of refrigerant flow in space heating operation)

The wall-mounted type and ceiling-mounted type air conditioners commonly used in non-ducted air conditioning and heat pump systems were used to compare the performance of R410A replacement candidates. The specifications of each of the products are detailed in Table 2. The wall-mounted type air conditioner consists of an inverter rotary compressor for a conventional system and inverter twin rotary compressor for the modified system. Both the conventional and modified systems have two fin-tube type heat exchangers, one indoor fan, one outdoor fan, a 4-way reversing valve and EEV. The ceiling-mounted type air conditioner consists of inverter twin rotary compressor for the conventional system and an inverter scroll compressor for the modified system. Both systems have two fin-tube type heat exchangers, one indoor fan, two outdoor fans, a 4-way reversing valve and EEV.

Table 2. Specification of products

Product	Wall-mounted type	Ceiling-mounted type
Capacity	12kBtu/hr	48kBtu/hr
Compressor	Inverter Twin Rotary	Inverter Scroll
	10.6cm^3/rev	31.6cm^3/rev
Indoor heat exchanger	Φ7 2R 15C 21FPI	Φ7 2R 12C 21FPI Louver L2084mm
	S-Fin(Half) L616.8mm	+ Φ7 1R 10C 21FPI Louver L1930mm
Outdoor heat exchanger	Φ7 2R 22C 18FPI Louver fin L667mm	Φ7 2R 64C 14FPI Wide Louver L950mm
EEV orifice inner diameter [mm]	Φ1.65	Φ2.0

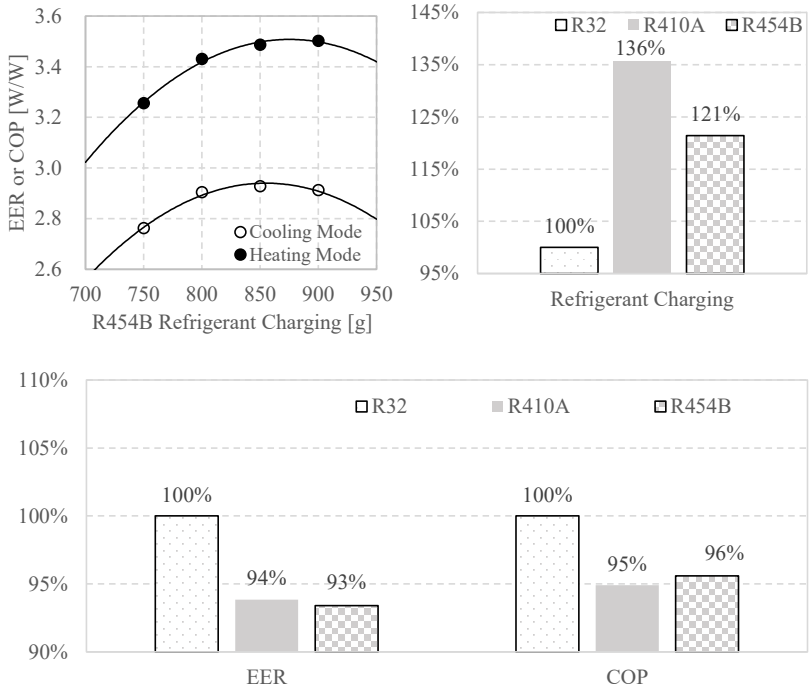
The baseline R410A test, R32 test and R454B tests have been completed as per ISO 13253 in a psychrometric calorimeter chamber at the conditions shown in Table 3 with the layout of the test apparatus detailed in Fig. 2 (ceiling-mounted schematic shown; wall-mounted system layout was similar). Each experimental parameter was recorded using a data acquisition system after the system reached a quasi-steady state. It was determined that the system is in the quasi-steady state when the measured parameters of the cycle do not change for 15 minutes after the change of the experimental conditions, such as the change of the compressor frequency. Then experimental data were recorded for 35 minutes at intervals of 5 seconds. The temperatures of the indoor chamber and the outdoor chamber were controlled in the range of -35-60ºC and 0-50ºC, respectively. Dry and wet bulb temperatures of the two chambers were controlled within the range of ±0.1ºC. All temperatures in the system are monitored using T-type thermocouples. The accuracy of the temperature measurements is estimated to be ± 0.2ºC.

Table 3. ErP test conditions and extra test conditions (EN14511 – Rated conditions, EN14825 – Part load conditions)

Conditions		Indoor		Outdoor	
		DB[ºC]	WB[ºC]	DB[ºC]	WB[ºC]
Cooling mode at rated condition		27	19	35	24
Heating mode at rated condition		20	15	7	6
SEER	Cooling A	27	19	35	24
	Cooling B			30	20
	Cooling C			25	16
	Cooling D			20	12
SCOP	Heating A	20	15	-7	-8
	Heating B			2	1
	Heating C			7	6
	Heating D			12	11
	Heating E			-10	-11
	Heating F			-8	-9
Cooling overload		32	23	48	29
		32	19	54	32
Heating low temperature		20	15	-5~-25	-

SEER is seasonal efficiency of a unit calculated for the reference annual cooling demand, which is determined from mandatory conditions given in this European Standard and used for marking, comparison and certification purposes. SCOP is seasonal efficiency of a unit calculated for the reference annual heating demand(s), which is determined from mandatory conditions given in this European Standard and used for marking, comparison and certification purposes.

The heating D condition is the lowest part load ratio condition. Therefore, to meet the part load of heating D condition, the frequency (Hz) of the compressor should be very low. It can miss the operational range of the compressor so the efficiency of the product may decrease despite having lower power consumption.



3. Results and discussions

3.1. Wall-mounted type air conditioner with inverter rotary compressor

As shown in Table 4 and Fig.3, R454B refrigerant charge size is 11% lower than the R410A charge. The R32 refrigerant charge size is 26% lower than R410A charge. The EER and COP of R454B are almost same with those of R410A. The EER and COP is 7% and 5% higher respectively for R32 compared to R410A. The discharge temperature of R454B is 5ºC higher than that of R410A in cooling standard condition and 4ºC higher than that of R410A in heating standard condition. The discharge temperature of R32 is 12ºC higher than that of R410A in cooling standard condition and 11ºC higher than that of R410A in heating standard condition.

Table 4. Comparison of performance (wall-mounted type)

Refrigerant	Refrigerant Charging [g]	Cooling mode (3.5kW at rated condition) EER [W/W]	Discharge Temperature [ºC]	Heating mode (4.0kW at rated condition) COP [W/W]	Discharge Temperature [ºC]
R410A	950	2.94	73	3.46	76
R32	700	3.14	85	3.65	87
R454B	850	2.93	78	3.49	80

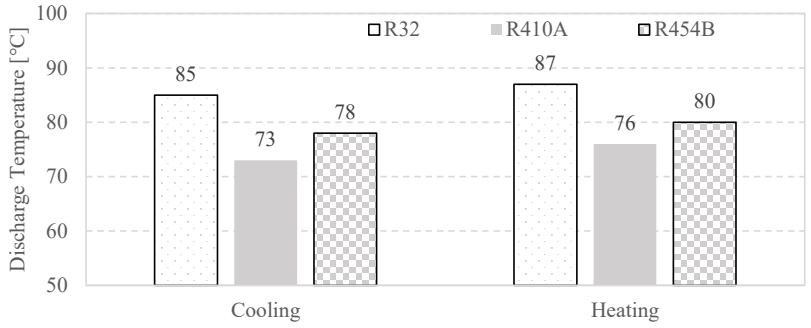


Fig. 3. Performance test results at rated conditions (wall-mounted type)

As shown in Fig. 4, as the ambient temperature increases in cooling condition and decreases in heating condition, R454B shows higher reduction of cooling capacity than R410A because of the higher discharge temperature. At high ambient temperature in cooling mode and cold climate condition in heating mode, buildings require high cooling and heating demand. So, in those conditions, it may be desired for the air conditioning system to increase the compressor frequency of an inverter compressor. When the inverter system is used in those conditions, the compressor frequency is limited by discharge temperature. The discharge temperature of compressor is affected by specific heat ratio (C_p/C_v) and the specific heat ratio of R454B is higher than that of R410A. Also, the molar mass of R454B is smaller than that of R410A, so the effect of refrigerant leakage in the compressor is larger for a R454B system compared to a R410A system. This could cause the reduction of volumetric efficiency of the compressor and higher discharge temperature. Thus, the capacity of R454B system decreases more abruptly than that of R410A in those conditions because of the higher discharge temperature.

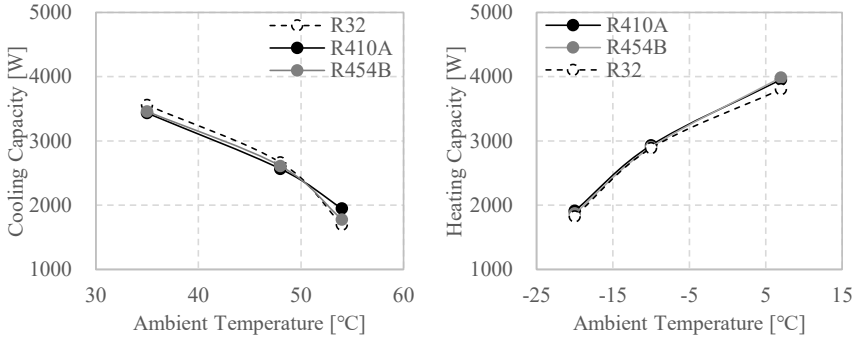

Fig. 4. The capacity comparison at high ambient temperature in cooling mode and cold climate condition in heating mode (wall-mounted type)

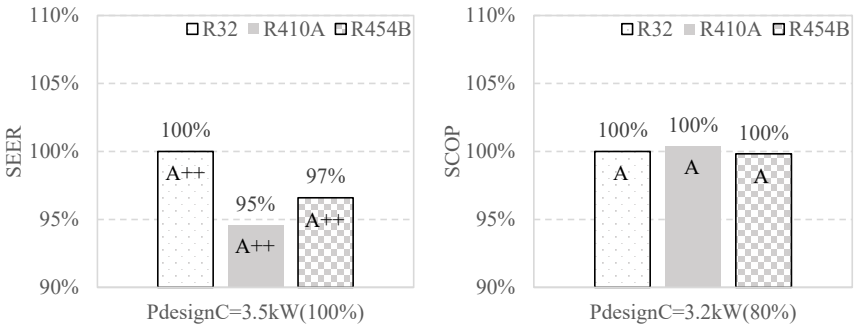
As shown in Fig. 5, The SEER is 2% higher and SCOP is almost equal for R454B compared to R410A. The SEER is 6% higher and SCOP is almost equal for R32 compared to R410A.



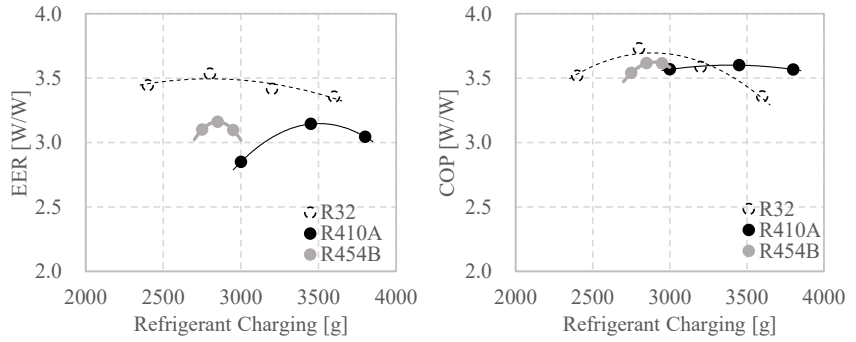


Fig. 5. Cooling and heating seasonal performance (wall-mounted type)

3.2. Ceiling-mounted type air conditioner with inverter scroll compressor

As shown in Table 5 and Fig. 6, R454B refrigerant charge size is 14% lower than the R410A charge and R32 refrigerant charge size is 19% lower than R410A charge. The EER and COP is 1% and 4% higher respectively for R454B compared to R410A. The EER and COP is 12% and 7% higher respectively for R32 compared to R410A. The discharge temperature of R454B is 6°C higher than that of R410A in cooling standard condition and 7°C higher than that of R410A in heating standard condition. The discharge temperature of R32 is 10°C higher than that of R410A in cooling standard condition and 20°C higher than that of R410A in heating standard condition.

Table 5. Comparison of performance (ceiling-mounted type)

Refrigerant	Refrigerant Charging [g]	Cooling mode (14.0kW at rated condition) EER [W/W]	Discharge Temperature [°C]	Heating mode (16.0kW at rated condition) COP [W/W]	Discharge Temperature [°C]
R410A	3450	3.14	66	3.50	73
R32	2800	3.53	86	3.73	83
R454B	3950	3.19	81	3.62	79

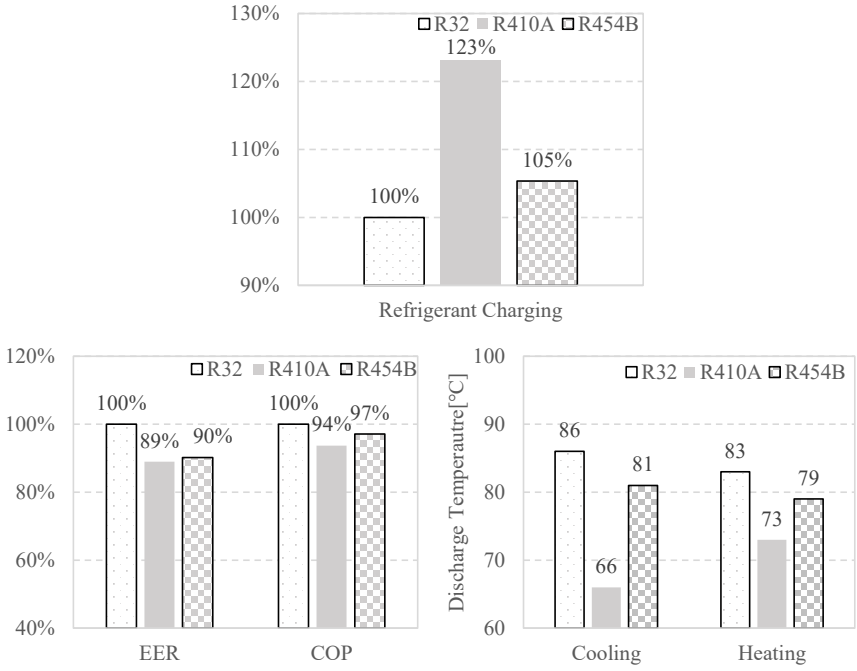

Fig. 6. Performance test results at rated conditions (ceiling-mounted type)

As shown in Fig. 7, as the ambient temperature increases in cooling condition and decreases in heating condition, R454B again shows higher reduction of cooling capacity than R410A because of the higher discharge temperature. Because of compressor current limitations, the maximum heating capacity of R32 is lower than that of R410A and R454B at the ambient temperature of 7°C.

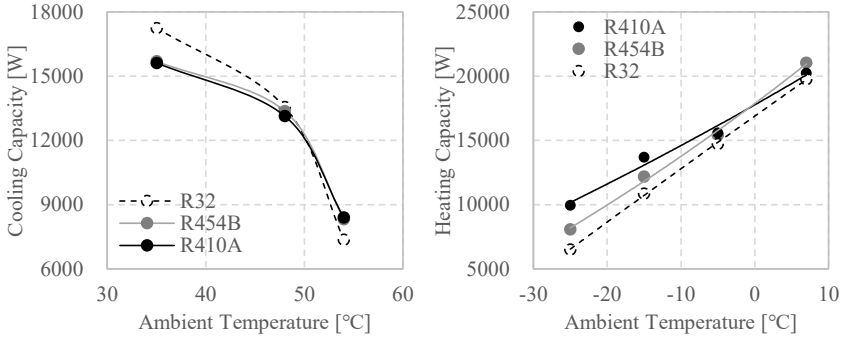

Fig. 7. The capacity comparison at high ambient temperature in cooling mode and cold climate condition in heating mode (ceiling-mounted type)

As shown in Fig. 8, the SEER and SCOP are 1% higher for R454B compared to R410A. The SEER and SCOP is 7% and 2% higher respectively for R32 compared to R410A.

