CFD analysis was carried out with STAR CCM+ using the Realizable k-ε model. The subject refrigerant is R290, and the values at 25 °C in atmospheric pressure calculated by REFPROP Ver. 8.0 are used as its physical properties. The value 1.12×10^{-5} (m^2/s) calculated from the molecular diffusion equation is used as the diffusion coefficient of R290, 2.1 (vol%) and 9.5 (vol%) are used as LFL and UFL values, respectively. Leakage analysis was carried out for reach-in, horizontal and vertical open refrigerated display cabinets. Analysis models and calculation results of the reach-in refrigerated display cabinet and the horizontal refrigerated display cabinet are shown below. Validity of the results of CFD analysis has been verified by simulation of R32 leak from an indoor unit of the residential air conditioner. In addition, CFD analysis when the refrigerant was R170 (molecular weight is 30.0, LFL is 3.1 (vol%)), R1270 (molecular weight is 42.1, LFL is 2.7 (vol%)) or R600a (molecular weight is 58.1, LFL is 1.8 (vol%)) was carried out. When the refrigerant is R170 or R1270, the duration of the flammable region and the mean flammable volume are smaller than the value of R290. As a result, when the refrigerant is R600a, the mean flammable volume was almost the same as the value of R290 and the duration of the flammable region was 10 to 20 % longer than the value of R290.

3.1. Analysis of refrigerant leakage from the reach-in refrigerated display cabinet

3.1.1. Analysis model of refrigerant leakage

Because the flammable region in the shop becomes the largest when the door is fully opened rapidly after refrigerant leakage inside the refrigerated space of the reach-in refrigerated display cabinet, CFD analyses were carried out for this case. The CFD model of the reach-in refrigerated display cabinet installed in the shop with an area of 24.01 m^2 is shown in Fig. 1. The display cabinet has 1.08 m^3 of refrigerated volume, and its external dimensions are 2.0 m in height, 1.542 m in width, 0.7 m in depth. The condensing unit consists of a compressor, a condenser and a fan installed in the lower part of the display cabinet. The air is sucked from the front of the condensing unit, passes through the rear side and is exhausted from the top of the display cabinet. Area of the

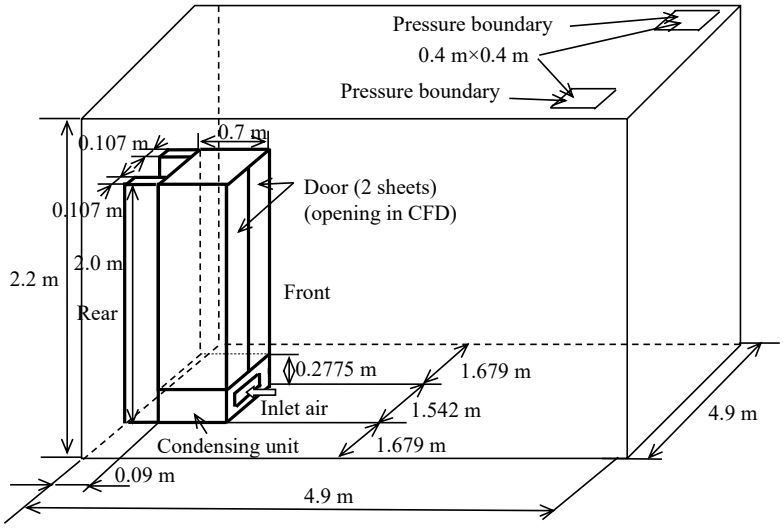

Fig. 1. CFD model of reach-in refrigerated display cabinet installed in the shop area with an area of 24.01 m^2

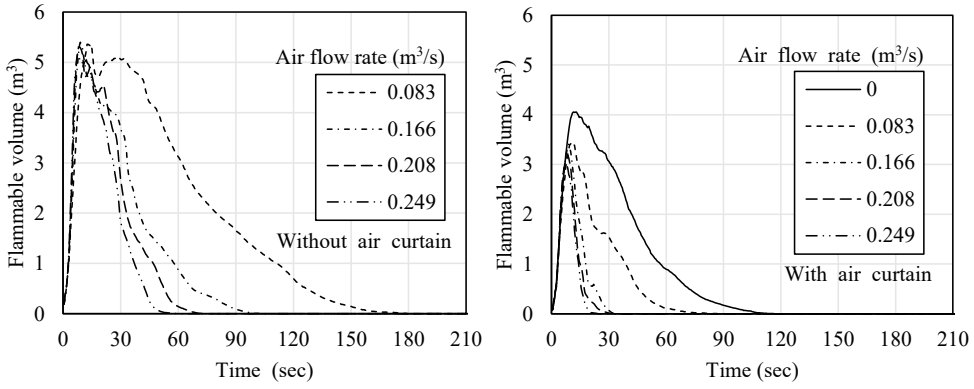
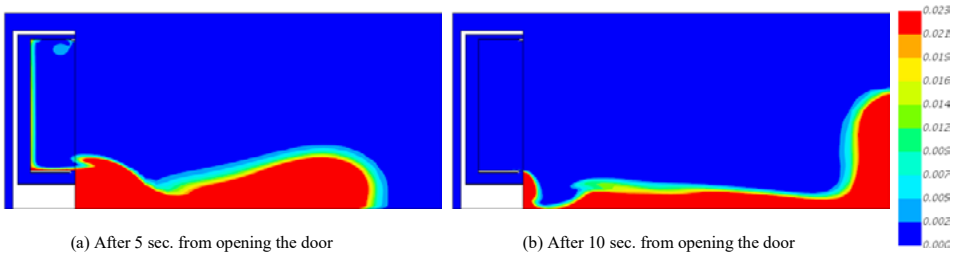
air inlet opening is set to 8.3×10^{-2} m^2 and the air flow rate is varied from 0 to 0.249 m^3/s, which corresponds to air velocity of 0 to 3 m/s. The display cabinet is assumed to be installed at the center of a wall of a shop with square-shaped floor, and the both corners of the ceiling opposite the display cabinet has the pressure boundaries



with a size of 0.4 m × 0.4 m. Both with and without the down flow air curtain from the top-front of the refrigerated space have been considered in this study. As an initial condition, the refrigerant concentration was set to be uniform in the refrigerated space. Then, the calculation was started from the state, and the refrigerant was assumed to fall naturally from the front of the display cabinet assuming that there was no door. These analyses assume the situation of the display cabinet with sliding doors. The air velocity of the air curtain is set to 2.08 m/s and the air flow rate is 0.137 m^3/s. CFD analyses were carried out for cases with the floor area of 17.14 m^2, 24.01 m^2, 36.00 m^2, 64.00 m^2 and 100.00 m^2 while the refrigerant amount was set to 0.358 kg and 0.5 kg. The dimensions of the shop were set to 4.14 m×4.14 m, 4.9 m×4.9 m, 6.0 m×6.0 m, 8.0 m×8.0 m and 10.0 m×10.0 m, respectively. The ceiling height of the shop was set to 2.2 m.

3.1.2. Calculation results of refrigerant leakage from inside of the refrigerated space

Fig. 2 shows the change with time in the flammable volume when the air flow rate of the condensing unit is varied when the floor area is 24.01 m^2 and the refrigerant amount is 0.5 kg. Fig. 2 (a) is the calculation results without the air curtain, (b) is the results with the air curtain. With the air curtain, the duration of the flammable region is shortened and the flammable volume is reduced, but the difference in values with and without the air curtain is not so great. In addition, when the air flow rate of the condensing unit is increased, the duration of the flammable region is reduced both with and without the air curtain, but the maximum value of the flammable volume is hardly reduced. Therefore, it is found when the door of the reach-in refrigerated display cabinet is suddenly opened that the large flammable volume is always generated outside the refrigerated space, although for a short time.