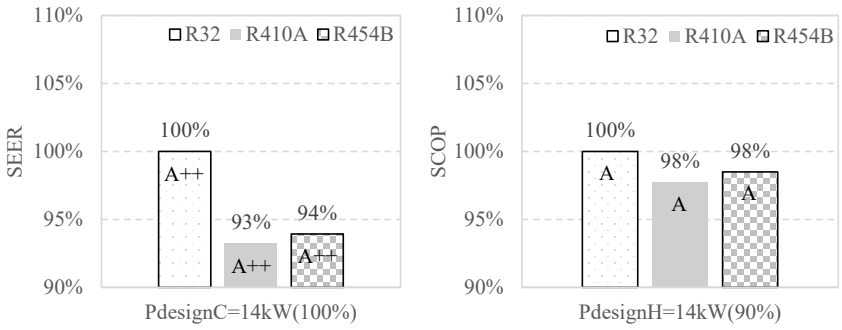

Fig. 8. Cooling and heating seasonal performance (ceiling-mounted type)

4. Conclusions

The performance of low GWP refrigerant alternatives for R410A was evaluated in light commercial air conditioning and heat pump systems and compared with R410A. Performance was tested in both wall-mounted and ceiling-mounted air conditioning and heat pump equipment. The energy efficiency and discharge temperature of R454B are slightly higher than R410A. The capacity of R32 was also higher in conjunction with higher discharge temperature, primarily because of the high value of specific heat ratio and small molar mass. As the ambient temperature increases in cooling condition and decreases in heating condition, the capacity of R32 system abruptly decreases because of the high discharge temperature.

The performance of R32 and R454B suggest they could be lower GWP alternatives to R410A in air conditioning and heat pump systems. Because of its similar properties and performance characteristics to R410A, R454B could be compatible in new system designs that are similar to R410A equipment. As research to develop replacement refrigerants for R410A has been on-going for several years, many small air conditioning and heat pump systems in Asia and Europe using R410A are being transitioned to R32. However the GWP of R32 may be too high to meet phasedowns being proposed around the world to reduce global warming over the long term. R454B is well-positioned to replace R410A with both good energy performance and with a lower GWP that could enable it to be a viable option further into the future. The lower GWP of R454B could enable it to be a promising long-term solution to help meet global CO_2 emissions goals and reduce the potential impact on the environment.

A parameter-estimation model for variable refrigerant flow heat pump systems

Aziz Mbaye[a*], Massimo Cimmino[a]

[a]Department of Mechanical Engineering, Polytechnique Montréal, 2900 Edouard Montpetit Blvd, Montreal H3T 1J4, Canada

Abstract

A variable refrigerant flow (VRF) model based on a simplified vapor compression cycle is presented. The outdoor unit and the indoor units are modelled separately. An optimization procedure is used to identify their parameters by minimizing the differences between the model predicted capacities and power input and manufacturer data. Calibration results show a root mean square error (RMSE) in range of 4%, 8.8% and 7.3% for the indoor unit total capacity, the outdoor unit capacity and power consumption respectively. Three configurations of VRF heat pump are evaluated using previously calibrated indoor unit and outdoor unit models. The results show that the model-predicted cooling capacity and power input are close to the manufacturer data with an average RMSE of 2.2% for both the power input and the cooling capacity.
Keywords: Variable refrigerant flow; Modelling and simulation, Model calibration

1. Introduction

Variable refrigerant flow (VRF) heat pump systems are growing in popularity for heating and cooling applications in buildings. When equipped with a heat recovery unit, VRF systems can provide simultaneous heating and cooling, with high efficiency, to different zones of the same building. To support their development, facilitate their design and evaluate their performance, simulation tools that model their behavior are necessary.

Lin et al. [1] gave a substantial review of recent development in modelling VRF heat pumps. VRF models range from detailed physics-based models to equation-fit models with varying levels of accuracy. Yan et al [2] developed a physical-based model for dual-evaporator air conditioning systems, including the effects of the pressure drop and the refrigerant piping length in the system performance. The model was developed by adding a second evaporator to an existing single-evaporator air conditioning system model. Hong et al. [3] developed a physical-based VRF model in EnergyPlus. The model validation using field test results of an instrumented house showed that the error associated with the VRF power demand is in range of 10%. Zhu et al. [4] implemented a modular transient VRF model in TRNSYS. Results showed an average deviation between simulation results and experimental data of 7.9%, 12.5% and 6.2% for the capacity, the power input and the coefficient of performance (COP), respectively. Cheung and Braun [5] proposed a component based gray box model for ductless multi-split systems with a variable frequency compressor. Parameters are first tuned using experimental data and then applied to the model. Comparisons between experimental data and simulation results after parameter tuning showed that the error in the power consumption is in range of 8%. More recently, Sun et al. [6] developed a general VRF model using graph theory. The model can simulate systems with arbitrary layouts and under various operating conditions including partial load operation. The model is validated using experimental data and the results showed deviations of 3% and 3°C for the capacity and the indoor unit (IU) temperature, respectively. While physical-based models have been shown to predict VRF behavior with acceptable accuracy, they are not widely used in energy simulation software such as EnergyPlus. They require inputs that are not readily provided in manufacturer literature and are typically computationally expensive. Some authors have proposed empirical equation-fit models using performance curves based on manufacturer data. Raustad [7] developed an equation-fit model implemented in EnergyPlus. A comparison of the model predicted energy use against field test results showed that the error is in range of 25% overall [8].

Kim et al. [9] showed that a proper calibration of Raustad's model can improve its accuracy. Experiments in an office building showed that the error decreased from 32.3% to 15.7% for the non-calibrated and calibrated models, respectively. Torregrosa-Jaime et al. [10] have developed an improved equation fit-model based on Raustad's model that adjusts better to the manufacturer data. They proposed to evaluate the VRF power consumption directly as a function of the operating temperatures and the partial load ratio (PLR) while the original model uses intermediate parameters that are inferred from the manufacturer data (i.e. energy input ratio as function of the temperature, energy input ratio as function of the PLR). For partial load operation, the model still loses accuracy and shows considerable variations with the manufacturer's data.

This paper presents the development of a model for the simulation of VRF heat pump systems based on a simplified thermodynamic cycle. The indoor units (IU) and the outdoor units (OU) that form the VRF heat pump are modelled independently so that various VRF configurations with multiple IUs can be evaluated. Model parameters are inferred from a parameter-estimation procedure on available manufacturer data to minimize the error between the model-predicted performance metrics (e.g. capacity, power input) and the performance data from the manufacturer. Calibrated OU an IU models are then assembled into various VRF system configurations.

2. Methodology

The VRF model is based on a simplified vapor compression cycle as proposed by Jin [11]. The benefit in such cycle is to reduce the number of the model parameters in order to facilitate the calibration process and to reduce the computational time since only few refrigerant states are required. Here, the Martin-Hou equation of state for R410A is used to evaluate the thermodynamic parameters of the refrigerant [12]. Figure 1 presents a pressure-enthalpy diagram of the simplified vapor compression cycle that relies on the following assumptions:

- There is no subcooling in the condenser; the refrigerant leaves the condenser (point B) in a saturated liquid state.
- The refrigerant leaving the evaporator (point C) is in a superheated vapor state with a constant degree of superheating.
- The sensible heat transfer (from point A to point C) in the evaporator is neglected, as it is small compared to the latent heat transfer.
- The expansion process through the electronic expansion valve (EEV) is isenthalpic.
- The pressure drops within the heat exchangers as well as those in the refrigerant pipes are neglected.

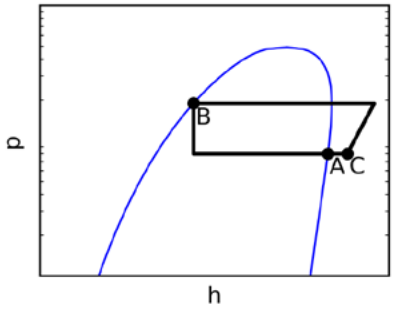

Fig. 1. P-h diagram of the simplified vapor compression cycle

3. Variable refrigerant flow heat pump model

3.1. Indoor unit model

The IU is likened to an air-refrigerant heat exchanger operating at a constant refrigerant temperature. The model parameters are the inside and the outside surface heat transfer coefficients (UA_{in} and $h_c A_{out}$). As shown in Figure 2, the model requires as inputs the air mass flow rate ($\dot{m}_{IU}$), dry bulb temperature ($T_{DB,IU}$), wet bulb temperature ($T_{WB,IU}$) and the total capacity ($\dot{q}_{IU}$). The outputs of the model are the sensible and latent capacities ($\dot{q}_{sen,IU}$ and $\dot{q}_{lat,IU}$) and the refrigerant evaporating (in cooling mode) or condensing (in heating mode) temperature (T_{ref}).

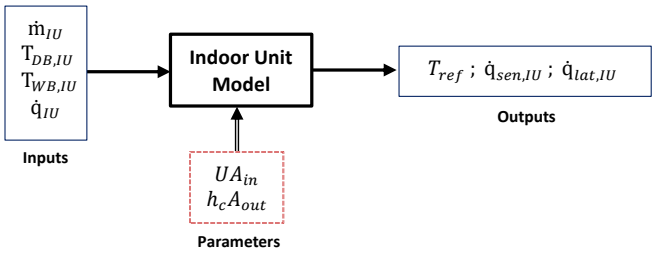

Fig. 2. Indoor unit model: parameters, inputs and outputs

The heat exchanger efficiency is calculated by the ε-NTU method:

$$UA = \frac{1}{\frac{1}{h_c A_{out}} + \frac{1}{UA_{in}}} \tag{1}$$

$$\text{NTU} = UA/\dot{m}_{IU} c_{p,a} \tag{2}$$

$$\varepsilon = 1 - e^{(-NTU)} \tag{3}$$

where NTU is the number of transfer units, UA is the global heat transfer coefficient, ε is the heat exchanger efficiency, and $c_{p,a}$ is the specific isobaric heat capacity of the moist air.

When the indoor unit operates as an evaporator (i.e., in cooling mode), condensation may occur at the outside surface of the cooling coil. Depending on the operating conditions, the cooling coil may be fully dry, fully wet or partially wet, and each case will affect the heat transfer coefficient. Therefore, the model of the IU should take account of whether it operates as an evaporator or condenser. In heating mode, there is no condensation and the IU operates as a sensible heat exchanger. The heat transfer rate is given by:

$$\dot{q}_{IU} = \varepsilon \cdot \dot{m}_{IU} c_{p,a} \left(T_{DB,IU} - T_{ref}\right) \tag{4}$$

In cooling mode, the outside surface of the coil is considered to be fully wet as proposed by Jin [11]. The heat exchanger behavior follows the enthalpy potential method. The total heat transfer from the air stream to the coil surface is a combination of sensible heat transfer ($\dot{q}_{sen,IU}$) and latent heat transfer ($\dot{q}_{lat,IU}$):

$$\dot{q}_{IU} = \dot{q}_{sen,IU} + \dot{q}_{lat} \tag{5}$$

$$\dot{q}_{IU} = \varepsilon_{eff} \dot{m}_{IU} \left(h_a - h_{a,e}\right) \tag{6}$$

$$\varepsilon_{eff} = 1 - e^{(-NTU_{eff})} \tag{7}$$

$$\text{NTU}_{eff} = UA_{eff}/\dot{m}_a c_{p,a} \tag{8}$$

where UA_{eff} is the effective heat transfer coefficient for the total (i.e. sensible and latent) heat transfer, h_a is the enthalpy of the moist air evaluated at the inlet air dry bulb and wet bulb temperature ($T_{DB,IU}$ and $T_{WB,IU}$), $h_{a,e}$ is the enthalpy of the moist air at the refrigerant evaporating temperature (T_{ref}), ε_{eff} and NTU_{eff} are the corresponding heat exchanger effectiveness and number of transfer units, respectively.

The effective heat transfer coefficient UA_{eff} is given by:

$$UA_{eff} = \frac{1}{\frac{1}{h_c A_{out}} + \frac{c_{p,a,s}}{c_{p,a}} \frac{1}{UA_{in}}} \tag{9}$$

where $c_{p,a,s}$ is the specific isobaric heat capacity of saturated air evaluated at the coil effective surface temperature.

The sensible heat transfer rate is evaluated analogically to a sensible heat exchanger from the outside surface heat transfer coefficient, considering a uniform coil surface temperature:

$$\dot{q}_{sen,IU} = \varepsilon' \dot{m}_{IU} c_{p,a} \left(T_{DB,IU} - T_{surf}\right) \quad (10)$$

$$\varepsilon' = 1 - e^{(-NTU_a)} \quad (11)$$

$$\mathrm{NTU}_a = h_c A_{out} / \dot{m}_{IU} c_{p,a} \quad (12)$$

where NTU_a is the number of air side transfer units, ε' is the air side effectiveness and T_{surf} is the effective surface temperature of the coil, which corresponds to the moist air dry bulb temperature at the coil.

The effective surface temperature is inferred from the corresponding enthalpy of saturated air $h_{a,s}$:

$$h_{a,s} = h_a - \dot{q}_{IU} / \dot{m}_{IU} \varepsilon' \quad (13)$$

3.2. Outdoor unit model

The OU model is based on the simplified heat pump cycle previously presented in Figure 1. It consists of two components: a compressor and a heat exchanger. The heat exchanger model is the same as presented in section 3.1 for the indoor units. Depending on the operation mode, it is considered as a sensible heat exchanger (i.e., condenser in cooling mode) or as a latent/sensible heat exchanger (i.e., evaporator in heating mode). Frost accumulation is not considered in the model. Figure 3 shows a schematic chart of the OU model with its parameters, inputs and outputs.

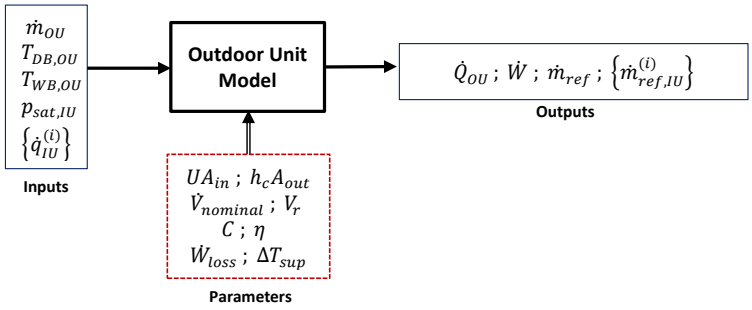

Fig. 3. Outdoor unit model: parameters, inputs and outputs

The scroll compressor is modelled according to Jin [11]. The compressor work is a result of isentropic compression at the built-in volume ratio followed by isochoric compression to the discharge pressure as described by Winandy et al. [13]:

$$\dot{W}_t = \frac{\gamma}{\gamma - 1} p_{eva} \dot{V}_{nominal} \left(\frac{\gamma}{\gamma - 1} \frac{p_{con}}{p_{eva} V_r} + \frac{1}{\gamma} p_r^{\frac{\gamma}{\gamma - 1}} - 1 \right) \quad (14)$$

where $\dot{W}_t$ is the theoretical compressor work, p_{eva} and p_{con} are the evaporating and condensing pressure, γ is the isentropic exponent of the refrigerant at the suction of the compressor, $\dot{V}_{nominal}$ is the nominal refrigerant volume flow rate, V_r is the built-in volume ratio between the discharge and the suction of the compressor and $p_r = V_r^{\gamma}$ is the built-in pressure ratio. In cooling mode, p_{con} is the refrigerant pressure in the OU heat exchanger and $p_{eva} = p_{sat,IU}$ is the pressure in the IU. In heating mode, $p_{con} = p_{sat,IU}$ is the refrigerant pressure in the IU and p_{eva} is the pressure in the OU heat exchanger.

The power input of the compressor is given by:

$$\dot{W} = \frac{\dot{W}_t}{\eta} + \dot{W}_{loss} \tag{15}$$

where η is the electromechanical efficiency of the compressor and $\dot{W}_{loss}$ are constant power losses.

Since the sensible heat transfer to the refrigerant is neglected in the evaporator, the evaporator heat transfer rate is evaluated from the enthalpy difference between points A and B of Figure 1:

$$\dot{Q}_{eva} = \left(\frac{\dot{V}_{nominal}}{v_{suc}} - \dot{m}_{leak}\right)(h_A - h_B) \tag{16}$$

where $\dot{Q}_{eva}$ is the total evaporator heat transfer rate, v_{suc} is the specific volume at the suction of the compressor, $\dot{m}_{leak}$ is the leakage mass flow rate in the compressor. Based on Chen et al. [14], the leakage mass flow rate can be estimated as a function of the condensing and evaporating pressures:

$$\dot{m}_{leak} = C\, p_{con}/p_{eva} \tag{17}$$

where C is the leakage coefficient. The total condenser heat transfer rate, $\dot{Q}_{con}$, can then be obtained by an energy balance:

$$\dot{Q}_{con} = -\left(\dot{Q}_{eva} + \dot{W}\right) \tag{18}$$

In cooling mode, $\dot{Q}_{con}$ and $\dot{Q}_{eva}$ are the OU heat rejection ($\dot{Q}_{OU}$) and the sum of the IU capacities $\left\{\dot{q}_{IU}^{(i)}\right\}$ respectively. In heating mode $\dot{Q}_{eva}$ is the OU heat absorption ($\dot{Q}_{OU}$) and $\dot{Q}_{con}$ is the sum of the IU capacities $\left\{\dot{q}_{IU}^{(i)}\right\}$.

3.3. Assembled VRF model

For the assembled VRF model, it is important to ensure that the refrigerant is always at the same pressure in each IU since many IUs with different operating conditions can be involved. The operating conditions are then evaluated by iteration. The refrigerant mass flow rate in the IUs is adapted to meet the required capacity. Figure 4 presents the calculation procedure for the VRF model in cooling mode that follows this sequence:

1. Initialize the IU and the OU operating conditions using the nominal values of the IU capacity, dry bulb temperature and wet bulb temperature and the OU capacity, power consumption dry bulb temperature and wet bulb temperature. These nominal values correspond to the rated conditions and performances in accordance to the ANSI/AHRI standard 1230. They can be found in the product datasheets.
2. Evaluate each IU refrigerant temperature ($T_{ref,IU}^{(i)}$) using Eq. 4.
3. Evaluate the minimum IU refrigerant evaporating temperature:

$$T_{sat,IU} = \min\left[T_{ref,IU}^{(i)}\right] \tag{19}$$

4. Evaluate the IU capacities $\dot{q}_{IU}^{(i)}$ using Eq. 4 and the minimum evaporating temperature.
5. Evaluate the refrigerant condensing temperature at the OU using Eq. 4.
6. Evaluate the evaporating pressure p_{eva}, the condensing pressure p_{con} and the enthalpies (h_A and h_B) from the refrigerant equation of state.
7. Evaluate the capacity ($\dot{Q}_{eva}$), the heat rejection ($\dot{Q}_{con}$) and the power consumption ($\dot{W}$) using Eqs. 14 – 18.

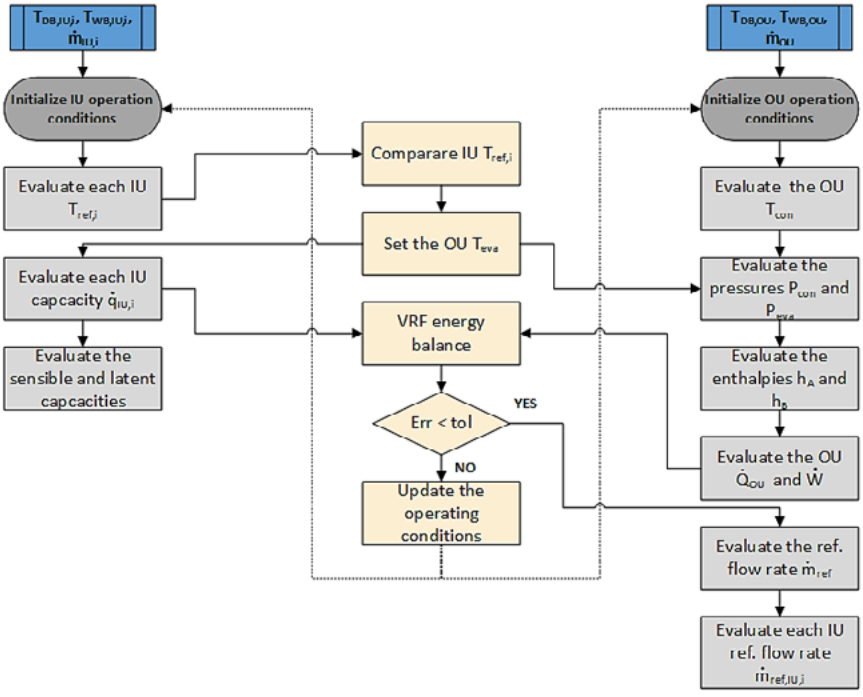

Fig. 4. Layout of the VRF heat pump model in cooling mode

8. Evaluate the errors in the VFR energy balance:

$$\Delta\dot{Q}_{eva} = \dot{Q}_{eva} - \Sigma_i \dot{q}_{IU}^{(i)} \tag{20}$$

$$\Delta\dot{W} = \dot{W} - \dot{W}^{-} \tag{21}$$

$$\Delta\dot{Q}_{con} = \dot{W} - \dot{Q}_{eva} - \dot{Q}_{con} \tag{22}$$

where $\dot{W}^{-}$ is the power consumption at the previous iteration.

9. Evaluate the sum of the heat rejection and power consumption absolute relative errors:

$$Err = \left|\Delta\dot{Q}_{con}/\dot{Q}_{con}\right| + \left|\Delta\dot{W}/W\right| \tag{23}$$

10. If Err is above the tolerance, update the VRF state for the next iteration:

$$\dot{Q}_{eva}{}^{+} = \dot{Q}_{eva} + \delta\Delta\dot{Q}_{eva} \tag{24}$$

$$\dot{Q}_{con}{}^{+} = \dot{Q}_{con} + \delta\Delta\dot{Q}_{con} \tag{25}$$

$$\dot{W}^{+} = \dot{W} + \delta\Delta\dot{W} \tag{26}$$

$$\dot{q}_{IU}^{(i)+} = \dot{Q}_{eva}{}^{+}\frac{\dot{q}_{IU}^{(i)}}{\Sigma_i \dot{q}_{IU}^{(i)}} \tag{27}$$

where δ is a relaxation coefficient. A relaxation coefficient of 0.7 and a tolerance of 10^{-8} are used in this study. The new VRF state is then used to reinitialize the IU and OU before the next iteration, starting from step 2.

11. If Err below the tolerance, evaluate the refrigerant mass flow rate for each IU using the refrigerant routines and Eq. 17:

$$\dot{m}_{ref} = \frac{\dot{V}_{nominal}}{v_{suc}} - \dot{m}_{leak} \tag{28}$$

$$\dot{m}_{ref,IU}^{(i)} = \dot{m}_{ref} \frac{\dot{q}_{IU}^{(i)}}{\sum_i \dot{q}_{IU}^{(i)}} \tag{29}$$

4. Calibration procedure

Parameters to the models are unknown, as manufacturers do not typically provide values of the VRF heat pump parameters. Here, parameters are estimated by calibration of the models over the published manufacturer performance data. The IU model has two parameters (UA_{in} and $h_c A_{out}$), while the OU model has 8 (UA_{in}, $h_c A_{out}$, $\dot{V}_{nominal}$, V_r, C, η, $\dot{W}_{loss}$ and ΔT_{sup}). For IUs, manufacturers usually provide data of latent and sensible capacities at different airflow temperatures (dry bulb and wet bulb) and flow rates. For OU, manufacturers provide the power consumption in addition to latent and sensible capacities at different airflow temperatures. Regarding IU, sometimes the air flow rate is given as a set of two or three values (corresponding to the fan speed control, e.g., Low, Med, Hi) and it is not clearly indicated which value is used to generate the data. In such case, the calibration is performed successively with the different values of air flow rate. The air flow rate that leads to the minimal error between the model and the data is retained.

4.1. Indoor unit

Component models for IUs as well as calibration routines are implemented in Python. The parameters that minimize the sum of squared errors between the model and the manufacturer data are identified using the Sequential Least Squares Programing method (SLSQP) from the Python SciPy library:

$$SSE_{IU} = \sum_j \left[\left(\frac{\dot{q}_{sen,IU}^{(j)} - \dot{q}_{sen,data}^{(j)}}{\dot{q}_{sen,data}^{(j)}} \right)^2 + \left(\frac{\dot{q}_{lat,IU}^{(j)} - \dot{q}_{lat,data}^{(j)}}{\dot{q}_{lat,data}^{(j)}} \right)^2 \right] \tag{30}$$

where for the set of data points (j): $\dot{q}_{sen,IU}^{(j)}$ and $\dot{q}_{lat,IU}^{(j)}$ are the IU model sensible and latent capacities, $\dot{q}_{sen,data}^{(j)}$ et $\dot{q}_{lat,data}^{(j)}$ are the latent and the sensible capacities form the IU manufacturer data

For the calibration procedure, it is important to choose proper guess values for the parameters to ensure that the result converges in any case. Cimmino et al. [12] proposed a procedure based on the nominal values of the capacity and power input to evaluate the guess parameters. This approach was implemented assuming a pinch value of 5K in the heat exchanger. The initialization of the IU parameters follows this sequence:

1. Set the refrigerant temperature difference : $\Delta T = 5\,°C$ (31)
2. Evaluate the IU heat transfer coefficients: $h_c A_{out} = UA_{in} = 2\dot{Q}_{nominal}/\Delta T$ (32)

4.2. Outdoor unit

While an OU embodies only a compressor and a single heat exchanger, a second heat exchanger is included in the calibration model to complete the cycle and evaluate the OU capacity and power input. The heat transfer of this heat exchanger is not taken into account in the cost function but its heat transfer coefficient is still calibrated. Moreover, the exchanger is assumed to operate in sensible heat transfer mode in the air side and the air mass flow rate is set to the same value as the one given by the manufacturer for the outdoor unit heat exchanger. The same method as for the IU is used to minimize the sum of squared errors between the model and the manufacturer data for the OU:

$$SSE_{OU} = \sum_j \left[\left(\frac{\dot{Q}_{OU}^{(j)} - \dot{Q}_{data}^{(j)}}{\dot{Q}_{data}^{(j)}} \right)^2 + \left(\frac{\dot{W}^{(j)} - \dot{W}_{data}^{(j)}}{\dot{W}_{data}^{(j)}} \right)^2 \right] \tag{33}$$

where for the set of data points (j): $\dot{Q}_{OU}^{(j)}$ and $\dot{W}^{(j)}$ are the OU model heat rejection and power consumption respectively and $\dot{Q}_{data}^{(j)}$ and $\dot{W}_{data}^{(j)}$ are the heat rejection and power consumption from the OU manufacturer data.

For the calibration procedure, the guess values assume a pinch value of 5K in the IU and OU heat exchangers. The heat transfer coefficient of the inside and the outside surface are set at the same initial value. The leakage mass flow rate is set at 1% of the refrigerant mass flow rate. The guess value of the electro-mechanical efficiency is chosen to be η = 0.95 and the superheating, ΔT_{sup} = 5K. The nominal values of the temperatures are the one at the rated condition.

The guess values of the OU parameters are evaluated with this following sequence in cooling mode:

1. Evaluate the refrigerant temperature:

$$T_{eva} = T_{DB,in,eva,nominal} - 5°C \tag{34}$$

$$T_{con} = T_{DB,in,con,nominal} + 5°C \tag{35}$$

2. Evaluate the evaporator heat transfer rate at nominal conditions:

$$\dot{Q}_{eva,nominal} = \dot{W}_{nominal} - \dot{Q}_{con,nominal} \tag{36}$$

3. Evaluate the evaporating pressure p_{eva} and condensing pressure p_{con} from the refrigerant equation of state.
4. Evaluate the specific volume and isentropic exponent at the compressor suction from the refrigerant equation of state using the condensing pressure p_{con} and the suction temperature $T = T_{eva} + \Delta T_{sup}$
5. Evaluate the volume ratio:

$$V_r = (p_{con}/p_{eva})^{\frac{1}{\gamma}} \tag{37}$$

6. Evaluate the nominal refrigerant volume flow rate:

$$\dot{V}_{nominal} = (\dot{m}_{ref} + \dot{m}_{leak})v_{suc} \tag{38}$$

$$\dot{m}_{ref} = \dot{Q}_{eva,nominal}/(h_A - h_B) \tag{39}$$

$$\dot{m}_{leak} = 0.01\dot{m}_{ref} \tag{40}$$

7. Evaluate the leakage coefficient:

$$C = \dot{m}_{leak}/(p_{con}/p_{eva}) \tag{41}$$

8. Evaluate the constant part of the power losses with the previously evaluated parameters and the theoretical power (Eq. 14):

$$\dot{W}_{loss} = \max(0, \eta\dot{W}_{nominal} - \dot{W}_t) \tag{42}$$

9. Evaluate the condenser and evaporator heat transfer coefficients:

$$\{UA_{eva}, UA_{con}\} = \dot{Q}_{eva,nominal}/5°C \tag{43}$$

10. Evaluate the evaporator internal and external heat transfer coefficients:

$$h_c A_{out,eva} = UA_{in,eva} = 2UA_{eva} \tag{44}$$

5. Results

5.1. Indoor unit calibration results

A commercial IU of 3.5 kW nominal capacity is used to verify the model and the calibration procedure in cooling mode. Values of sensible and latent heat transfer rates are given for different sets of dry bulb and wet bulb temperature. The temperature range goes from 22.7°C to 31.1°C for a total of 24 data points. Two air mass flow rates (0.104 kg/s and 0.168 kg/s), corresponding to two fan speeds, are given in the data. The calibration is performed with each of the two air mass flow rates and the best result is retained. The guess values and the calibration result of each parameter are shown in Table 1. Figure 5 shows the comparison between the model predicted and the manufacturer provided values of the IU sensible, latent and total capacities.

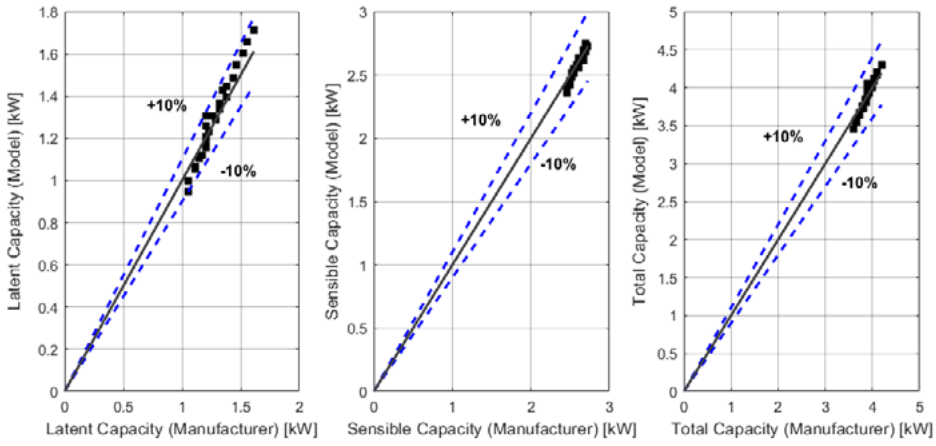

Fig. 5. Comparison of manufacturers and calibrated IU capacities

Table 1. IU parameters calibrated with manufacturer data

Parameters	Guess values	Calibrated values
UA_{in} $[W/K]$	1406.4	1543.1
$h_c A_{out}$ $[W/K]$	1406.4	1567.6

The root mean square error (RMSE) is 4.9%, 1.5% and 1.9% for the latent, sensible and total capacities, respectively. The maximum difference between values from the model and the manufacturer data is 10.3%, 4% and 4% for the latent, sensible and total capacities, respectively. The error on the latent capacity is caused by the assumption of a coil that is completely wet. The results are acceptable in the context of energy simulation, considering that the total capacity is the most relevant performance metric in this case. Various IU sizes from different manufacturers have been also verified and similar results have been obtained.

5.2. Outdoor unit calibration results

The OU model and calibration method is also verified against manufacturer data. Data from a 10.5 kW nominal capacity outdoor unit is used to calibrate the model in cooling mode. The nominal coefficient of performance (COP) of the OU is 3.37. As the OU heat exchanger operates as a condenser, only the external heat transfer coefficient ($h_c A_{out}$) is calibrated. Table 2 shows the guess values and the calibration result of each parameter and Figure 6 shows the comparison between the model and the manufacturer data of power and capacity.