Next, the refrigerant concentration distribution at the center of the display cabinet in the store after 5 sec. and 10 sec. from opening the door are shown. Fig. 3 and Fig. 4 are figures when the floor area is 24.01 m^2, refrigerant amount is 0.5 kg, without the air curtain and the air flow rate of the condensing unit is 0 m^3/s and 0.166 m^3/s, respectively. In both cases, flammable region spreads over the entire floor surface or entire ceiling surface in a short time. As for A3 refrigerant, a relay or a thermostat of electrical equipment in the shop, a lighting switch, plugging/unplugging of power outlet and hot surfaces such as heaters are also ignition sources, and there is a risk of ignition even if the flammable region is generated for several seconds. The calculation results with the air curtain were almost the same as those without the air curtain

Since there are several types of the reach-in refrigerated display cabinet with different air flow pattern in the refrigerated space, e.g. top-face-forward discharge and bottom-front suction type refrigerated cabinet (air curtain type system), and top-rear discharge and upper-front suction type refrigerated cabinet, risk assessment by JRAIA is based on the worst-case scenario of having no air curtain, and the values with and without the air flow rate of the condensing unit are used as operating and stopping value, respectively. Fig. 5 and Fig. 6 show the calculation results of the mean flammable volume and the duration of the flammable region without the air curtain. The figures show the case with the air flow rates of 0 m^3/s and 0.166 m^3/s (air velocity of 2.0 m/s), respectively. In the figures, the horizontal axis shows the value obtained by dividing the refrigerant amount (M) by the floor area (A) inside the shop. Both the mean flammable volume (V_v) and the duration of the

Fig. 5. Duration and volume of flammable region of air flow rate 0 m^3/s without the air curtain

(a) Mean flammable volume (b) Duration of the flammable region

Fig. 6. Duration and volume of flammable region of air flow rate 0.166 m^3/s without the air curtain

flammable region (T_v) can be expressed as a function of the value M/A. The obtained least squares approximate equations are expressed by Eq. (1) to Eq. (3), and at the air flow rate of 0.166 m^3/s, the duration of the flammable region does not change so much and is expressed as an average value as shown in Eq. (4). These equations are shown as solid lines in Fig. 5 and Fig. 6, respectively. In the case of leakage inside the reach-in refrigerated display cabinet, the flammable region outside the refrigerated space did not disappear even when the air flow rate of the condensing unit was increased. This is the same even when there is the air curtain in front of the refrigerated space.

$V_v=1.36\times10^2\times(M/A)+1.34$ (air flow rate ; 0 m^3/s) (1)

$T_v=4.61\times10^5\times(M/A)^2-4.76\times10^3\times(M/A)+1.38\times10^1$ (air flow rate ; 0 m^3/s) (2)

$V_v=2.68\times10^1\times(M/A)+1.08$ (air flow rate ; 0.166 m^3/s) (3)

$T_v=1.32$ (air flow rate ; 0.166 m^3/s) (4)

3.1.3. Refrigerant leakage from the condensing unit

As a result of CFD analyses of refrigerant leakage from the condensing unit at the bottom of reach-in refrigerated display cabinet, the duration of the flammable region was almost the same as the value of the horizontal refrigerated display cabinet described in section 3.2.2 and the mean flammable volume was about half of the value of horizontal refrigerated display cabinet, when the air flow rate of the condensing unit was 0 m^3/s. CFD analysis showed that the influence of the difference in the leak rate on the generation of the flammable region was small when the refrigerant leaked from the condensing unit at the bottom of the refrigerated display cabinet. Since the lower opening area of the condensing unit of the reach-in refrigerated display cabinet was half of that of the horizontal refrigerated display cabinet, the mean flammable volume was likewise halved. And, regardless of the kind of refrigerant, if the airflow rate of the condensing unit was increased, the flammable region was not generated outside the refrigerated display cabinet in the case of refrigerant leakage from the condensing unit.

3.2. Analysis of refrigerant leakage of the open refrigerated display cabinet

3.2.1. Analysis model of refrigerant leakage from the condensing unit of the horizontal display cabinet

CFD analyses were carried out for refrigerant leakage from the condensing unit at the bottom of the horizontal refrigerated display cabinet. The CFD model is shown in Fig. 7. The external dimensions of the display cabinet are 0.81 m in height, 1.8 m in width and 1.09 m in depth. The condensing unit consists of a compressor, a condenser and a fan installed in the lower part of the display cabinet. Air is sucked from one side of the condensing unit and exhausted from another side. Area for both air inlet and outlet openings were set to 6.89×10^{-2} m^2 (0.733 m×0.094 m), and the air flow rate was varied from 0 to 0.207 m^3/s, which corresponds to air velocity of 0 to 3 m/s. The display cabinet is assumed to be installed at the center of a square-shaped shop floor. At the opening of the condensing unit, the value k and ε were set to 1×10^{-4}, the refrigerant concentration was set to 100% when the air flow rate was 0 m^3/s, and the concentration when the air flow rate exceeded 0 m^3/s was set to calculated value. When the air flow rate was 0 m^3/s, the refrigerant was leaked evenly from both air inlet opening and air outlet opening. The refrigerant was leaked from the air outlet opening when the air flow rate was over 0 m^3/s. CFD analyses were carried out for the cases with the floor area of 15.21

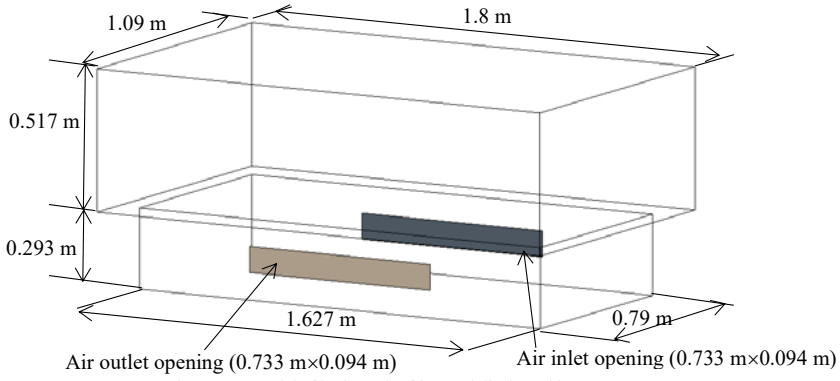

Fig. 7. CFD model of horizontal refrigerated display cabinet

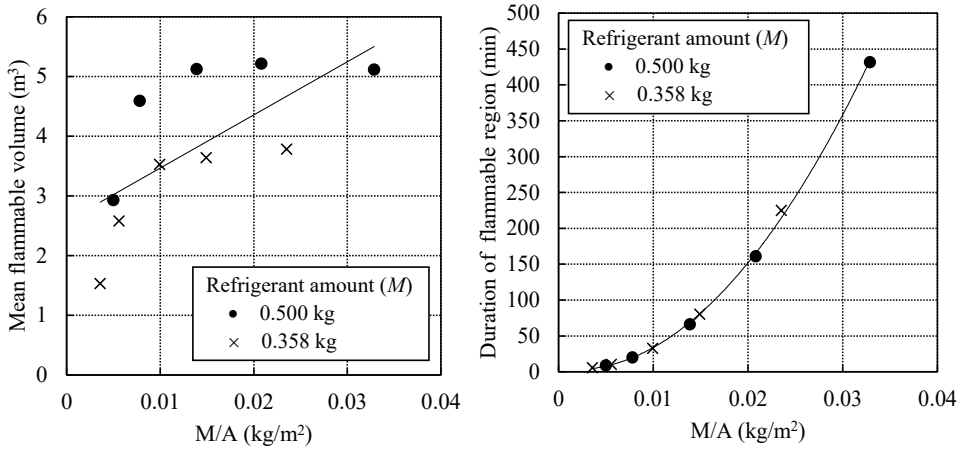
m^2, 24.01 m^2, 36.00 m^2, 64.00 m^2 and 100.00 m^2 while refrigerant amount was 0.5 kg. The dimensions of the shop were set to 3.9 m×3.9 m, 4.9 m×4.9 m, 6.0 m×6.0 m, 8.0 m×8.0 m and 10.0 m×10.0 m, respectively. The ceiling height of the shop was set to 2.2 m.