An RMSE of 2.1% and 2.3% is obtained for the power input and the capacity, respectively. The maximum differences are 8.8% and 7.3% for the power input and the capacity, respectively. Similar results have been obtained with OUs of different capacities and from different manufacturers.

Table 2. OU parameters calibrated with manufacturer data.

Parameters	Guess values	Calibrated values
UA_{in} $[W/K]$	-	-
$h_c A_{out}$ $[W/K]$	2491	1016.1
$\dot{V}_{nominal}$ $[m^3/s]$	0.001	0.0026
V_r $[-]$	2.16	2.45
C $[kg/s]$	0.0091	0.0
η $[-]$	0.95	0.99
$\dot{W}_{loss}$ $[W]$	358.7	0.0
ΔT_{sup} $[°C]$	5.0	0.5

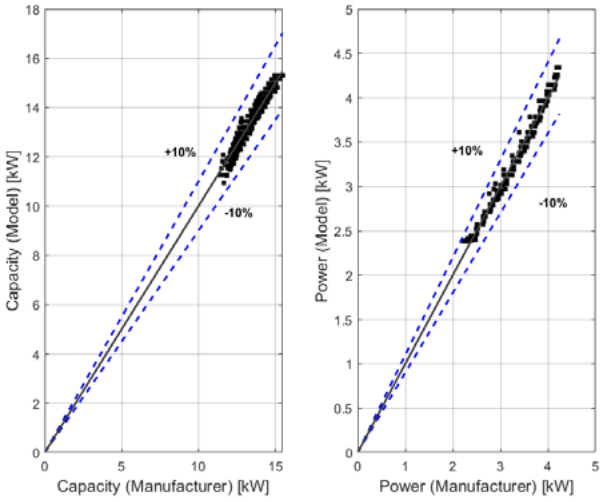

Fig. 6. Comparison of manufacturers and calibrated power and capacity of the OU

5.3. VRF model results

The VRF model is verified by assembling an OU and several IUs. Since manufacturers do not communicate data of assembled VRF units, the performance metrics of the model are compared to the available manufacturer data for the corresponding OU. Previously calibrated OU and IUs are used to build different configurations of VRF units. Table 3 and Table 4 show the parameters of the IUs and OU considered. The parameters are obtained by calibration, while the air mass flow rates are the values given by the manufacturer and used during the calibration process. Three cases corresponding to three VRF configurations are evaluated.

Table 3. Calibrated indoor units used to build VRF configurations.

Indoor unit	Capacity $[kW]$	$h_c A_{out}$ $[W/K]$	UA_{in} $[W/K]$	$\dot{m}_a$ $[kg/s]$
A	2.6	1192	506	0.162
B	3.5	1567	1543	0.168
C	5.3	4312	3211	0.231
D	7	5723	3630	0.272

The units are assembled to maintain a capacity ratio between OU and IUs equal to one. In case 1, the OU is paired to 3 IUs (2A + 1C). In case 2, 3 IUs of same capacity (3B) are connected to the OU. In case 3, the OU is paired to 2 IUs (1B + 1D). Comparisons of the VRF input power and capacity between the calibrated model and the OU manufacturer data are shown on Figure 7. Table 5 shows that the RMSE is in range of 1.8% to 3.5% for the power input and 1.9% to 5.1% for the capacity.

Table 4. Calibrated outdoor unit used to build VRF configurations.

Parameters	Values
UA_{in} $[W/K]$	1834
$h_c A_{out}$ $[W/K]$	-
$\dot{V}_{nominal}$ $[m^3/s]$	0.002325
V_r $[-]$	2.807
C $[kg/s]$	0.0
η $[-]$	0.81
$\dot{W}_{loss}$ $[W]$	0.0
ΔT_{sup} $[°C]$	1
$\dot{m}_a$ $[kg/s]$	2.162

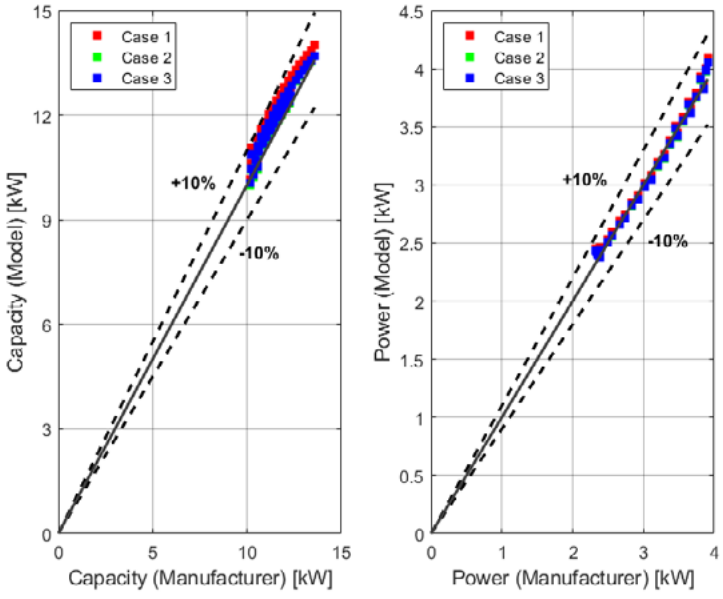

Fig. 7. Comparison of assembled VRF and manufacturer power and capacity

Table 5. VRF configurations and RMSE values compared to manufacturer data

Case	Configuration	Error on the Power		Error on the Capacity	
		Maximum	RMSE	Maximum	RMSE
1	OU + IUs {A, A, C}	5.2%	2.1%	8.3%	5.1%
2	OU + IUs {B, B, B}	4.4%	3.5%	6.3%	1.9%
3	OU + IUs {B, D}	4.4%	1.8%	6.2%	3.3%

6. Conclusions

A model for an air source variable refrigerant flow heat pump is presented. The model is based on a simplified vapor compression cycle to reduce the number of thermodynamic properties evaluation and maintain a low computational time. The IUs and OU are modelled separately so that various VRF configurations with multiple IUs can be considered. Models for the units and a calibration procedure were implemented in Python. The parameters of the models are calibrated by using manufacturer data and by minimizing the differences between the model's performance metrics and those given in manufacturer data.

Different configurations of VRF heat pumps were evaluated by using previously calibrated IUs and OU. Comparison with manufacturer data showed that the model predicts very closely the input power and the capacity of the outdoor unit. A maximum root mean square error of 2.9% and 2.8% were observed respectively for the capacity and the power input. Future work will be devoted to the implementation of a partially wet coil in the heat exchanger model, defrosting in heating mode, the extension of the model for partial load operation and heat recovery.

Abstract

The challenge for long-range electric vehicles is to increase the driving distance by maintaining the highest battery energy density level and by managing energy efficiently. An effective battery thermal management system is required to control the operating temperature of the battery for optimal battery energy density. For efficient energy management, more efficient cabin heating system is needed because they consume a lot of energy during winter. In this paper, the performance of the dual coolant-cooled battery cooling system was studied. In addition, the heat pump system that utilizes battery waste heat was studied to further improve the energy efficiency of the existing heat pump using the ambient air heat and power electric module waste heat. The results showed that a dual coolant-cooled battery cooling system combined with a radiator and Air Conditioning (AC) system can reduce power consumption by 75% at the ambient temperature of 15°C compared to using the AC system only. In addition, the use of battery waste heat in the heat pump system increased mileage by up to 9% at the low ambient temperature of -7°C.

1. Introduction

As environmental regulations on greenhouse gas emissions tighten, interest in Electric Vehicles (EVs) has increased [1]. The main issues for the development of EVs are to select an appropriate energy storage system and to use the battery energy efficiently to improve mileage [2]. Lithium-ion (Li-ion) batteries are considered to be the most suitable energy storage devices for EVs because they have a higher energy density, higher power, lighter, lower self-discharge rate, and a longer lifespan than other rechargeable batteries such as nickel-cadmium [3]. However, since the performance of the Li-ion batteries is sensitive to varying temperature, the driving distance of the EVs will be reduced if the battery temperature is not controlled properly [4]. Therefore, the Battery Thermal Management System (BTMS) is needed to increase the mileage of EVs. Pesaran [5] suggested that the Li-ion battery operating temperature range should be maintained between 15°C and 35°C and the maximum temperature difference should be kept below 5°C.

Hyundai Motor Company (HMC) defines “short-range EVs” as the vehicles with below 200 miles/one full charge represented by Ionic EV and “long-range EVs” as vehicles with over 200 miles/one full charge represented by Kona EV. For long-range EVs, high current is used to reduce charging time, thus the heat generation inside the battery and On Board Charger (OBC) can be more increased [6]. This additional battery waste heat requires a more powerful battery cooling system, but on second thought, it can be used as cabin heating for EVs. For Mitsubishi I-MIEV, the driving distance is reduced by up to 45% during heating operation and up to 27% during indoor AC operation [7]. By utilizing the waste heat of the battery in addition to the

E-mail address: tkim@skku.edu.

waste heat of the power electric (PE) module, it is possible to improve the heating performance to minimize the reduction of the EVs mileage. Therefore, in order to improve the mileage, a cooling system is needed to maintain the battery temperature properly, and its waste heat is effectively utilized for cabin heating.

In this paper, a dual coolant-cooled battery cooling system that can use both radiator and AC system was studied as a way to relieve the self-heating of high energy density batteries and high-efficiency heat pump system that utilizes battery waste heat as well as conventional PE waste heat was studied.

2. Main subject

2.1. Application of dual coolant-cooled battery cooling system

2.1.1. Importance of battery thermal management

The performance of Li-ion batteries is closely related to temperature, so it is important to understand the heat generation inside the battery. According to Thomas and Newman [8], Li-ion cells are known to generate heat by reversible entropy, resistive dissipation, a concentration gradient of cells and relaxation of chemical reactions, as expressed by Gu et al. [9] in Eqn. (1). Q is the heat generation rate, I is the current through the cell, U is the battery open-circuit voltage, and V is the cell voltage.

$$\dot{Q} = I(U - V) - I(T\frac{dU}{dT}) \quad (1)$$

The relationship of battery lifespan to temperature is shown in Fig. 1 [10], which shows that the battery life will be drastically reduced when the temperature is out of the proper level. In addition, the relationship between the performance of the battery and the temperature has been studied extensively. Amine et al. [11] showed a capacity reduction of 72% as a result of repeating 140 charge and discharge cycles with a C/2 discharge rate at 55°C. Ehrlich [12] studied the performance decrease after 500 iterations at 1C discharge rate at 45°C. Therefore, battery performance is directly related to the driving distance of the EVs, requiring a suitable cooling system to dissipate battery heat.

2.1.2. Cooling system for battery thermal management

The battery cooling system was reviewed by Kim et al. [13] in terms of cycles. According to them, the independent use of air-cooled cooling system and system without vapor compression cycle (VCC) for long-range EVs battery cooling are difficult due to the efficiency and performance limitations of the system. Mahle [14] also compared each system using the VCC as shown in Table 1 and found that the liquid (coolant) cooling system is superior in terms of cooling performance and efficiency. The air-cooled cooling system utilizes cabin air for the battery cooling, and only needs some additive parts such as fans and ducts, so it is advantageous in terms of weight and price. However, due to the low heat capacity (Cp) of the air, as shown in Eqn. (2), a large amount of an air flow rate ($\dot{m}$) is required to remove heat (Q) generated from the battery, resulting in larger fan power consumption and bulky ducts and manifolds. Therefore, it is difficult to accumulate a large number of cells in a limited pack because the spacing between the battery cells must be wide, which makes it difficult to apply to long-distance EVs. Liquid cooling systems, on the other hand, are suitable for long-distance EVs as they use liquid coolant with higher heat capacity and higher heat transfer rates than air, which allows the battery to be cooled more effectively with less mass flow rate.

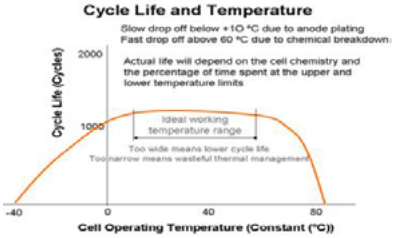

Fig. 1. Battery life graph according to battery temperature [10]

$$\dot{Q} = \dot{m} C_p \Delta T \tag{2}$$

2.1.3. Dual coolant-cooled battery cooling system

In the case of Kona EV, HMC's long-range EVs, the heat generation of the PE module and battery increased more than twice compared to Ionic EV under HMC cooling test conditions as shown in Fig. 3. The Kona EV is limited to existing air-cooled battery cooling systems in order to keep the battery temperature at an appropriate level. Therefore, a liquid-cooled cooling system has been developed and applied. According to the battery cooling method, the structure of the battery is different as shown in Fig. 4, and the research of the dual coolant-cooled battery cooling system for cooling the coolant has been conducted.

A dual coolant-cooled battery cooling system is used to cool the battery with the radiator and AC system by constructing the battery cooling system circuit as shown in Fig. 5 (a). The battery coolant line is connected to the cooling circuit for the PE module and OBC so that the battery can be cooled through the existing radiator without any additional parts. On the side of the refrigerant circuit, the system consists of the evaporator for cabin cooling and the battery chiller for the battery cooling. Therefore, the dual coolant-cooled battery cooling system can be installed by the addition of minimal parts to the existing cooling system and AC systems. The cooling mode of this system is operated as follows. First, if the battery cell temperature is lower than the coolant temperature passing through the radiator, the battery cooling line is disconnected from the PE module cooling line and the coolant flows into the battery chiller, where the cold refrigerant flows. Second, if the battery cell temperature is higher than the coolant temperature through the radiator, the AC is not activated to cool the coolant while the battery cooling line is connected to the PE module cooling line to cool the battery with coolant cooled by ambient air temperature in the radiator as shown in Fig. 5 (c). By adding a 3way valve to the coolant circuit, the two modes described above can be operated.

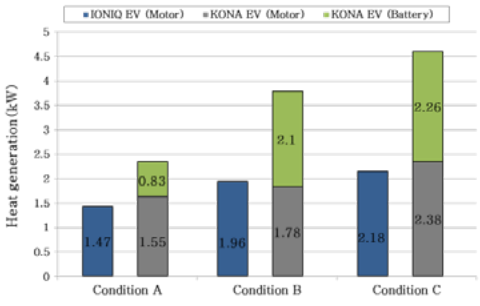

Fig. 3. Ionic EV and Kona EV Heat generation value

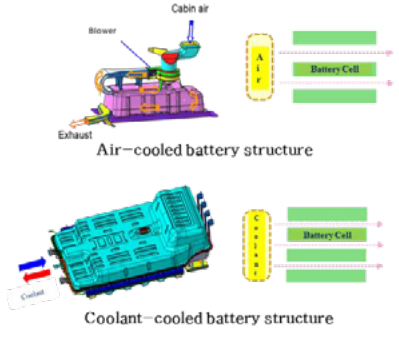

Fig. 4. Comparison of battery structures by cooling method

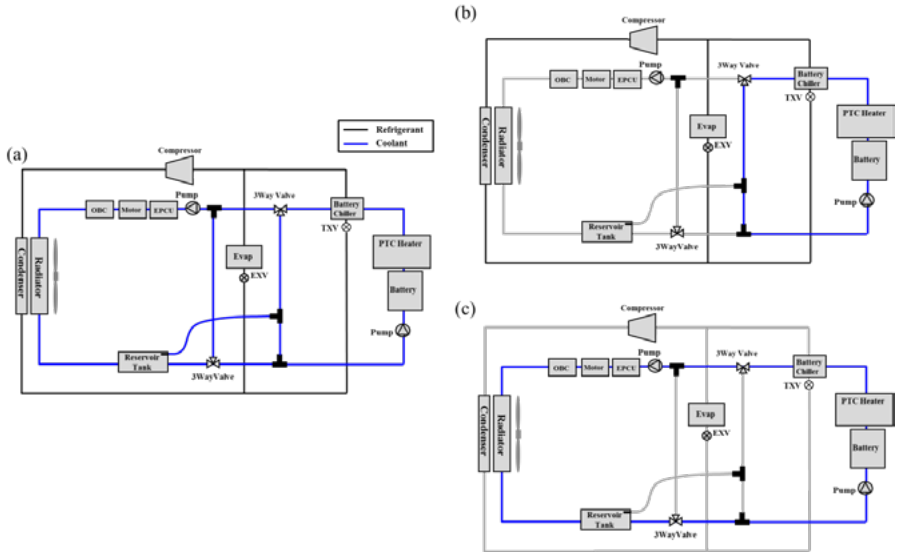

Fig. 5. (a) Dual coolant-cooled battery cooling system circuit diagram, (b) battery cooling mode utilizing AC system, (c) battery cooling mode utilizing radiator

The specifications of the main components of the dual coolant-cooled battery cooling system applied to Kona EV are shown in Table 2. Existing Ionic EV components were basically used, and the newly added battery chiller was evaluated for the different number of plates in consideration of the heat generated from the HMC cooling evaluation condition to look for the optimum capacity. The battery chiller test results are shown in Fig. 6. As the number of plates increased, the cooling performance was improved by an enlarged heat transfer area, but the pressure drop of the coolant decreased. In this study, 20 plates were selected in consideration of the HMC target for the chiller heat dissipation.