3.2.2. Calculation results of refrigerant leakage from the condensing unit of the horizontal display cabinet

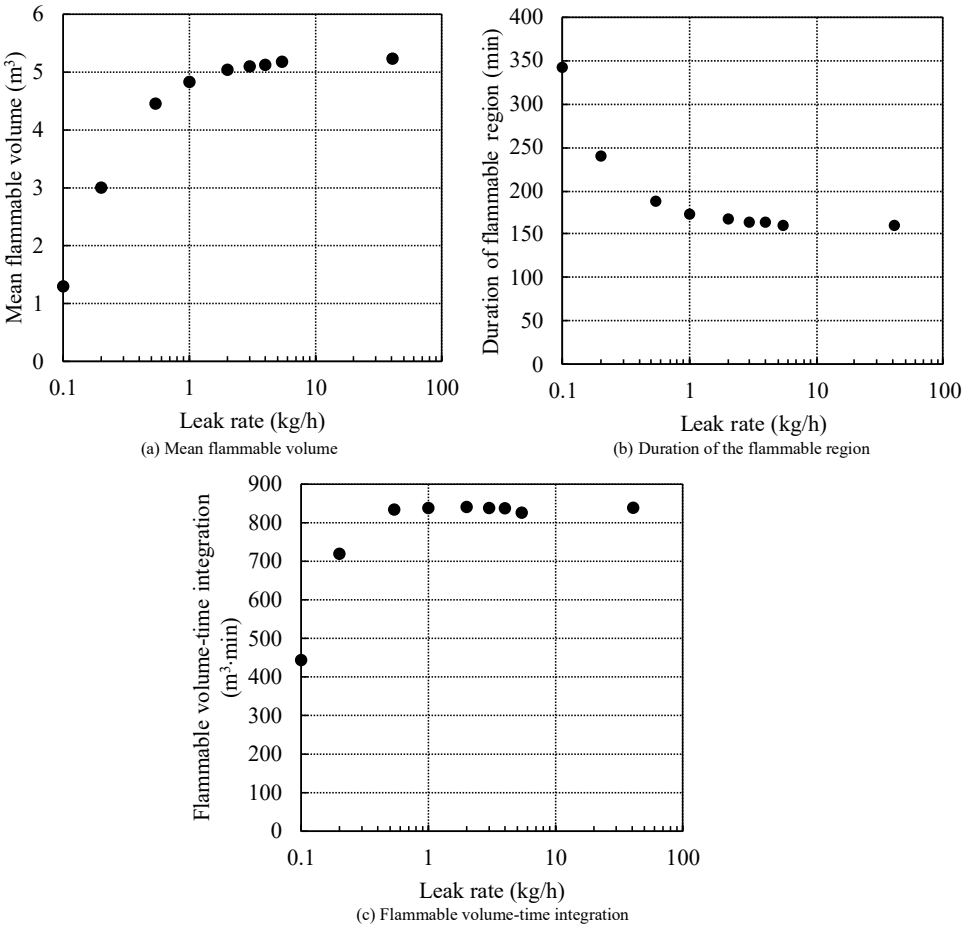
At the first, the calculations were performed when the leak rate was set to the value at which the total refrigerant amount was leaked in 4 minutes. The leak rate was 7.5 kg/h for 0.5 kg, and 5.37 kg/h for 0.357 kg. Fig. 8 shows the calculation results of the mean flammable volume and the duration of the flammable region when air flow rate of the condensing unit of the horizontal refrigerated display cabinet is 0 m^3/s. Its horizontal axis shows the value obtained by dividing the refrigerant amount (M) by the area (A) inside the shop. Both the mean flammable volume (V_v) and the duration of the flammable region (T_v) can be expressed as a function of the value M/A. The obtained least squares approximate equations are expressed by Eq. (5) and Eq. (6) and as solid lines in Fig. 8, respectively. If the airflow rate of the condensing unit was increased, flammable region was not generated outside of the refrigerated display cabinet at the time of refrigerant leakage from the condensing unit.



$$V_v=8.90\times10^{1}\times(M/A)+2.58 \quad \text{(air flow rate ; 0 } m^3/s) \tag{5}$$

$$T_v=4.41\times10^{5}\times(M/A)^2-1.42\times10^{3}\times(M/A)+3.94 \quad \text{(air flow rate ; 0 } m^3/s) \tag{6}$$

As for the leakage from the condensing unit, when the air flow rate of the condensing unit was set to 0.150 m^3/s calculated by Eq. (7) proposed by Colbourne et al. [2], no flammable region was generated outside the display cabinet. Similar results were obtained when the refrigerant was changed to R170, R1270, or R600a.



$$Q \geqq \frac{5\times\sqrt{A_0}\times w^{3/4}}{h_0^{1/8}\times\{G\times(1-F)\}^{5/8}} \tag{7}$$

Next, the calculations were performed when the leak rate was varied from 40.71 to 0.1 kg/h when the shop area of 24.01 m^2, the refrigerant amount of 0.5 kg, and the condenser air flow rate of 0 m^3/s. The calculation results of the mean flammable volume, the duration of the flammable region and the flammable volume-time integration are shown in Fig. 9. The mean flammable volume is almost the same when the leak rate is 2 kg/h or faster, and begins to decrease when the leak rate becomes slower than that, and the value at the leak rate of 0.2 kg/h was about 60% of that at 2 kg/h and the value at 0.1 kg/h was about 25%. The duration of the flammable region increases when the leak rate is decreased because the time from the start to the end of the refrigerant leakage becomes long. The flammable volume-time integration was almost the same at leak rate of 0.54 kg/h or faster, and begins to decrease when the leak rate becomes slower than that, but the value at 0.1 kg/h is about 50% of that at 0.54 kg/h. Therefore, the refrigerant leak from the condensing unit at the bottom of the display cabinet generates a sufficiently large flammable region even of the slow leak rate, and it is necessary to calculate the ignition probability considering all leaks including slow leak in the risk assessment. The slow leak rate is 1 kg/h for R32 and 0.54 kg/h when converted to R290.

(a) Mean flammable volume

(b) Duration of the flammable region

(c) Flammable volume-time integration

Fig. 9. Calculation results when leak rate varies

3.2.3. Refrigerant leakage from inside the refrigerated space of the open refrigerated display cabinet

Since the air curtain is formed in the upper opening of the horizontal refrigerated display cabinet and built-in refrigerated display cabinet has a small refrigerant amount, almost of the refrigerant leaked inside of the refrigerated space does not leak outside the refrigerated space.

As a result of CFD analysis for refrigerant leakage from inside of the vertical refrigerated display cabinet, a slight flammable region was generated outside the refrigerated display cabinet when there was no airflow outside the refrigerated display cabinet. However, there was nearly no generation of the flammable region outside the display cabinet, even with little airflow, when there was the condensing unit at the bottom.

3.2.4. Refrigerant leakage from the condensing unit of the vertical refrigerated display cabinet

Behavior at the time of refrigerant leakage from the condensing unit at the bottom of the vertical refrigerated display cabinet is the same as the condensing unit of the reach-in refrigerated display cabinet.

4. Calculation of Ignition Probability and Safety Measures

4.1. Equations for calculating ignition probability

Temporal encounter probability (P_t) representing the time rate of contacting between the ignition source and the flammable region is calculated by using Eq. (8), based on the theory of geometric probability[3], using

the total time of the target stage (T_a), the duration of the flammable region (T_v), the duration of the ignition source (T_I) and the frequency of occurrence of ignition source (n). Here, the frequency of occurrence of ignition source (n) is the number of times that the ignition source is ignited within the total time of the target stage (T_a). The coefficient k is a coefficient representing the abundance ratio of the ignition source, dissemination rate of the electric equipment, or the degree of concentration when operation of the ignition source concentrates in a certain time zone. Spatial encounter probability (P_s) is calculated by Eq. (9), using the mean flammable volume (V_v) and the volume of the target space (V_a). Ignition probability (P) is calculated by Eq. (10), using the temporal encounter probability (P_t), the spatial encounter probability (P_s) and the refrigerant leak probability (P_R).

$$P_t=k\times[1-\{1-(T_I+T_v)/T_a\}^n] \quad (8)$$

$$P_s=V_v/V_a \quad (9)$$

$$P=P_t\times P_s\times P_R \quad (10)$$

Assuming the allowable value of ignition probability is on the level of a serious accident occurring once every 100 years, the allowable value was set to 5.26×10^{-9} by using 1.9 million units which is the number in operation in the market. Also, since the work is carried out by experts, the allowable value at the time of work was set to 5.26×10^{-8} which is 10 times the value for usage.

4.2. Calculation of ignition probability at usage stage and safety measures

Ignition probability for convenience stores in Tokyo, Japan was investigated. Table 1 shows the main ignition sources assumed at the usage stage. Static electricity is assumed to occur at a humidity of 30% or less, the occurrence probability was set to 18.7 % at the shop temperature and the discharge time was set to 1 μsec. It is assumed that ignition does not occur if air is flowing around the brush motor at velocity sufficiently higher than the burning velocity of the refrigerant, and ignition occur only when the brush motor turns on. The electric spark discharge time was set to 5 msec. Additionally, ignition accidents involving electrical equipment were also taken into consideration, based on survey data of the National Institute of Technology and Evaluation (NITE). The air flow rate of the condensing unit of the display cabinet was assumed to be set at the air flow rate at which flammable region does not generate. Regarding leakage from the condensing unit, it is assumed

Table 1 Ignition sources assumed at the usage stage

Name	Type	T_i (sec.)	n	k	Note
Coffee machine	Electric spark	5×10^{-3}	186	1	Relay operates when selling
Switch of deep frying machine	Electric spark	5×10^{-3}	10	1	Cooking every 4 hrs in a span of 20 hrs
Chinese-style buns steamer	Electric spark	5×10^{-3}	10	1	Cooking every 4 hrs in a span of 20 hrs
Heating appliance for “Oden”	Electric spark	5×10^{-3}	10	1	Cooking every 4 hts in a span of 20 hrs
Power outlet	Electric spark	5×10^{-3}	4	0.5	Unplugging twice a day for cleaning; occurrence ratio: 50 %
Light switch	Electric spark	5×10^{-3}	4	1	Switch on/off twice a day
Copier	Electric spark	180	50	1	50 times in a day, usage time 3 min. per time
Brush motors of other equipment	Electric spark	5×10^{-3}	144	0.01	Turn on 6 times in a hour. dissemination rate: 1 %
Static electricity (door of reach-in refrigerated display cabinet)	Electrostatic spark	1×10^{-6}	434	0.187	Taking out iced coffee
Static electricity (exterior of open refrigerated display cabinet)	Electrostatic spark	1×10^{-6}	22	0.187	Shoppers touch metallic parts
Static electricity (other doors)	Electrostatic spark	1×10^{-6}	22	0.187	Assumed to share the same value as above
Electronic lighter	Open flame	5	5	1	Five people trying ignition in a day
Combustion type boiler	Open flame	3.6×10^{4}	1	0.0001	Use 10 hrs in a day, Dissemination rate: 0.01%

Table 2 Safety measures for usage stage

Safety measures

that no flammable region is generated during operation, but flammable region is generated during stoppage such as defrosting or system failure. The mean flammable volume and the duration of the flammable region were calculated by Eq. (5) and Eq. (6), respectively. As for the refrigerant leakage from inside the refrigerated space of the reach-in refrigerated display cabinet, Eq. (3) and Eq. (4) were used to calculate the mean flammable volume and the duration of the flammable region at operation, and Eq. (1) and Eq. (2) were used for cases of stoppage. The effective area in the shop where the leaked refrigerant can diffuse is set to 84.7 m^2, and the refrigerant amount of each refrigerated display cabinet is set to 0.5 kg. M/A was set to 0.0059 in Eq. (1) through Eq. (6). It is assumed that no flammable region is generated outside the refrigerated space at the time of refrigerant leakage from inside of the refrigerated space of the open refrigerated display cabinet. It is necessary to also consider the slow leak rate in the risk assessment for A3 refrigerants, shown in Fig. 9, though only the rapid leak rate, 10 kg/h for R32 (5.4 kg/h when converted to R290), or higher was considered in the risk assessment for A2L refrigerants. Refrigerant leakage probability in usage was calculated based on the survey results of refrigerant leak accidents in the market involving built-in refrigerated display cabinets manufactured by JRAIA member companies. The refrigerant leak probability was set to 1.00×10^{-3}.
As a result, the ignition probability exceeded the allowable value, and fell to the allowable value or less by taking the safety measures shown in Table 2. In the reach-in refrigerated display cabinet, the ignition probability exceeds the allowable value even if only a slight flammable region is generated outside the refrigerated space when the door is suddenly opened after the refrigerant leak in the refrigerated space. It was possible to prevent the generation of the flammable region outside the refrigerated space at the time of opening the door suddenly by detecting the refrigerant leakage in the refrigerated space in the reach-in refrigerated display cabinet and shutting off the refrigerant circuit. As a result, the ignition probability was reduced to be not higher than the allowable value. It was also confirmed that the ignition probability became not more than the allowable value even if the duration of flammable region was set to the value of R600a.

4.3. Calculation of ignition probability at various working stage and safety measures

In the various working stages, such as transportation, storage, installation, repair and disposal, ignition sources were assumed and the ignition probabilities were calculated. Table 3 shows the main ignition sources assumed at each stage. Transportation on a minivan with an internal volume of 2.9 m^3 was assumed as the transportation stage. Storage was assumed to be in a medium-sized warehouse of 1000 m^2 or a small-sized warehouse of 15 m^2 in storage stage. For installation, repair and disposal, ignition sources described in Table 1 were considered in addition to the ignition sources at the time of work since such work is carried out while using the equipment in the shop. Static electricity is assumed to occur at a humidity of 30% or less, and the occurrence probability was set to 18.7 % annually at shop temperature, 54.5% in winter at shop temperature, 3.2% at outdoor temperature, and the discharge time was set to 1 μsec. As for the refrigerant leakage probability, the value was calculated for each stage by using the value of human error or similar value. The mean flammable volume and the duration of the flammable region were calculated by Eq. (3) and Eq. (4) for the value at the

Table 3 Ignition sources assumed at each working stage

Name	Type	T_i (s)	n	k	Note
Common; Smoking by workers	Open flame	4.5×10^{1}	1/hour	0.282	Cigarette smoked: 1 stick/person/hrs; ignition time with lighter: 5 sec.; duration of high cigarette temperature: 40 sec.; smoking rate: 28.2%

Table 4 Safety measures for working stage

Stage	Safety measures
Transportation (for minivan transportation only)	1. Marking of warning of risk of fire on the product 2. Using a portable leak detector and ventilating after detection of leakage
Storage	1. Use of work gloves to prevent electrostatic discharge 2. Marking of warning of risk of fire on the product and packing
Installation	1. Use of work gloves to prevent electrostatic discharge 2. Marking of warning of risk of fire on the product 3. Using a portable leak detector and stopping the working at the time of leakage
Repair	1. Use of work gloves to prevent electrostatic discharge 2. Using a portable leak detector and diffusing refrigerant to the surroundings at the time of leakage (e.g. electric fan, paper fan)
Disposal	1. Use of work gloves to prevent electrostatic discharge 2. Using a portable leak detector and stopping the working at the time of leakage

time of leakage inside the refrigerated space, and Eq. (5) and Eq. (6) for the value at the time of leakage from the condensing unit.

As a result, the ignition probability exceeded the allowable value at all stages, and fell to the allowable value or less by taking the safety measures for each stage shown in Table 4. It was also confirmed that the ignition probability became not more than the allowable value even if the duration of flammable region was set to the value of R600a.

5. Conclusion

For built-in refrigerated display cabinet using A3 refrigerant, CFD analysis of refrigerant leakage from inside the refrigerated space and from the condensing unit of each display cabinet were carried out, and risk assessments at the stages of usage and working were carried out by using the CFD results. This led to the clarification of methods to ensure safe operation of the equipment.

(1) Flammable region was generated outside of the refrigerated space when the door was opened suddenly after all refrigerant leaked in the reach-in refrigerated display cabinet. Approximate equations using R290 were introduced to calculate the mean flammable volume and the duration of the flammable region without the air curtain and with or without the airflow of the condensing unit.

(2) Equations were introduced to calculate the mean flammable volume and the duration of the flammable region with or without the airflow of the condensing unit in case of refrigerant leakage of R290 from the condensing unit of the horizontal refrigerated display cabinet.

(3) Flammable region was not generated when the air flow rate was set to a specified value or higher at the time of refrigerant leakage from condensing unit.

(4) Risk assessments were carried out by identifying the ignition sources at the stages of usage and working for a convenience store. The ignition probability using A3 refrigerants such as R290 or R600a at the usage stage did not exceed the allowable value by taking safety measures, such as the product function enabling the fan of the condensing unit to keep operating even while defrosting, the function of detecting refrigerant leakage into the refrigerated space of reach-in refrigerated display cabinet and the function of shutting off the refrigerant leakage into the refrigerated space at the time of refrigerant leakage. The safety measures at each stage of working were also clarified.