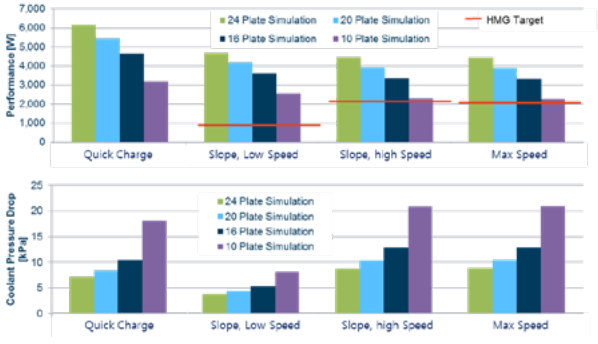

Fig. 6. Battery chiller performance test results

2.1.4. Effect of dual coolant-cooled battery cooling system

The two modes of the dual coolant-cooled battery cooling system proposed in this paper were evaluated by comparing the cooling mode using the AC system and the cooling mode using the radiator. The system bench test for each mode under the same conditions at an ambient air temperature of 15°C showed that AC utilization mode increased cooling performance by 1.57% compared to radiator utilization mode, but consumption power increased by 75%, resulting in a 58.3% reduction in COP (Fig. 7 (a).). In addition, the comparison of the two modes with the initial temperature conditions of 30°C, 110km/h and three-hour continuous driving conditions at ambient air temperature of 25°C showed improvement of up to 4% in terms of vehicle power consumption by reducing cooling power consumption when using the radiator compared to cooling using the AC system (Fig. 7 (b).). In other words, the use of a radiator was advantageous in terms of efficiency compared to using an AC system to cool the battery at low outside temperatures. This is because the compressor consumes a lot of electricity to operate the AC system. If the ambient temperature is high, the cooling mode utilizing the AC system will only operate because the battery cannot be cooled by utilizing the radiator.

2.1.5. Optimal control of battery cooling and cabin cooling

The biggest problem with the application of the battery cooling system using AC is the temporary rise in indoor discharge temperature due to increased cooling load when the battery cooling system is operated. In such a case, a sudden hot wind occurs during the operation of the AC, which may cause customer dissatisfaction such as unpleasantness and odor in terms of AC productivity. The conventional thermal expansion valve allows only passive expansion in proportion to the temperature and pressure of the vapor phase refrigerant passing through the chiller. There was a problem of instantaneous flow of refrigerant to the chiller side during operation of the battery cooling system and during indoor cooling, resulting in a rapid increase of the indoor discharge temperature. In order to solve this problem, an electronic expansion valve that can actively control the opening amount is applied to the battery side, and the superheat degree is controlled after stabilizing the evaporator temperature. As a result, the cooling performance was stabilized by preventing an initially large flow rate to the chiller side. The solenoid thermal expansion valve is applied to the evaporator side for the cabin cooling to realize the battery cooling on mode when the AC is off and the battery cooperative control point of view.

2.2. Cabin heating using battery waste heat

2.2.1. Importance of battery waste heat

EVs without engine waste heat sources use electric heaters with an efficiency of 0.8 to 0.9 when heater operation is required, such as spring and autumn comfort temperature control and winter heating. However, when the electric heater is used, the driving distance of the vehicle is excessively reduced because the power consumption is large. Therefore, in order to maintain the driving distance during heating, it is advantageous to use a heat pump system with high efficiency (COP of 2 to 3) by utilizing an external heat source. However, this system has a problem that it is difficult to secure the heat source as the outside air temperature is lower in winter so that the operating condition is limited at a low temperature below -10°C. The existing Ionic EV heat pump system utilizes the PE module waste heat as well as the outside air heat to increase efficiency. In

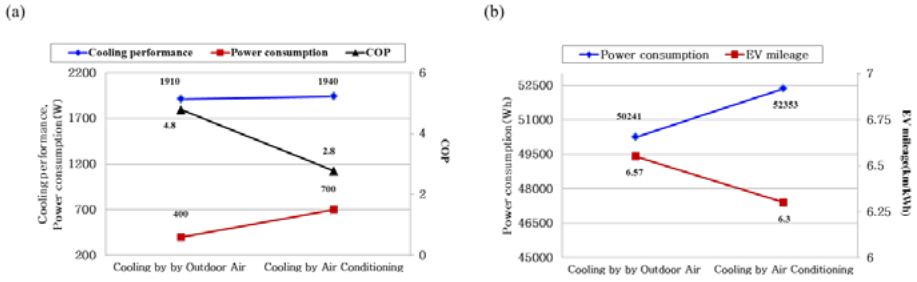

Fig. 7. Comparison of Battery Cooling Mode with Ambient Temperature and Battery Cooling Mode with A ((a) ambient air temperature 15°C conditions, (b) ambient air temperature 25°C and 110 km/h driving conditions)

long-range EVs, battery generated heat is greatly increased in addition to the PE module, numerous studies have been conducted on heat pump systems utilizing battery waste heat [14]. However, as shown in Table 3, there were very few EVs using heat pump system utilizing battery waste heat. Therefore, research on the heat pump system utilizing battery waste heat as well as the outdoor heat source and waste heat of the PE module is needed to minimize the reduction of driving distance.

Table 3. Heat Pump Operating Modes of Global EVs

Application Mode	HYUNDAI IONIQ EV	TESLA	GM BOLT EV	NISSAN LEAF	HYUNDAI KONA EV (This Paper)
Heating of waste heat recovery in PE module	O	X	X	△	O
Heating of waste heat recovery in PE module and batteries	X	X	X	X	O
Heating and Dehumidification of waste heat recovery in PE module	O	X	X	△	O
Heating and Dehumidification of waste heat recovery in PE module and batteries	X	X	X	X	O
Heating of waste heat recovery in PE module (Recognition of frost formation)	O	X	X	X	O
Heating of waste heat recovery in PE module and batteries(Recognition of frost formation)	X	X	X	X	O

2.2.2. Utilization of battery waste heat

In the existing short-range EVs, as shown in Fig. 8 (a), the heat pump was operated using only waste heat from the PE module, and the battery heat was thrown into the air. In this paper, to improve the performance of the heat pump system, the system that utilizes the waste heat from the battery, OBC and PE module is constructed by using the dual coolant-cooled battery cooling system as shown in Fig. 8 (b). A more specific schematic of this system is shown in Fig. 9. This system circulates coolant through PE module, OBC, and battery, and recovers waste heat through heat exchange with refrigerant in waste heat recovery chiller and uses it for heat pump heating.

2.2.3. Performance and efficiency impact of increasing battery waste heat

To analyze the heat pump performance according to the amount of waste heat, the proposed system was evaluated while increasing the waste heat to 0.55kW, 1kW, and 2kW under the condition of -20°C and 50km/h. The refrigerant pressure-enthalpy diagram to the evaluation of the system is shown in Fig. 10 (a). As the waste heat is increased, the evaporative pressure and temperature and condensation pressure and condensation are increased, and the heating performance is improved, but the refrigerant flow rate is increased by increasing the density of refrigerant entering the compressor. This is because the refrigerant does not have to be expanded to lower pressure in order to recover waste heat. More specific performance results are shown in Fig. 10 (b). Increasing the waste heat by 1.45 kW, the heating capacity is increased by 0.6 kW, but the compression work is increased by 0.15 kW, and the heating efficiency is increased from 2.33 to 2.57.

Table 4. Power consumption of cabin heating according to the use of battery waste heat

Application mode	Compressor power consumption (kWh)	PTC power consumption (kWh)	Heating power consumption (kWh)	Heating power savings (%)
Battery waste heat not used	0.574	0.5	1.074	Base
Battery waste heat used	0.52	0.354	0.874	18.6

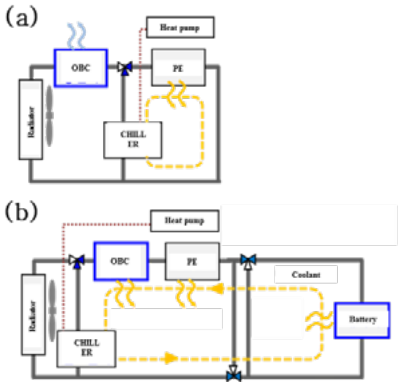

Fig. 8. Electric vehicle heat pump system ((a) utilization of waste heat from PE module, (b) utilizes waste heat from PE module, OBC and battery)

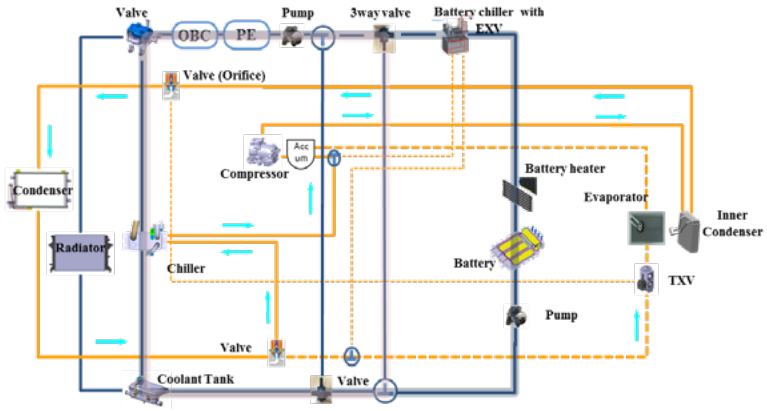

Fig. 9. Heat pump system circuit diagram using battery waste heat

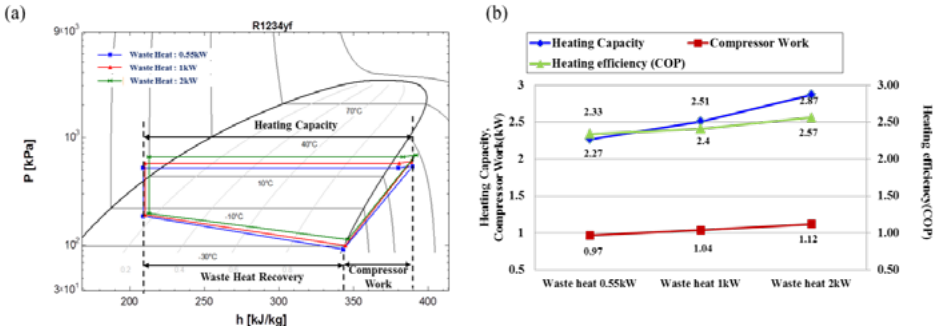

Fig. 10. (a) System refrigerant pressure-enthalpy diagram according to waste heat, (b). Evaluation result of heating performance according to waste heat

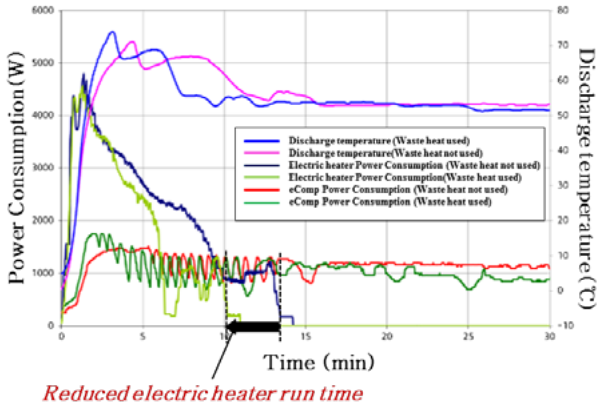

Fig. 11. Evaluation result of heating performance with or without battery waste heat

In order to confirm the effect of the heat pump system using the battery waste heat, the use of the waste heat during the cabin heating at normal temperature 0°C, FATC (Full Auto Temperature Control) 23°C and vehicle speed 50km/h after charging was compared and evaluated. The results of the performance assessment based on the availability of waste heat for 30 minutes are shown in Fig. 11. More simply, the numerical results are shown in Table 4. The reduction of electric heater consumption by improving the efficiency of the heat pump system reduced the heating power consumption by 0.2kWh, resulting in 18.6% reduction in heating power consumption. Calculating these effects as mileage improvements is estimated to be 6.8%. According to the real vehicle assessment, the Ionic EV had a 19% difference in driving distance when heating on / off, but the Kona EV reduced the difference by 9% due to the improved efficiency of the cooling AC system due to the increase of available waste heat source.

3. Conclusion

In this paper, the following conclusions were obtained through the study of the dual coolant-cooled battery cooling system and the heat pump system utilizing battery waste heat.

(1) A dual coolant-cooled battery cooling system is to supply low-temperature cooling coolant to the battery. It is possible to supply low-temperature coolant by heat exchange through AC system in chiller or heat exchange through outdoor air temperature in the radiator.

(2) When using the AC system to cool the battery, the cooling performance increased by 1.57% compared to the radiator utilization mode under ambient air temperature of 15°C, but the power consumption increased by 75%, resulting in a 58.3% reduction in overall efficiency (COP). In other words, if the ambient temperature is low, it is better to use the radiator to cool the coolant than the AC system.

(3) With 1.45 kW waste heat, heating capacity is increased by 0.6 kW, but compression work is increased by 0.15 kW. Therefore, it is advantageous to recover waste heat since heating efficiency is increased from 2.33 to 2.57.

(4) Utilizing waste heat generated when charging batteries, heating consumption power was reduced by 0.2 kWh due to reduced use of electric heater when operating heat pumps, resulting in an 18.6% reduction in AC consumption power, improving driving fuel economy by 6.8%.

(5) As a result of the evaluation of low-temperature, full-charging driving distance certification, Ionic EV had a 19% difference in driving distance when heating was turned on / off. On the other hand, Kona EV narrowed the gap by 9% due to the improved efficiency of the cooling AC system as the available heat source and waste heat increased.

Approaching optimal high pressure by charge management in transcritical CO_2 heat pump water heater

Yu-Jia He, Xing-Yu Liang, Jia-Hao Cheng, Liang-Liang Shao*, Chun-Lu Zhang*

School of Mechanical Engineering, Tongji University, Shanghai 201804, China

Abstract

Transcritical CO_2 cycle has been widely applied in heat pump systems. Optimal high pressure is crucial to the performance of transcritical CO_2 heat pump water heater (HPWH). However, current techniques for high pressure control cannot meet the requirements of easy-to-implement and low COP loss simultaneously. From the perspective of charge management, this work aims to approach optimal high pressure in CO_2 HPWH without high pressure control.

By modeling a running CO_2 HPWH, we in-depth investigated the relationship between optimal high pressure and refrigerant charge. It was found that for practical systems, the essence of optimal high pressure control is to manage optimum refrigerant charge of the system. If the optimum charge of the system remains constant under any working conditions, the system can be guaranteed at optimal high pressure with fixed refrigerant charge. Then the influence of water inlet temperature, water outlet temperature and ambient temperature on optimum refrigerant charge was analyzed. Two system design methods with the aim of minimizing the change of optimum charge under different working conditions are presented, which are re-sizing heat exchangers and adding additional refrigerant reservoir. The minimum average COP loss of the redesigned system can be reduced to only 2.82% and 0.67%, respectively.