Acknowledgements

This study was carried out by member companies of JRAIA, Mitsubishi Electric and its affiliate, Sanden Retail Systems, Okamura, Toshiba Carrier, Nakano Refrigerators, Panasonic, Fukushima Industries, Fuji Electric, and Hoshizaki. Observers from each company are Hiroichi Yamaguchi, Makoto Handa, Takeshi Shinmyou, Masahiro Onoguchi, and Akio Oki, who cooperated with this study. The authors would like to deeply appreciate these members support.

Nomenclature

A	shop area (m^2)
A_0	area of air outlet (m^2)
F	coefficient (safety factor), equal to 0.25
G	LFL (kg/m^3)
h_0	height of centerline of air outlet (m)
k	coefficient
M	refrigerant amount (kg)
n	frequency of occurrence of ignition source
P	ignition probability
P_R	refrigerant leak probability
P_s	spatial encounter probability
P_t	temporal encounter probability
Q	air flow rate of outlet air (m^3/s)
T_a	total time of target stage (s)
T_i	duration of the ignition source (s)
T_v	duration of the flammable region (s)
V_a	volume of target space (m^3)
V_v	mean flammable volume (m^3)
w	refrigerant leak rate (kg/s)

[a]Department of Mechanical and Industrial Engineering, Ryerson University, Toronto, M5B 2K3, Ontario, Canada

Abstract

This preliminary study is part of a bigger cloud-based Smart Dual Fuel Switching System (SDFSS) for hybrid heating, ventilation and air conditioning (HVAC) systems. The SDFSS being developed enables flexible and cost-optimized control between the natural gas furnace and air source heat pump (ASHP), allowing simultaneous reduction in energy costs and greenhouse gas (GHG) emissions. To meet the optimal energy consumption requirements and satisfaction of the residents, the employment of smart sensors and software are broadly used. By using experimental data retrieved from an actual near net-zero energy house (nNZEH), this study investigates the GHG emissions as well as the energy costs from the combined electricity consumption of the ASHP and the natural gas consumption from the furnace. The results demonstrate the potentials for large-scale implementation and deployment of such smart control strategy for hybrid residential HVAC system of natural gas furnace and air source heat pump in reducing overall GHG emission in a cost-effective manner in cold climate of province of Ontario, Canada where relatively expensive but clean source of electricity is available. These results demonstrate the potential for large-scale implementation and deployment of a SDFSS in colder climates such as in Canada.

1. Introduction

To minimize the negative impacts of climate change, the United Nations Framework Convention on Climate Change (UNFCCC) developed the Paris Agreement [1]. This Agreement aimed to unite all countries to mitigate the impacts of and to adapt to climate change and find ways to reduce greenhouse gas (GHG) emissions. After signing this Agreement, Canada also introduced the Pan-Canadian Framework on Clean Growth and Climate Change (the Pan-Canadian Framework) to help address the impacts of climate change nationwide. Similar to the Paris Agreement, the Pan-Canadian Framework encourages innovation and the development of technology to find efficient energy solutions to help minimize climate change impacts. Additionally, the Federal Government of Canada has recently introduced taxes for carbon pollution. Moreover, the Pan-Canadian Framework has set an ambitious target to reduce GHG emissions by 30% by 2030 and by 80% by 2050, relative to 1990 levels [2].

A breakdown of Canadian GHG emissions by sector is shown in Figure 1, demonstrating that the residential sector produces a significant portion of GHG emissions. Moreover, Canada Green Building Council (CaGBC) established a building code to reduce energy use by 50% for one million homes in Toronto while working to meet Canada's 2030 goals of constructing net-zero energy buildings (NZEB)s. To achieve this goal, one of

Canada's strategic plans for promoting systems and technologies that minimize natural gas and fossil fuel usage while increasing the use of clean electricity.

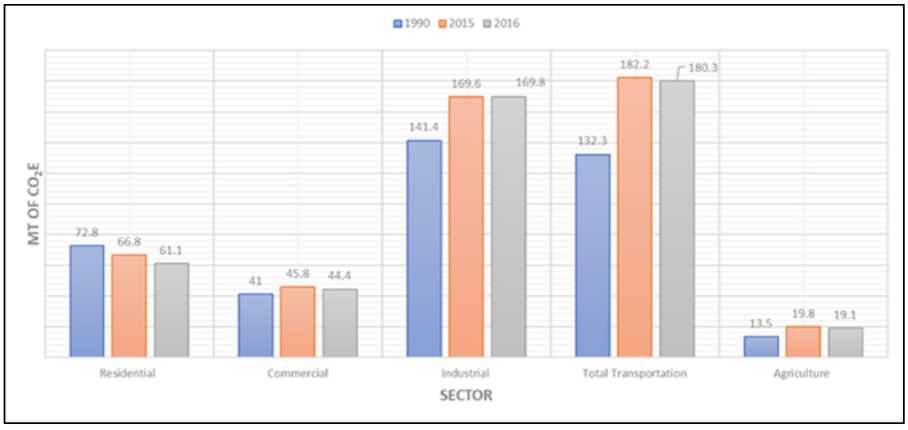

Fig. 1. Breakdown of Canadian GHG emissions by sectors [3]

Buildings are Ontario's third-largest source of emissions, representing about 19% of the province's total GHG emissions. Additionally, the residential sector's heating demand contributes to 80% of the total household energy consumption [3]. This suggests that energy consumption in buildings is a key contributor to GHG emissions. Regardless of the type of fuel that is being used for space heating, energy demands are increasing in the Canadian residential sector. Meanwhile, the combination of North America's cold climate condition and outdated HVAC control systems is contributing to higher energy consumption and increasing GHG emissions.

Even though most governments and scientists agree on being fossil-free as soon as possible, there is still room for greater technological innovation to help achieve their goal of reducing GHG emissions and energy costs. Therefore, it is important to introduce a technology that addresses this transition period before Canada becomes 100% carbon neutral.

For Canada to meet its energy reduction commitments by 2030 and 2050, low fossil fuel energy sources such as an ASHP could be considered an alternative to help reduce natural gas usage in residential buildings. However, only using electricity to meet residential buildings' heating/cooling demands is not feasible technically and economically as electricity is more expensive than natural gas in Canada [citation]. With this being said, hybrid electric ASHPs and natural as (NG) furnace systems are viewed as a lower-cost option that is better for the environment [4, 5, 6].

Although numerous research work has been conducted for managing the energy demand, smart dual fuel switching systems (SDFSS) are rarely found in the literature. The studies mentioned in [7] and [8] discussed three strategies for operating the energy demand of an archetype house through the optimal utilization of an electric air-source heat pump (ASHP) and a natural gas-fired mini-boiler using a predictive controller. To address this, a working cloud- based SDFSS prototype was implemented and tested for a one-year period in 2018 to account for the entire heating and cooling seasons. The house is located in the town of Strathroy, Ontario, Canada and is a near net-zero energy house (nNZEH). This paper studies the effects of the newly developed SDFSS system and its ability to reduce GHG emissions while considering the economic impacts of electricity and NG consumption from the HVAC equipment.

2. Case Study Description

The developed SDFSS system was implemented in a newly constructed house with 2586 sqft of conditioned living space (combined main floor and basement) and is owned and occupied by a retired couple with two dogs. A photograph of the house is presented in Figure 2. The house has a rooftop mounted PV (photovoltaic) array with a total capacity of 8.745 kWp and uses a hybrid electric ASHP, a NG furnace, and an electric enthalpy recovery ventilation (ERV) for its heating, cooling, and ventilation needs. The house uses NG for its domestic hot water production, cooking range and fireplace. The ASHP is used for both the heating and cooling needs of the house depending on the season.

Additionally, the ASHP defrost was taken into account. Hence, the ASHP was disabled to operate below the balance point temperature [13]. In this case, the NG furnace was used as an auxiliary system. The cloud-based SDFSS implemented operates based on the temporal thermal demand of the house and optimizes its HVAC operation using short-term weather forecast information to minimize the operating cost for a few hours on the cloud server. The SDFSS then communicates with the house's HVAC system via a connected smart thermostat to operate either the ASHP or the supplementary heater, and in this case, an NG furnace [9]. The ASHP operates as an air-conditioning system during the cooling season. A computer platform and a physical communication interface board were developed to mimic and observe the behaviour of the SDFSS. The developed system iterates an algorithm consisting of various temporal parameters such as time of day, TOU price of electricity, outdoor temperature, ASHP performance/capacity, NG furnace performance and thermal demand of the house to select the most cost-effective fuel source for the given hour. The TOU electricity pricing scheme is demonstrated in Figure 3. As an added benefit, this system also reduces GHG emissions since the NG furnace is optimally substituted by an ASHP powered by a relatively clean source of electricity to meet the space heating demand of the house dynamically on an hourly basis.

Fig. 2. Exterior photographs of the house

The cloud based SDFSS implemented operates based on the temporal thermal demand of the house and optimizes its HVAC operation, using short-term weather forecast information, to minimize the operating cost for the next few hours on the cloud server. It then communicates with the house's HVAC system, via a connected smart thermostat, to operate either the ASHP or the supplementary heater, in this case a NG furnace [9]. The ASHP operates as an air-conditioning system during the cooling season. In addition to computer platform developed to mimic and observe the behavior of SDFSS, the physical communication interface board was developed to test the actual system. The developed system iterates an algorithm consisting of various temporal parameters such as time and day, TOU price of electricity, outdoor temperature, air-source heat pump performance/capacity, natural gas furnace performance and thermal demand of the house to select the most cost-effective fuel source for the given hour. TOU electricity pricing scheme is demonstrated in Figure 3. As an added benefit, this system also reduces the GHG emission since the NG furnace is optimally substituted by an ASHP powered by the relatively clean source of electricity to meet the space heating demand dynamically on an hourly basis.

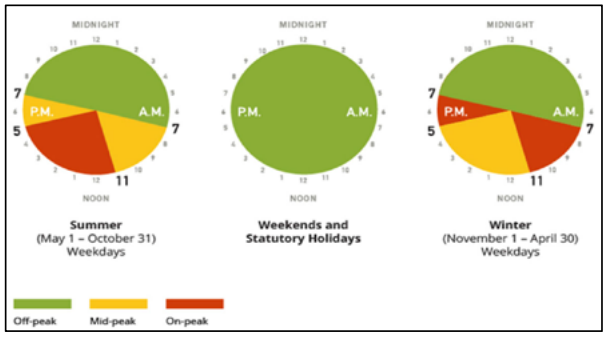

Fig. 3. TOU electricity pricing scheme [12]

The main focus of this study is to examine the environmental and economic impacts of implementing a cloud-based SDFSS for hybrid residential HVAC systems. By using experimental data retrieved from an actual near net-zero energy house, this study aims to investigate the reduction of GHG emissions as well as the energy costs associated with the electricity consumption of the ASHP and the NG consumption from the furnace. Therefore, a net zero energy building (NZEB) in Ontario, Canada was studied to investigate the viability of the SDFSS. The preliminary analysis demonstrated that the implemented SDFSS is a cost-effective and environmentally-friendly alternative to conventional HVAC equipment used in North American cold climates.

3. Methodology

The SDFSS modelled, developed, and implemented at the studied house accounts for the following factors in deciding whether the NG furnace or the ASHP should be operated at a specific time to meet space heating demand (HD) of the house [4]:

- π_{TOU}: TOU electricity price which changes based on hour of the day such as off-peak, mid-peak, on-peak hours [10]
- π_{NG}: Natural gas price (which is constant during the day)
- COP_{ASHP}: Coefficient of performance of the ASHP which is derived from the manufacturer's data and then calibrated with experimental data [5, 10]
- $\eta_{FURNACE}$: Efficiency of the NG furnace (89% with multiple measurements on site)
- NG energy density: 10.395 kWh/m^3 [R]
- T_{amb}: Ambient outdoor dry bulb temperature

To estimate HD of the house, a TRNSYS model was developed. This model is depicted in [10]. The curve for the COP_{ASHP} formulated from manufacturer's data and then calibrated with the experimental data is as follows:

$$COP_{ASHP} = 0.0053T_{amb}^2 + 0.0.0834T_{amb} + 2.8545 \quad (1)$$

Hourly space heating demand (HD) of the house is expressed in terms of COP_{ASHP}, $\eta_{FURNACE}$, consumption from ASHP (D_{elec}), consumption from NG furnace (D_{NG}) as the following equations:

$$D_{elec} = HD/COP_{ASHP},\ D_{NG} = HD/\eta_{FURNACE} \quad (2)$$

Based on the consumption of the equipment calculated, the total cost from ASHP operation (C_{ASHP}) and the total cost from NG furnace (C_{NG}) are defined as follows:

$$C_{ASAP} = D_{elec} * \pi_{TOU},\ C_{NG} = D_{NG} * \pi_{NG} \quad (3)$$

The SDFSS decides whether ASAP or NG furnace should be in operation based on the cheapest total cost amongst C_{ASAP} and C_{NG}. The data-driven SDFSS model consisted of an optimization algorithm which was ran hourly.

4. Results

From Equation 1, 2, and 3; CASAP, CNG, DNG, Delec are calculated for the period where the SDFSS was in operation. The first day of the data retrieval was on the 16th of February 2018. The first day of activating the SDFSS was on the 7th of November 2018, and the final day of the SDFSS experimentation was on the 6th of December 2018. The broader study also concluded on December 6th, 2018.

The average hourly GHG emission factors (in gCO_2eq/kWh) from the Ontario grid were taken from [11]. Along with the TOU dependency based on heating and cooling season, the weekends and statutory holidays are considered as the off-peak hours for the operation of the ASHP. Therefore, the day of the week and these holidays are also included in the analysis.

A detailed analysis of the outcomes of the SDFSS in terms of cost (in CAD) and GHG emissions released (in $kgCO_2/day$) from the HVAC equipment used during this period is depicted in Table 1. It is observed that on some days, only one type of the HVAC equipment was active. On other days, the switching happened during the day. So, there was both electricity and NG consumption from HVAC equipment. GHG emissions occurred from both HVAC systems. The results demonstrate that the NG furnace releases relatively more GHG emissions, but it is cost-effective. Similarly, the ASHP releases relatively less GHG emissions, but it is more expensive than NG.

To further analyse the outcomes of the SDFSS introduced, the actual loads of the HVAC equipment were analysed along with the average outdoor temperature, the average minimum temperature, and the average maximum temperature on the days when the SDFSS was in operation. This analysis is demonstrated in Figure 4. It should be noted that spreading temperature is the absolute difference of the maximum and minimum outdoor temperature of a specific day. Additionally, Figure 5 depicts the GHG emissions from the HVAC equipment when the SDFSS was in operation.

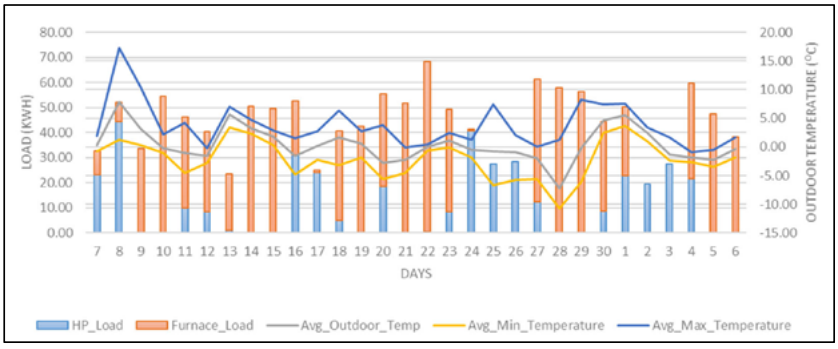

Fig 4. Ambient temperature and loads from the HVAC equipment when the SDFSS in operation (from 7th of November to 6th of December 2018)