Keywords: Heat pump water heater; Transcritical CO_2 cycle; Optimal high pressure; Refrigerant charge management

Nomenclature

A	cross-sectional area in pipe (m^3)	V	volume (m^3)
COP	coefficient of performance (-)	v	specific volume ($m^3 \cdot kg^{-1}$)
DB	dry bulb	WB	wet bulb
EXV	electronic expansion valve	x	flowing vapor mass quality (-)
HPWH	heat pump water heater	$\dot{m}$	mass flow rate (kg s^{-1})
L	length (m)	p	pressure (kPa)
M	refrigerant charge (kg)	T	temperature (°C)
S	slip ratio		
Greek symbol			
α	void fraction	ρ	density ($kg \cdot m^{-3}$)

1. Introduction

With the increasing awareness of environmental protection around the world, natural refrigerants, as carbon dioxide, have received extensive attention. Since transcritical CO_2 cycle was first proposed by Lorentzen [1, 2] in the 1990s, it has been successfully applied in heat pump systems [3-5]. The heat transfer process (gas cooling) of transcritical CO_2 cycle is in the supercritical region, which leads to high discharge temperature and large temperature glide. Therefore, CO_2 heat pump water heater (HPWH) is capable of matching water temperature profile, and supply high temperature water with rather high efficiency [6].

In supercritical region, temperature of CO_2 is independent of pressure. The change of discharge pressure will affect cooling capacity and power consumption simultaneously. Consequently, optimization of discharge pressure is crucial to system efficiency. In open literature, two main methods can be concluded for high pressure control: offline method and online method.

The offline method is primarily proposed and then thoroughly investigated. It is to fit the correlations of optimal high pressure and other parameters of the system based on thermodynamic model or experimental data. Kauf [7] first proposed a linear equation of optimal high pressure with a single variable. On this basis, Liao, Zhao [8] analyzed the influence of gas cooler outlet temperature, the evaporating temperature and compressor performance on optimal high pressure. Regressions were made to various forms of correlations. Sarkar, Bhattacharyya [9] conducted energetic and exergetic analyses for optimization, and developed correlations of optimal high pressure with gas cooler outlet temperature and the evaporating temperature. Later, many researchers have in-depth investigated different forms of optimal high pressure correlations in transcritical CO_2 cycle [10-14].

Although the offline method is simple and easy to implement, the coefficients of correlations are closely related to the structure of the system. Meanwhile, it was found by Cecchinato, Corradi [15] that the direct use of pressure control correlations might cause huge performance deterioration up to -30% in HPWHs. Furthermore, the research of Liang, He [16] indicates that for CO_2 HPWH, multiple factors will influence the optimal high pressure, resulting in complexity of control correlations.

Given the drawbacks of offline correlations, researchers recently explored a more effective way, called online method. Cecchinato, Corradi [15] proposed that a real-time algorithm is a more effective and robust solution for determining the optimal high pressure. Minetto [17] took the lead in using real-time control algorithm in a CO_2 HPWH. Zhang and Zhang [18] used the steepest descent method to update the set value of the high pressure, and realized the real-time control of the single-stage transcritical CO_2 system by using the PI controller. Later, more comprehensive work has been conducted by researchers on real-time control problems [19-23].

However, the real-time optimization algorithm of on-line method is rather complex, with long time of optimization and high cost of hardware implementation. In a word, there are still many problems unsolved in control of optimal high pressure in transcritical CO_2 system. How to achieve the optimal performance rapidly while ensuring the stability of the system still has not been fundamentally solved.

In this work, a new approach for system optimization of CO_2 HPWH is proposed. From the perspective of charge management, this work aims to approach optimal high pressure in CO_2 HPWH and spare the traditional high pressure control methods. In section 2, a simulation model based on a running CO_2 HPWH was established. In section 3, we quantitively analyzed the relationship between optimal high pressure and refrigerant charge, then proposed charge management approach. In section 4, main factors affecting optimum charge are analyzed. In section 5, two system design methods with the aim of minimizing the change of optimal charge are presented.

2. Modeling and validation

In this section, we tested a running CO_2 HPWH and established its simulation model using GREATLAB [24].

2.1. Test unit

The test unit was officially put into operation in May 2018, and the external influences such as fouling of heat exchangers are negligible. Therefore, the practical characteristics of the CO_2 HPWH can be truly reflected. The nominal heating capacity of this unit is 140kW, with water entering temperature 15°C and water supply temperature 55°C. Fig. 1 shows the schematic of the unit. Tap water is directly heated in the CO_2 HPWH, and then stored in high temperature water tank for further use.

Field test on the unit was conducted in April 2019. Refrigerant parameters and water temperatures were manually collected from the machine's control panel. Besides, in order to gain more information on the evaporator, measurement of evaporator tube wall temperatures was conducted, as shown in Fig. 2. is a summarization of the data collection.

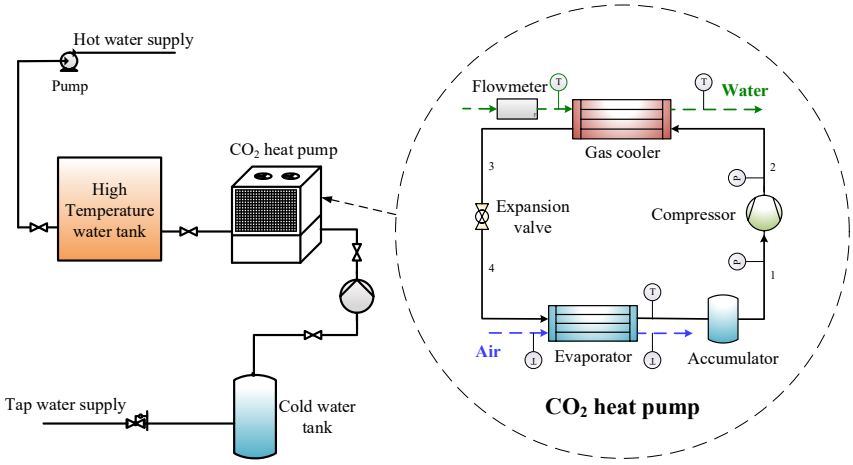

Fig. 1 Schematic of the tested CO_2 HPWH

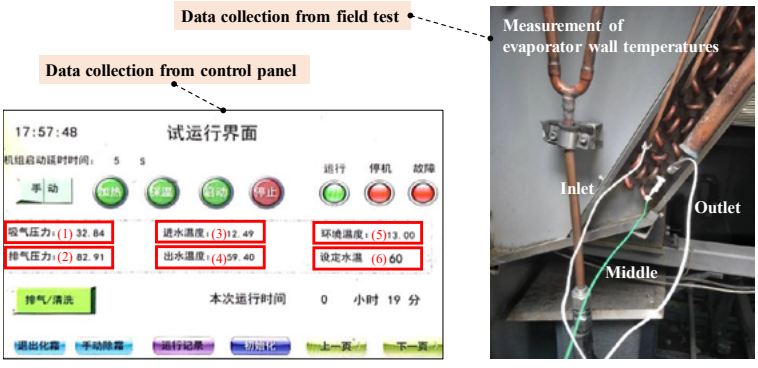

Fig. 2 Field data collection

(1) Suction gauge pressure, 32.84bar. (2) Discharge gauge pressure, 82.91bar. (3) Water entering temperature, 12.49°C. (4) Water leaving temperature, 59.40°C. (5) Ambient temperature, 13.00°C. (6) Set supply water temperature, 60°C.

Table 1 Information of data collection

Parameters	Measurement	Uncertainty
Refrigerant pressures	Panel readings	± 0.5%
Refrigerant /water temperatures		± 0.5°C
Air velocity	Air flow anemometer	± 3%
Dry bulb temperature of air	Humidity & temperature meter	± 1°C
Relative humidity of air		± 3%
Evaporator wall temperatures	Temperature meters	± 0.5°C
Hot water supply	Flow meter	± 3%

2.2. System modeling

2.2.1. Components models

According to the known information, we established a simulation model of the test unit using GREATLAB. GREATLAB is a series of in-house developed software, which focuses on refrigeration, heat pump, and air-conditioning systems modeling and analysis. Detailed information on modeling can be found in the GREATLAB references [24, 25]. Specification of the unit and component models used for system simulation are listed in **오류! 참조 원본을 찾을 수 없습니다.**.

Tube-by-tube incremental model is adopted for air-cooled finned-tube evaporator modeling. Incremental model can take detailed geometric parameters of evaporator into account, as well as air maldistribution and refrigeration distribution of the coil. Fig. 3 shows the screenshot of finned-tube heat exchangers modeling tool in GREATLAB. The geometric and other operating parameters of the actual heat exchanger are input into the modeling tool to predict the performance of the heat exchangers, including refrigeration or heating capacity, refrigerant and air temperature profiles, refrigerant and airside pressure drops, etc.

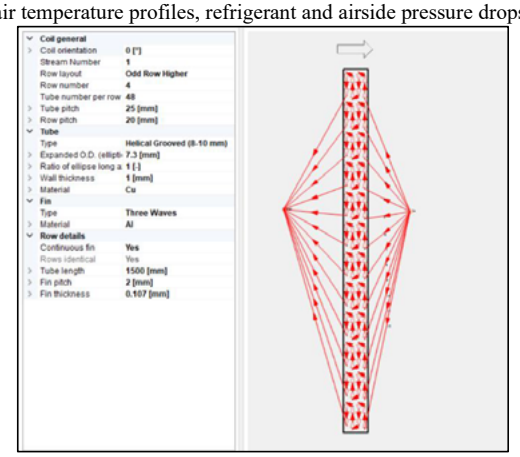

Fig. 3 Screenshot of finned-tube heat exchangers modeling tool

Table 2 Specification of the test unit

Name	Specification	Simulation model type
Refrigerant	CO_2	REFPROP 9.0[26]
Compressor	Reciprocating, single-speed	Curve-fitting model
Evaporator	Finned-tube; 4 rows; 1700mm × 914.4mm × 56mm	Incremental tube-by-tube model
Gas cooler	Brazed plate	1D incremental model
Expansion device	EXV	Curve-fitting model
Fan	4 axial fans for evaporator, single speed	Curve-fitting model

A curve-fitting model was used to describe the performance of single-speed reciprocating compressor. Namely [27],

$$y = c_1 + c_2 p_e + c_3 p_c + c_4 p_e^2 + c_5 p_e p_c + c_6 p_c^2 + c_7 p_e^3 + c_8 p_e^2 T_c + c_9 p_e p_c^2 + c_{10} p_c^3 \quad (1)$$

where y represents power consumption or refrigerant mass flow rate of the compressor. p_e and p_c stand for the suction pressure and discharge pressure for transcritical compression cycles, respectively. Coefficients c_1 - c_{10} are curve-fitted with relevant data of the compressor from manufacturer.

The Electronic expansion valve and fan were modeled using performance curves provided by the manufacturer.

Finally, with all component models in place, we developed the system model in GREATLAB [24], as shown in Fig. 4. The system solver is based on the Newton-Raphson algorithm.

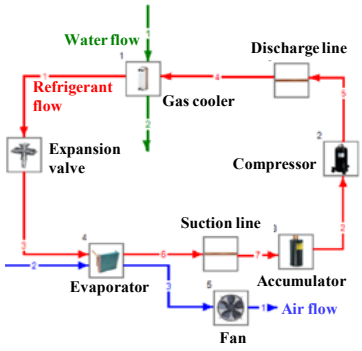

Fig. 4 Screenshot of CO_2 HPWH model in GREATLAB

2.2.2. System charge model

The total refrigerant charge of system is calculated by adding up the charge present in each component and connecting tubes, as described by

$$M = M_{\mathrm{EVAP}} + M_{\mathrm{GC}} + M_{\mathrm{COMP}} + M_{\mathrm{other}} \tag{2}$$

The evaporator is divided into two-phase section and superheat section based on the state of refrigerant. Total charge of the evaporator is calculated by summing up the charge in each discrete element:

$$M_{\mathrm{EVAP}} = M_{\mathrm{TP,e}} + \int_0^{V_{\mathrm{SH,e}}} \rho \mathrm{d}V \tag{3}$$

The total mass in two-phase section can be obtained by

$$M_{\mathrm{TP,e}} = \int_0^{L_{\mathrm{TP}}} \rho_{\mathrm{TP}} A \mathrm{d}L = \int_0^{L_{\mathrm{TP}}} [\alpha\rho_{\mathrm{G}} + (1-\alpha)\rho_{\mathrm{L}}] A \mathrm{d}L \tag{4}$$

where α represents void fraction. ρ_{G} and ρ_{L} are the density of gas and liquid, respectively. A stands for the cross-sectional area in pipe.

Therefore, the accuracy of calculated refrigerant charge is closely related to average density in two-phase section, which is determined by void fraction. Void fraction represents the cross-sectional area occupied by vapor,

$$\alpha = A_{\mathrm{G}}/A \tag{5}$$

It is assumed that the liquid and vapor phases are separated into two streams that flow through the tubes with different velocities, u_{G}, u_{L} [28]. The void fraction is generally represented as a function of various types of properties. As for refrigerant in-tube flow, it can be described as

$$\alpha = \frac{1}{1+s\left(\frac{1}{x}-1\right)\frac{\rho_{\mathrm{G}}}{\rho_{\mathrm{L}}}} \tag{6}$$

where x represents flowing vapor mass quality, namely,

$$x = \frac{\dot{m}_{\mathrm{G}}}{\dot{m}_{\mathrm{L}}+\dot{m}_{\mathrm{G}}} = \frac{\dot{m}_{\mathrm{G}}}{\dot{m}} \tag{7}$$

S is the slip ratio, estimated differently by various investigators. The zivi method [29] is mostly recommended on the basis of simplicity, where S is given by

$$S = \left(\frac{\rho_G}{\rho_L}\right)^{-\frac{1}{3}} \tag{8}$$

Due to the fluid properties of CO_2, transcritical CO_2 cycle is under high working pressures. The density ratio of gas and liquid is much smaller than traditional refrigerants. Given this, the slip ratio S is considered as a constant value of 1 during the calculations and the model is reduced to a homogeneous one.

In gas cooler, the refrigerant is supercritical single-phase fluid. Thus, the charge is calculated by the 1D incremental model:

$$M_{GC} = \int_0^{V_{GC}} \rho dV \tag{9}$$

As for the compressor, refrigerant in compressor contains single-phase vapor inside the cylinder and refrigerant dissolved in lubricant oil.

$$M_{COMP} = \rho_{COMP} V_{COMP} + M_{oil} \tag{10}$$

Finally, the refrigerant charges in the connecting tubes are calculated assuming the tubes to be adiabatic.

2.3. Model validation

In order to validate the accuracy and reliability of the simulation model, we conducted a comparison of simulation results and test data under same operating condition. The tap water entering temperature is 12.5°C, water supply temperature is 59.4°C and ambient temperature is DB 11.6°C / WB 9.0°C.

The comparison results are shown in **오류! 참조 원본을 찾을 수 없습니다.**. The error between simulation results and test data is less than 5%, which indicates desirable accuracy and reliability of the simulation model.

Table 3 Comparison of simulation results and test data

Parameter / unit	Test	Simulation	Error
Suction pressure / bar	34.4	33.8	-1.8%
Discharge pressure / bar	84.9	83.9	-1.2%
Evaporator entering temperature / °C	4.5	4.7	0.2
Evaporator leaving temperature / °C	10.3	9.6	-0.7
Dry bulb temperature of outlet air / °C	7.2	6.9	-0.3
Hot water supply / L s^{-1}	0.67	0.70	4.3%

On the other hand, the simulation model of CO_2 HPWH built in GREATLAB has also been well validated in our previous work [30]. The model was established to predict monthly power consumption of CO_2 HPWHs, as illustrated in Fig. 5. The predicted results were in good agreement with actual data, with only 0.6% deviation in sum.

Therefore, the simulation model can well predict the performance of CO_2 HPWH and be used for in-depth analysis of the system.

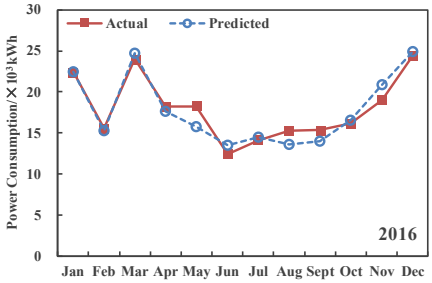

Fig. 5 Comparison between predicted and actual monthly power consumption in 2016 [30]

3. Optimal high pressure and refrigerant charge

In this section, we quantitively investigated the relation of compressor discharge pressure and overall refrigerant charge of system. Then from the perspective of charge management, a new approach for system optimization is proposed.