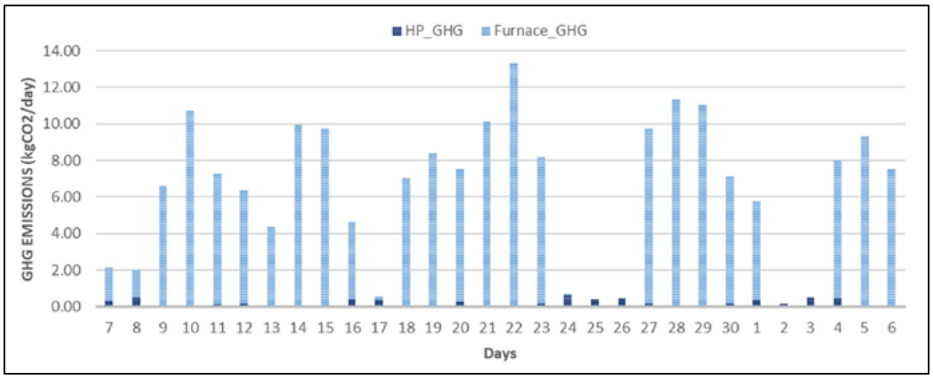

Fig 5. GHG emissions from the HVAC equipment when the SDFSS in operation (from 7th of November to 6th of December 2018)

The COP and capacity of the ASHP depend on the ambient outdoor temperature, which has led HVAC manufacturers to have a built-in temperature sensor on their ASHP. The ambient outdoor temperature of the specific location of the house is required in defining and meeting the thermal demand of the house. Therefore, the ambient outdoor temperature is a pivotal factor in this analysis to observe the smart switching optimal temperatures based on the introduced algorithm of the SDFSS. Table 2 depicts the marginal TOU electricity pricing based on TOU tiers such as off-peak, mid-peak, and on-peak hours [12]. The electricity prices from the consumption of electricity from ASHP are calculated based on the criteria given in Table 2. However, NG marginal price is \$0.3038/m^3 and has been fixed.

Table 2. Marginal TOU electricity pricing

Off-peak	\$0.092/kWh
Mid-peak	\$0.124/kWh
On-peak	\$0.163/kWh

Moreover, the costs and GHG emissions released from the electricity and NG consumption by the hybrid HVAC equipment when SDFSS is active and inactive were compared. For instance, when the thermostat switching setting was fixed at 0°C, the days with almost the same outdoor temperature conditions were analyzed. Table 3 demonstrates the analysis considered the entire month of February 2018. When the SDFSS was inactive, a fixed fuel switching temperature was introduced at 0°C, where ASHP operated when the outdoor temperature was above 0°C. Otherwise, when the outdoor temperature was below 0°C, the NG furnace was operated. For the SDFSS, the ASHP was in operation during the off-peak TOU hours and when the ambient temperature was above the optimal switching points. When on-peak and mid-peak TOU hours and the ambient temperature was below the optimal switching points, the NG furnace was in operation.

Table 3. A detailed analysis on ambient temperature, cost, GHG, and loads from the HVAC equipment when the switching point was at 0°C (from 16th of February to 28th of February 2018)

After analysing the cost and GHG emission values for the days that had similar ambient temperature values, it is observed that the SDFSS cost less while preserving lower GHG emissions. For instance, on the 16th and

17th of November 2018, the SDFSS was active and on the 22nd of February 2018, the SDFSS was inactive, and the switching was at a fixed temperature of 0°C. The days that had similar conditions were defined based on maximum difference in ambient temperatures. The overall costs and GHG emissions released these days are a significant depiction of the SDFSS better than the conventional HVAC equipment in terms of these criteria.

As previously mentioned, the electricity prices are more costly than natural gas prices in Ontario, Canada. Therefore, a supplementary analysis was conducted to exhibit the overall applicability of the SDFSS on operating ASHP. Figure 6 shows the overall cost from operating ASHP, when the SDFSS is active and inactive. Following the methodology defined above, the associated ambient temperatures were taken into account to compare them with the days when the SDFSS was operating. The operational costs from the ASHP were mapped against the days in November 2018. It is seen that when the SDFSS was in operation, the electricity cost from the ASHP was more economical than the conventional testing period. When the SDFSS was active, the cost did not exceed $1.50.

In contrast, when the SDFSS was inactive, the costs reached up to $4. The ASHP was less expensive during the operation of the SDFSS because when the extreme outdoor temperatures and the on-peak hours of electricity pricing occurred, the NG furnace was turned on for operation to meet the space heating demand. As NG furnace was not operated consistently, the SDFSS switched between the NG furnace and the ASHP. The GHG emissions were not higher than the conventional periods, where there was a fixed switching temperature at 0°C.

The comparison of GHG emissions obtained from the operation of the ASHP between the days, when the SDFSS was in operation (in November 2018) and other days in the heating season are demonstrated in Figure 7. This comparison was performed while considering the mean difference in ambient temperatures between the days with similar weather conditions and the days when SDFSS was in operation. Based on these differences, the GHG emissions from the consumption of the HVAC equipment were compared. It is observed that in November 2018 as the SDFSS was active, the GHG emissions were relatively lower than the period, where the fixed switching temperature was in operation.

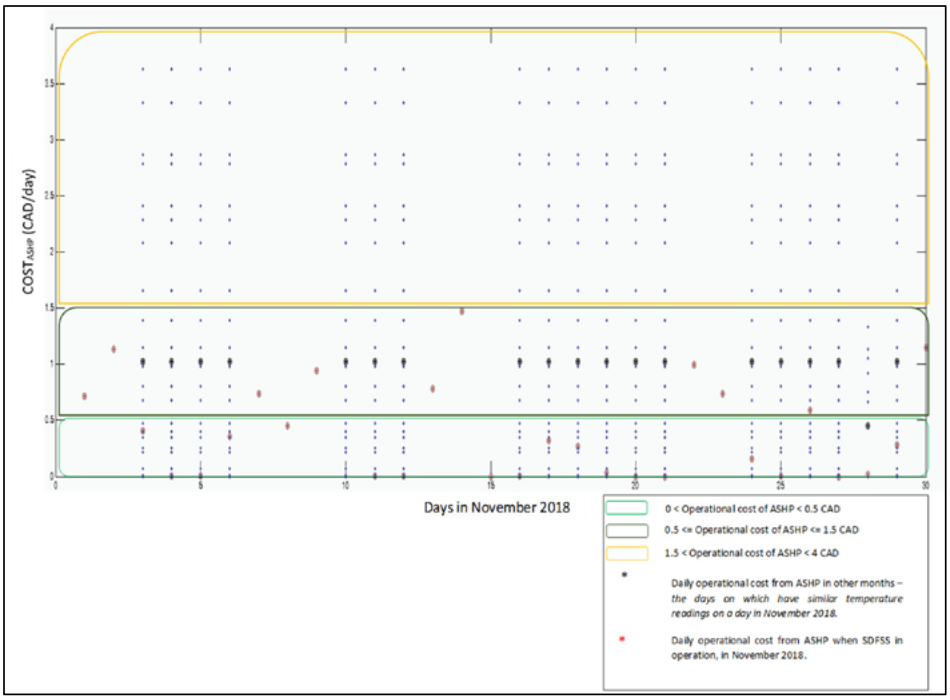

Fig. 6. Comparison of operational cost of ASHP between the days when SDFSS in operation (in November 2018) and other days in the heating season

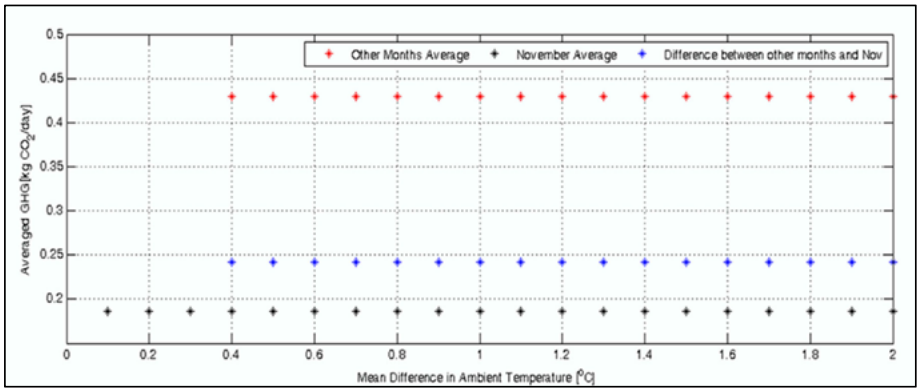

Fig. 7. Comparison of GHG emissions obtained from the operation of ASHP between the days when SDFSS in operation (in November 2018) and other days in the heating season

5. Conclusion

This study introduced a unique and innovative approach to account for the balance between economic and environmental impacts of the residential space heating in cold climates by proposing a flexible, cost effective, and clean energy solution. The technology, called the SDFSS, was developed, installed, and implemented at a Net Zero Energy House in Strathroy, Ontario, Canada. The SDFSS estimates the optimal switching point temperatures by considering various temporal factors such as TOU electricity prices, the efficiency of the NG furnace, the COP and capacity of the ASHP, and NG prices. Using Internet of Things (IoT) technologies and cloud servers, the data from the heating of the house when the SDFSS was in and out of operation were retrieved and analyzed in detail. This study focused on the environmental and economic impact of implementing these alternative technologies, called cloud based SDFSS for hybrid residential HVAC systems, in the transitioning period of prior being completely fossil-fuel free. The preliminary analysis demonstrated that the implemented SDFSS is a cost-effective, flexible, and environmentally friendly alternative to conventional HVAC equipment used in the North American cold climate.