Based on previous research, the pressure in the high side of transcritical CO_2 cycle is determined by refrigerant charge, inside volume and temperature, as described by [31]

$$p = p(v, T) = p\left(\frac{V}{m}, T\right) \tag{11}$$

As a result, three basic approaches to controlling high pressure can be found in practical transcritical CO_2 systems. However, in most cases, inside volume of high side is fixed and temperature/pressure relation will be influenced by leakage. Thus, high-side charge control is mostly adopted pressure control method.

In systems with high-side charge control, a refrigerant buffer must be provided to ensure the evaporator won't be flooded or dried out. High-side pressure is controlled by adjusting the expansion valve, which will change the balance between mass flow rate of compressor and valve flow rate, thereby changing refrigerant mass in high side. Therefore, controlling high pressure is essentially regulating the amount of refrigerant charge actually running in the system.

Based on this deduction, we made some calculations to investigate the relation of refrigerant charge (charge in accumulator is not counted) and discharge pressure. The results are shown in Fig. 6. As the discharge pressure changes, the COP will reach the maximum value, and the corresponding pressure is the optimal high pressure. Meanwhile, with the increase of discharge pressure, the refrigerant charge of the system increases monotonously. It is indicated that the discharge pressure is in a one-to-one correspondence with refrigerant charge. Therefore, the change in discharge pressure can be truly reflected by the change in the charge amount. Furthermore, the optimal high pressure also corresponds to the optimum charge of the system. That is to say, when the refrigerant charge in the system is optimum, the system is under optimal high pressure.

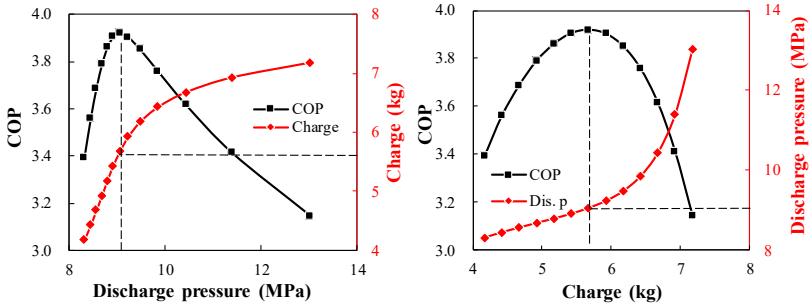

Fig. 6 The relation of optimal high pressure and optimum refrigerant charge

In a word, it was found that for practical systems, optimal high pressure control is fundamentally to manage optimum refrigerant charge of the system. Based on this conclusion, we propose that: if the optimum charge of the system remains constant under any working conditions, then the system can be guaranteed at optimal high pressure with fixed refrigerant charge. In this situation, the control objective of expansion valve switches to superheat rather than discharge pressure, which is the same as subcritical systems. Therefore, if reasonable system design methods are carried out with the aim of keeping optimum charge fixed, then the traditional high pressure control methods can be replaced by superheat control with fixed system charge.

4. Parametric analysis of optimum charge

In this section, parametric study of main factors affecting optimum charge of CO_2 HPWH and their effects is carried out. For a running CO_2 HPWH, ambient temperature, water entering and leaving temperatures are

main external factors affecting optimal high pressure. Since frosting has a significant influence on system performance, ambient wet bulb temperature is selected for further analysis. Relevant calculation conditions are shown in **오류! 참조 원본을 찾을 수 없습니다.**. At each working condition, optimum charge of system under which COP reaches maximum value is calculated. To further demonstrate the root cause of the change in optimum charge, schematic diagrams of the change of charge in each component are drawn.

Table 4 Calculation conditions

Group	Ambient temperature (wet bulb) /℃	Relative humidity	Water entering temperature /℃	Water leaving temperature /℃
A	[-25, 25]	0.6	15	55
B	15	0.6	[1, 30]	55
C	15	0.6	15	[40, 90]

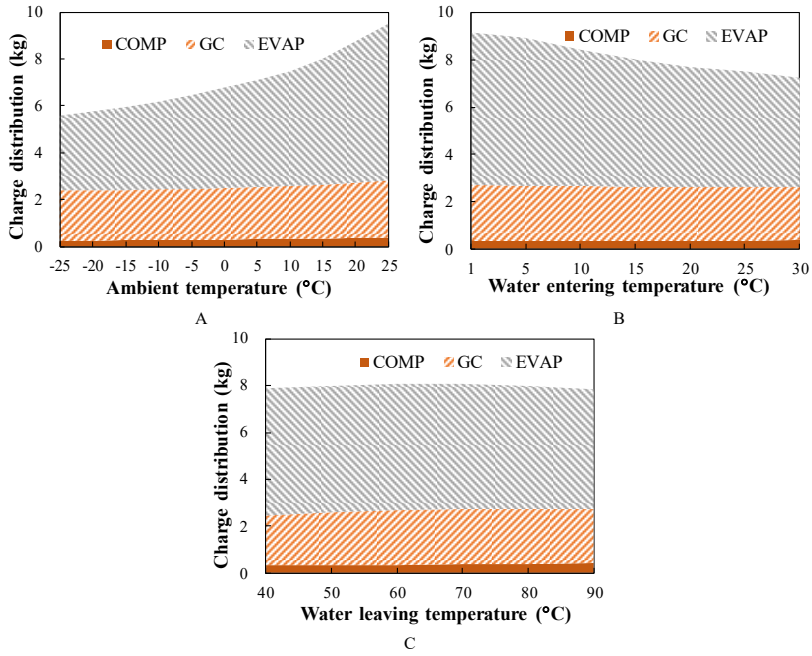

Fig. 7 The change of refrigerant charge in each component

As shown in Fig. 7A, with the increase of ambient temperature, the optimum charge of system increases by 69.6%. The change in evaporator is the main influencing factor, which accounts for 90% of the total increase. The contribution from gas cooler and compressor is 7.8% and 1.8%, respectively. The main cause is that rise of ambient temperature will lead to an increase in the evaporating temperature, resulting in significant density change in evaporator. However, the density change at high pressure side is relatively small, so that charge in gas cooler is almost unchanged.

Similarly, Fig. 7B illustrates the influence of water entering temperature on optimum charge. The optimum charge decreases by 27.9% with the increase of water entering temperature. The contribution of the change in evaporator is 97%, while of gas cooler and compressor is 4.0% and 0.5%, respectively. Since the gas cooler in HPWH is counterflow heat exchanger, an increase in water entering temperature will cause the rise of refrigerant temperature leaving gas cooler. Consequently, vapor quality of CO_2 entering evaporator will increase, resulting in mass decrease in evaporator.

The water leaving temperature has little influence on optimum charge, as shown in Fig. 7C.

In a word, ambient temperature and water entering temperature will both lead to significant change in optimum charge of CO_2 HPWH. Among all components, change in evaporator has the leading effect, while change in gas cooler and compressor have limited influence.

5. System charge management methods

According to the parametric analysis in section 4, the optimum charge of CO_2 HPWH will be influenced by working conditions, of which change in evaporator has major influence. As proposed in section 3, if optimum charge remains constant under any working condition, high pressure control in CO_2 HPWH can be replaced by traditional superheat control with fixed system charge. Therefore, in this section, two system charge management methods with the aim of restraining the change of optimum charge are proposed. Comparison with optimal high pressure system is also conducted.

5.1. Heat exchangers resizing

In the test unit, the evaporator is finned-tube heat exchanger, while gas cooler is compact brazed-plate heat exchanger. Refrigerant stored in evaporator is much more than in gas cooler. Therefore, re-sizing heat exchangers is proposed to improve the distribution of refrigerant in each component, so that the influence of change in evaporator can be restrained. Re-sized heat exchangers should also meet the nominal heating capacity requirement of the CO_2 HPWH.

Two approaches are adopted for re-sizing heat exchangers. On the one hand, reduce the inside volume of evaporator. The evaporator of the test unit is equipped with conventional 7mm heat exchange tube, which is now changed into 5mm tubes. The use of small diameter tubes can reduce charge by 30~40% in heat exchangers. Meanwhile, the capacity is ensured by increasing the number of tubes. Geometric parameters of the original and resized evaporators are listed in **오류! 참조 원본을 찾을 수 없습니다.**.

On the other hand, increase the inside volume of gas cooler. Considering the cost constraints and heat transfer capacity requirements, the number of gas cooler plates is increased by 20%.

Table 5 Geometric parameters of evaporator

Parameters	Original	Resized
Row number	4	5
Tube number	48	60
Outer diameter	7.45 mm	5.25mm
Tube pinch	25mm	19.05mm
Row pinch	20mm	11.4mm
Length between tube sheets	1.5 m	1.5m
Circuit number	12	30
Flow configuration	Cross-counter flow	Cross-counter flow
Fin pitch	1.4 mm	1.4 mm
Fin thickness	0.115 mm	0.115 mm
Fin type	Wavy	Wavy

Based on the simulation model built in section 2, we established a new system model with superheat control instead of high pressure control. In new model, the overall system charge is fixed and the accumulator is eliminated, thus referred as fixed-charge system. In the following analysis, we quantitively compared the system performance of optimum system (with optimal high pressure control) and fixed-charge system.

Considering that for air-source CO_2 HPWH, ambient temperature varies in a larger range than water entering temperature, it is chosen as independent variable for further analysis. The charge of fixed-charge system is the optimum charge when ambient temperature is 0°C.

Fig. 8 illustrates the impact of ambient temperature on charge distribution after re-sizing heat exchangers. The relative change of optimum charge is 55.9%, 13.7% less than original system. The comparison of COP is shown in Fig. 9A. When ambient temperature varies from -25-10°C, COP of optimum system and fixed-charge system is very close. However, when ambient temperature is above 10°C, the COP of fixed-charge system drops significantly. Because in fixed-charge system, the evaporator occupies more refrigerant when ambient temperature increasing. It will cause charge in gas cooler far below the optimal value, thus resulting in COP attenuation. In this situation, the average COP loss of fixed-charge system compared with optimum system is 3.51%.

Besides, COP loss could be further restrained by optimizing the charge of fixed-charge system. As shown in Fig. 9B, optimal charge exists for fixed-charge system, where average COP loss is only 2.82%.

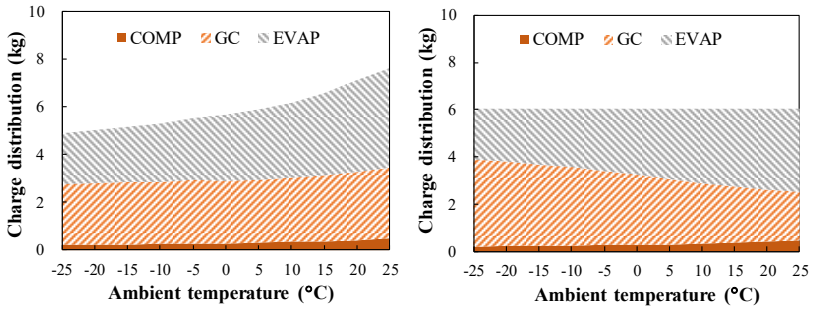

Fig. 8 Impact of ambient temperature on charge distribution after re-sizing heat exchangers

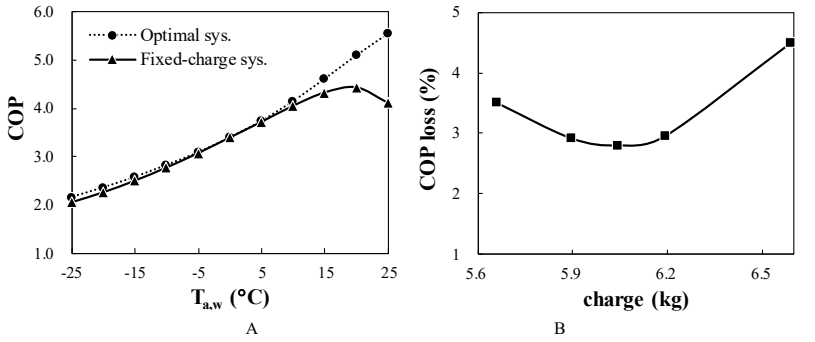

Fig. 9 COP comparison between optimum system and fixed-charge system / Impact of refrigerant charge on COP Loss in fixed-charge system

5.2. Additional refrigerant reservoir

However, the performance improvement achieved by re-sizing heat exchangers is limited for fixed-charge system. As analyzed in Section 4, change in evaporator is the predominant factor affecting optimum charge of system. If change in evaporator can be restrained, the optimum charge will remain constant in most situations. Accordingly, adding additional refrigerant reservoir is proposed in this work to make up for the change in evaporator.

Similarly, ambient temperature is chosen as independent variable. The root cause of change in evaporator is the density change affected by the evaporating temperature. Based on parametric analysis, with the increase of ambient temperature, the charge in evaporator will also increase. To offset the change in evaporator, the possible location for an additional component is the inlet and outlet of gas cooler. **오류! 참조 원본을 찾을 수 없습니다.** displays the impact of ambient temperature on density at different locations. With the increase of ambient temperature, the refrigerant density at the inlet of gas cooler and evaporator both increase. However, at the outlet of gas cooler, refrigerant density is rather large and slightly decreases. Therefore, if a reservoir is added at the outlet of gas cooler, overall charge of system will increase that change in evaporator will be weakened. Moreover, the slight decrease of density can make up for the increase in evaporator.

Table 6 Impact of ambient temperature on refrigerant density at different locations

Ambient temperature /°C	Density of CO_2 /kg·m^{-3}		
	Evaporator	GC inlet	GC outlet
-25	37.9	121.9	864.7
-15	50.5	142.2	863.5
-5	66.8	164.4	861.0

5	88.2	189.0	857.8
15	119.7	219.5	853.5
25	171.5	265.0	856.6

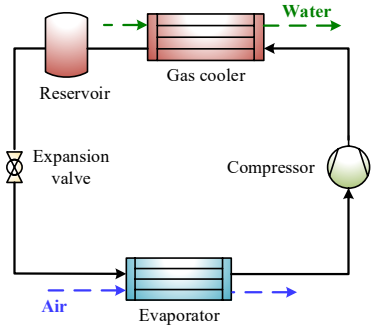

Fig. 10 CO_2 HPWH with additional reservoir at the outlet of gas cooler

Therefore, we added a reservoir at the outlet of gas cooler, as shown in Fig. 10. By changing the volume of the reservoir, we compared the system performance of optimum system and fixed-charge system. As shown in Fig. 11, when volume of high-pressure reservoir increases, the relative change of optimum charge decreases from 72% to 11%, and the average COP loss of fixed-charge system decreases from 6.35% to 0.76%. This also proved that with the decrease of the change of optimum charge, optimal system performance can be ensured by fixing refrigerant charge.

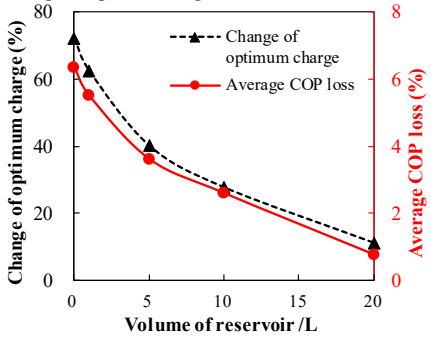

Fig. 11 Impact of reservoir volume on COP Loss and change of optimum charge

Fig. 12 illustrates when the volume of reservoir is 20L, the change of refrigerant charge in optimum system and fixed-charge system. In optimum system, with the increase of ambient temperature, charge in evaporator increases while charge in refrigerant reservoir is in decline. Therefore, the relative change of total charge decreases significantly to only 11.0%. In fixed-charge system, the change in evaporator will be offset by refrigerant reservoir, thus reducing its impact on gas cooler. In this situation, the average COP loss of fixed-charge system is only 0.76%. Moreover, with the increase of volume of reservoir, the average COP loss will be further reduced.

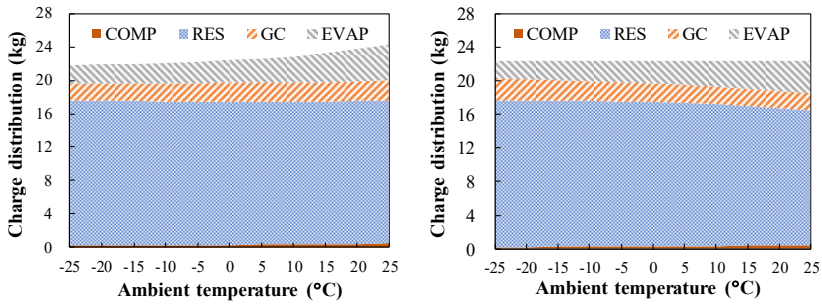

Fig. 12 The change of refrigerant charge after adding additional opponent

In summary, with reasonable charge management methods, the change of optimum charge can be effectively restrained. Then traditional high-pressure control methods can be replaced by fixing charge for robust and efficient control.

6. Conclusions

In this work, new charge management method is proposed to approach optimal high pressure rather than pressure control in CO_2 HPWH. By developing simulation model on a running CO_2 HPWH, the relation of discharge high pressure and refrigerant charge is thoroughly investigated. At last, two charge management methods are presented. Main conclusions can be drawn as follows.

The high pressure control in practical systems is fundamentally to manage refrigerant charge optimum. If optimum charge remains constant under any working condition, then the system can be guaranteed at optimal high pressure with fixed refrigerant charge.

Ambient temperature and water entering temperature both have noteworthy influence on optimum charge. Among all components, the change in evaporator has decisive effect on the change of optimum charge, accounting for 90% and 97%, respectively.

Two system charge management methods aimed at restraining the variation of optimum charge are proposed. After re-sizing heat exchangers, the change of optimum charge is 13.7% less than original system. The minimum average COP loss of fixed-charge system verses optimum system is 2.82%. After adding a high-pressure reservoir at the outlet of gas cooler, the change of optimum charge is 58.6% less than original system. The minimum average COP loss is only 0.76%.

Abstract

Diffusion absorption refrigeration (DAR) system is driven by thermal energy supplied to the bubble pump. The refrigerant is heated and regenerated while flowing through the bubble pump. For this reason, the operating characteristics of the DAR cycle significantly depend on the bubble pump performance. This study focuses on the influence of the bubble pump on the operation of DAR cycle on the aspects of the cross-sectional area and the heat input. The DAR cycle uses a mixture of low GWP refrigerant and organic absorbent as the working fluids: R1234ze(E) and N,N-dimethylacetamide(DMAC). Experiments are conducted with various conditions to estimate the operating performance. The results show that the evaporation temperature tends to decrease as the cross-sectional area of the bubble pump increases, though it increases when the cross-sectional area exceeds a certain optimum level. It also turns out that the increased heat input lowers the evaporation temperature in the overall cross-sectional area range of 7.917mm^2 – 17.814mm^2.

Keywords: DAR, Refrigeration cycle, Absorption, Bubble pump, Measurement

1. Introduction

A diffusion absorption refrigeration(DAR) cycle is used for creating a cooling effect only with a heat supply. Conventional working fluids used in this system are ammonia and water which are used as refrigerant and absorbent, respectively. However, without compressor nor electric pump, this cycle has relatively a low coefficient of performance(COP). Besides, the toxicity of ammonia and high system pressure are other unfavorable characteristics.

Derived from these practical problems, there have been numerous studies focusing on enhancing COP and substituting ammonia with new refrigerants. Zohar et al. [1] announced improvements in COP when using a partially detached bubble pump compared to the one with integrated structure. Zohar et al. [2] also numerically simulated the DAR cycle operation using five different refrigerants (R22, R32, R124, R125 and R134a) and DMAC as a common absorbent, then compared the results to the ammonia/water system. Wang et al. [3] performed a numerical investigation on the DAR cycle performance operating with a binary refrigerant, R23/R134a, and an organic absorbent, DMF. Koyfman et al. [4] conducted experiments using R22 and DMAC as working fluids and analyzed the results with respect to heat input.

However, due to the serious global warming problems, adopting the low GWP refrigerants instead of the conventional refrigerants with high GWPs is taken as an important concern. And there is still a need for further research to apply such refrigerants to the DAR system. Motivated from these issues, this study focuses on experimental investigation on the operation characteristics of a low GWP refrigerant based DAR cycle. R1234ze(E) is used as refrigerant and N,N-dimethylacetamide(DMAC) is used as absorbent. Helium is chosen as auxiliary gas. After constructing the refrigeration cycle with bubble pumps with various cross-sectional

* Corresponding author. Tel.: 82-2-3290-5952; fax: 82-2-922-3260.
E-mail address: ytkang@korea.ac.kr.

areas, the evaporation temperature is measured for each case. Heat input is also varied in order to find its influence on the evaporation temperature.

2. Experiments

2.1. Experimental setup and procedure

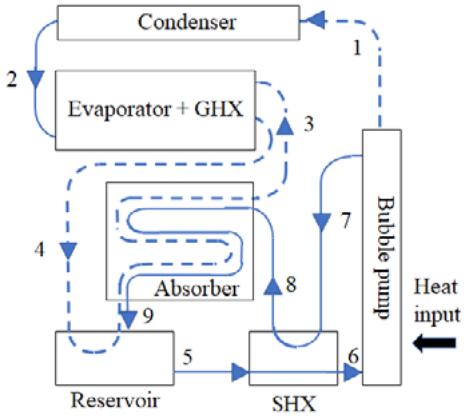

Fig. 1. Schematics diagram of the DAR cycle

Fig. 1 shows the schematic diagram of the DAR cycle. The insulated bubble pump is placed on the right side, in which the refrigerant vapor is generated(1). The condenser is installed at the top where the saturated liquid refrigerant comes out and enters the evaporator(2). The auxiliary gas and the unabsorbed refrigerant vapor also join at the evaporator(3), and evaporation takes place due to the low partial pressure. After the evaporation process, the gas mixture flows to the absorber(4) through the gas heat exchanger. Flowing upward inside the absorber, the refrigerant vapor is absorbed to the solution and the strong solution drips into the reservoir(9). The strong solution is supplied to the bubble pump after flowing through the solution heat exchanger(5, 6). After the refrigeration vapor generation, the remaining weak solution returns to the absorber(8, 8) from the top of the bubble pump(7).

The experiment is conducted by the following procedure:

(1) Separate the bubble pump from the system and set it with a new bubble pump of desired cross-sectional area.
(2) Prepare a mixture of absorbent and refrigerant to make up the concentration of experiment condition.
(3) Make the experimental setup to a vacuum state and inject the working fluid.
(4) Charge helium gas so that the internal system pressure reaches 4.5bar.
(5) Supply heat to the bubble pump with an electric heater.
(6) Measure the temperature of the evaporator using thermocouples attached to the wall.

2.2. Cross-sectional area of bubble pump

A set of experiments are conducted in order to investigate the influence of cross-sectional area on the operating temperature characteristics of DAR cycle, especially the evaporation temperature. For each test, bubble pump is replaced with a new one with different cross-sectional area. The rest of the system components and experiment conditions are maintained. The detailed experimental conditions are summarized in Table 1.

Table 1 Experiment conditions for comparisons of different cross-sectional areas

Cross-sectional area [mm^2]	Pressure [bar]	Heat input [W]	Concentration [wt%]
7.9	4.5	70	35
17.8	4.5	70	35
31.7	4.5	70	35

2.3. Heat input

Another set of experiments are performed to see the effect of heat input to the bubble pump on the cycle operation. Maintaining the basic experimental conditions of Experiment 2.2, different values of heat input are given for every type of bubble pump. The detailed conditions are given in Table 2.

Table 2 Experiment conditions for comparison of different heat inputs

Heat input [W]	Pressure [bar]	Cross-sectional area [mm^2]	Concentration [wt%]
50	4.5	7.9, 17.8, 31.7	35
70	4.5	7.9, 17.8, 31.7	35

3. Results and discussion

3.1. Cross-sectional area of bubble pump

Fig. 2 presents the evaporation temperature versus the cross-sectional area of bubble pump. Three different cross-sectional areas were tested, and the evaporation temperature was measured after the system reached a steady state. From the experimental results, it turns out that the evaporation temperature initially decreases when the cross-sectional area increases. But continuous area increase eventually leads to the increment in the evaporation temperature. Provided with the heat input of 70W, the evaporation temperatures are measured as -2.1°C, -5.2°C and 1.1°C when the cross-sectional area changes from 7.9mm^2 to 31.7mm^2. As the bubble pump gets larger, the pressure drop along the bubble pump decreases. It results in the bubble pump efficiency enhancement and more refrigerant vapor is generated, thus reducing the evaporation temperature. However, with further increasing area, the solution can only be heated up to lower the temperature under same heat input condition, causing the reduction in the refrigerant vapor generation. Also, the large cross-sectional area disrupts the formation of slug flow inside the bubble pump, which is essential in order to pump up and circulate the solution through the vertical pipe. These factors together contribute to lower refrigerant generation and higher evaporation temperature at 31.7mm^2.

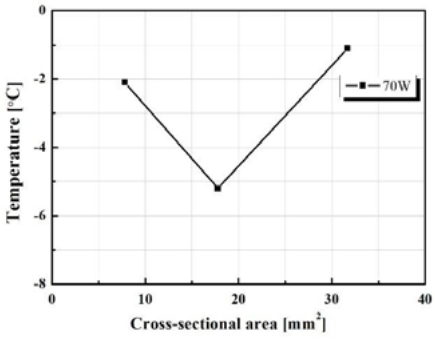

Fig. 2. Measured evaporation temperature with bubble pumps of different cross-sectional areas

3.2. Heat input

Maintaining the fundamental experimental conditions, a decreased amount of heat input is given to evaluate the influence of heat input on the evaporation temperature. The heat input value is initially set as 50W. Generally, with the increased heat input, the evaporation temperature shows a meaningfully decreasing tendency. Fig. 3 shows the evaporation temperature change when the bubble pump has a cross-sectional area of 7.9mm^2. The temperature is measured to be 0.99℃ with 50W of heat input. But it reaches a lower temperature of -2.1℃ when 70W of heat is supplied. This behavior is also observed when the cross-sectional area is increased to 17.8mm^2, as depicted in Fig. 4. As more heat is given to the bubble pump, the evaporation temperature decreases from -1.08℃ to -5.2℃. However, as seen in Fig. 5, an exceptional temperature change is observed when using a bubble pump with a larger cross-sectional area of 31.7mm^2. It turns out that the system fails to operate as a refrigerator when only 50W of heat is provided. Moreover, the system is incapable of reaching a steady state during the test time. The system shows a normal operational behavior when a larger heat input, 70W, is given. The evaporation temperature is measured as 1.1℃. Regarding the COP, the growing temperature difference between the evaporator and the surrounding leads to the increase of heat transfer. Therefore, for both heat inputs, 50W and 70W, highest COPs were obtained at lowest evaporation temperature and the values were 0.1356 and 0.1157 respectively.

The consequential temperature drop by the increased heat input is due to the increased generation of refrigerant vapor. As more thermal energy is consumed, the refrigerant mass flow rate increases, thus lowering evaporation temperature. However, when the cross-sectional area is enlarged too far, minimum value of heat needed to generate enough amount of refrigerant vapor also grows. For this reason, it is not able to obtain the cooling effect with a heat input of 50W when the cross-sectional area is 31.7mm^2.

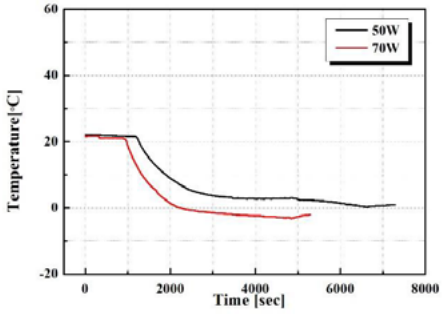

Fig. 3. Measured evaporation temperature with different heat inputs to 7.9mm^2 bubble pump

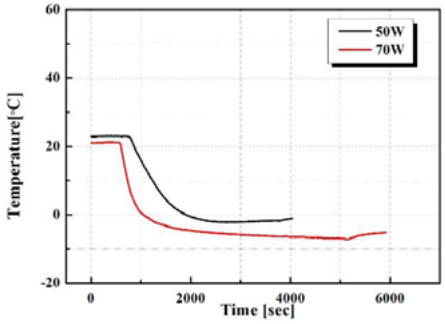

Fig. 4. Measured evaporation temperature with different heat inputs to 17. 8mm^2 bubble pump

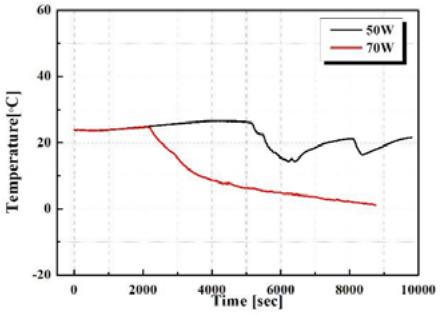

Fig. 5. Measured evaporation temperature with different heat inputs to 31.7mm^2 bubble pump

4. Conclusions

In this study, the evaporation temperatures of the DAR system using R1234ze(E) and DMAC are measured depending on the variations of cross-sectional area of bubble pump and heat inputs. The tested cross-sectional areas are 7.9mm^2, 17.8mm^2 and 31.7mm^2. Both 50W and 70W of heat inputs are given to all types of bubble pumps for comparisons. The following conclusions are drawn from the present study.

- The optimum cross-sectional area for 70W of heat input is 17.8mm^2 and the achieved evaporation temperature is -5.2℃.
- Using the bubble pump with the cross-sectional area of 7.9mm^2, the evaporation temperature decreases from 0.99℃ to -2.1℃ as heat supply increases from 50W to 70W.
- Using the bubble pump with the cross-sectional area of 17.8mm^2, the evaporation temperature decreases from -1.08℃ to -5.2℃ as heat supply increases from 50W to 70W.
- Enlarged cross-sectional area requires a higher heat supply for normal operation of the system. The system is unable to reach a steady low temperature when only 50W is given to the bubble pump with the cross-sectional area of 31.7mm^2.

Abstract

In Japan, from 2011 to 2016, risk assessment of each type of equipment using A2L refrigerants was carried out and JRAIA standards which prescribed safe operating method were created, resulting in the relaxation of law was realized. In order to respond to demand in recent years to further lower GWP, risk assessment of built-in refrigerated display cabinet using A3 refrigerants was carried out. CFD analyses on refrigerant leakage from inside or outside the refrigerated space of each refrigerated display cabinet was carried out, the flammable volume was calculated, the ignition sources were investigated, and the ignition probability was calculated. Risk assessments were carried out at each stage of transportation, storage, installation, usage, service, and disposal. In this paper, the contents of the study and safe operating method created as a result are summarized.

Keywords: CFD analysis; Flammable volume; Ignition source; Risk assessment; Display Cabinet

1. Introduction

The use of A2L refrigerants for HVAC&R products was investigated in Japan from 2011 to 2016. Risk assessments of the products have been carried out[1], to establish methods for ensuring the safe use of the products using A2L refrigerants, resulting in the relaxation of relevant regulation and followed by product launches in Japanese market. However, further reduction of GWP are expected in response to the Kigali Amendment to the Montreal Protocol, and the Japan Refrigeration and Air Conditioning Industry Association (JRAIA) has been carrying out the risk assessment for built-in refrigerated display cabinets using A3 refrigerants.

In this paper, the duration and the mean volume of flammable region obtained by CFD analysis for each refrigerated display cabinet were formulated. The investigative findings on the characteristic ignition sources in the stages of usage and working are shown, and the methods for ensuring safe operation are explained.

2. Method of Risk assessment

Ignition probability is calculated by multiplying the temporal encounter probability representing the time rate of contacting between the ignition source and the flammable region, the spatial encounter probability representing the spatial distribution of the flammable region and the refrigerant leakage probability. Flammable region is the area where refrigerant concentration is between the lower flammability limit (LFL) and the upper flammability limit (UFL). Flammable volume is the volume of the flammable region, the time when flammable region exists is the duration of the flammable region, and the flammable volume-time integration is obtained by multiplying the duration of the flammable region and the mean flammable volume. Temporal encounter probability is calculated by using the duration of the flammable region, the duration of the ignition source and the frequency of occurrence of ignition source. Spatial encounter probability is calculated by dividing the mean

* Corresponding author. Tel.: +81-3-3432-1671; fax: +81-3-3438-0308.
E-mail address: Yamashita.Koji@aj.MitsubishiElectric.co.jp.

flammable volume by the volume of the target space. The duration of the flammable region and the mean flammable volume are obtained by CFD analyses. The ignition probability is obtained by calculating the average of the ignition probabilities weighted by operating rate for both the operation and stoppage (e.g. due to system failure) of the air circulating fan.

3. CFD Analysis of Refrigerant Leakage