Future work will examine the potential benefits, in terms of reduction of operating cost and GHG emissions of such cloud-based SDFSS for hybrid residential HVAC system in meeting different GHG emission reduction targets by 2030 and 2050 with the recently introduced federal carbon taxes of $20/tonne, $30/tonne, $40/tonne, and $50/tonne of CO_2 from 2019 to 2022.

[b]Department of Mechanical Engineering, Korea University, Seoul, 02841, Republic of Korea

Abstract

In this study, type 1 and type 2 combined absorption heat pump system using R32/DMAC is developed for heating and cooling applications. Waste heat from the heat with low temperature (below 90℃) is utilized as the heat source. R32 and an organic fluid of DMAC(Dimethylacetamide) are used as refrigerant and absorbent, respectively. Additionally, the combined heat pump system has two splitters placed after the generator outlet and condenser outlet. Cooling, heating and system coefficient of performance (COP) are calculated according to the change of generator temperature. The maximum cooling COP is estimated as 0.400, the maximum heating COPs with and without superheat are 0.196 and 0.161, respectively. Maximum system COP is estimated as 0.596. It is found that the heating performance of the system is more sensitive to the generator temperature than the cooling performance.

Keywords: 1st and 2nd Type Combined Absorption heat pump, COP, Low temperature heat source, R32

1. Introduction

Research and development on low GWP refrigerants have been actively proceeded. In addition, fossil fuels are the main cause of micro dust that directly affects the respiratory diseases, and regulations on the use of fossil fuel are being tightened. International efforts are being made in response to these environmental regulations. After the Fukushima nuclear accident in 2011, Japan declared its de-nuclearization policy and halted the nuclear power plant sequentially, causing the problems in energy supply and demand. To solve this problem, they have introduced Ene-farm that uses hydrogen as an alternative energy. The Ene-farm is a combined fuel cell system that generates 0.7kW of auxiliary power in consideration of economic feasibility, and the waste heat from the electricity production process is used for heating. The amount of waste heat generated in the process in fuel cells takes about 50% of total chemical energy and the operating temperature ranges from 80 to 1300℃ depending on electrolyte type of each fuel cell. Waste heat from Ene-farm is only used as a hot water supply device, so its use is limited. In addition, as the operating temperature of the PEMFC is only 70-80℃ [1], the waste heat from this is more limited. Furthermore, although research on energy recovery system using solar energy is being actively conducted, its use is also limited because it generates 60 to 70℃ when solar energy is collected.

Regarding the development of absorption cycles, working fluid pairs(refrigerant/absorbent) are as important as all the components of absorption cycles. H_2O/LiBr and NH_3/H_2O are most widely used at present. Despite the outstanding performance of the existing pairs, as shown in Table 1, these pairs have some critical disadvantages. H_2O/LiBr doesn't work under the generator temperature of 90℃ and it has the freezing problem under 0℃. To deal with these problems, the use of an alternative refrigerant and absorbent as a working pair for the absorption refrigeration cycle has been proposed. Therefore, in this study, a sorption heat pump that uses waste heat from the low temperature heat source(which is lower than the temperature of 90℃)

* Corresponding author. Tel.: 82-2-3290-5952; fax: 82-2-922-3260.
E-mail address: ytkang@korea.ac.kr.

is proposed. The sorption heat pump system uses alternative refrigerant and organic liquid as absorbent, which can solve the problems mentioned above at the same time.

Table 1 Characteristics of representative refrigerants for absorption refrigeration system

	NH_3/H_2O	**$H_2O/LiBr$**
Absorbent	H_2O	LiBr
Refrigerant	NH_3	H_2O
Crystallization	N	Y
Toxicity	Y	N
Flammability	Y	N
Disadvantages	1. Flammable, Explosive, Toxic 2. Regulated by national regulations	1. Frozen/refrigeration system: Not applicable 2. Difficulty in air cooling due to high boiling point of refrigeration

2. Simulation Methodology

2.1. Description of Type 1 and Type 2 combined sorption heat pump

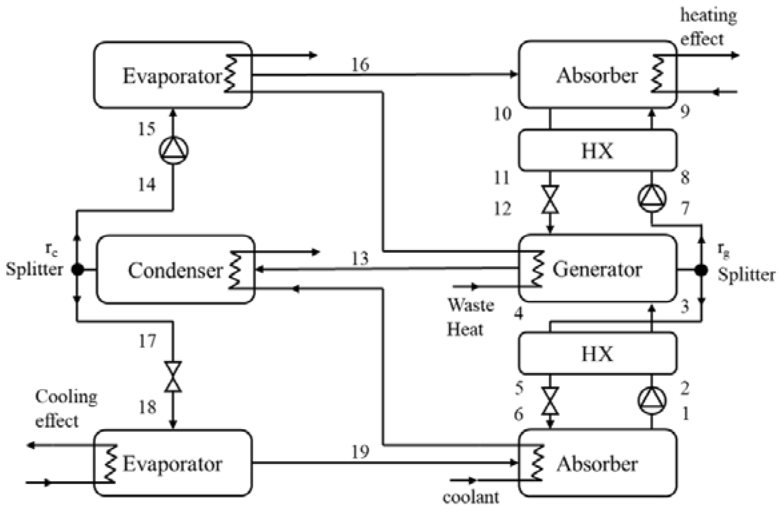

Figure 1. Schematic diagram of type 1 and type 2 combined sorption heat pump cycle

Figure 1 is a schematic diagram of Type 1 and Type 2 combined sorption heat pump system. The refrigerant and absorbent mixed solution is transferred from the low temperature absorber to the generator through the pump and the generated refrigerant which is recovered at the generator by absorbing the waste heat from the low temperature heat source moves to the condenser. Splitter attached to the generator splits the solution to be transferred to the high and low temperature absorbers. The refrigerant transferred to the condenser is fully condensed in the condenser. The liquid refrigerant is transferred to the high temperature evaporator and the low temperature evaporator through a splitter attached to the condenser. The refrigerant transferred to the high temperature evaporator is compressed by a pump, and the refrigerant transferred to the low temperature evaporator is expanded in the expansion valve. In the high temperature evaporator, the residual heat which already supplied to the generator is absorbed by the refrigerant.

The evaporated refrigerant from the high temperature evaporator is absorbed in the high temperature absorber, raises the temperature of the high temperature absorber outlet solution, and transfers heat to the heating target. Whereas, the refrigerant transferred to the low temperature evaporator is evaporated while cooling the target system in the low temperature evaporator and is retrieved to the low temperature absorber.

2.2. Selection of refrigerant and absorbent pair

After considering toxicity, safety, stability, flammability and corrosivity problems, R32 which is an alternative refrigerant for R410A and R407C has received much attention in recent years. R32 has about one third lower GWP than that of R410a and has an ODP of zero. Furthermore, R32 requires less charge as it has a 20% higher volumetric capacity. By considering the critical-point which is higher than R410A's, heat capacity and saturation pressure difference, R32 is finally selected. Due to the negligible vapor pressure, good thermal and chemical stability and solubility with many refrigerants, DMAC is considered as a promising absorbent for the combined sorption cycles.

2.3. Cycle modelling of the sorption cycle

During the cycle simulation process, the following assumptions are made.
(1) Steady state.
(2) The pressure drop is negligible.
(3) Condensation and evaporation occur completely in condenser and evaporator, respectively.
(4) The effectiveness of the solution heat exchanger is assumed 0.8. [2]
The entire simulation of the sorption heat pump is carried out using the Engineering Equation Solver (EES).

2.3.1. Mass and species conservations

Principles of mass and energy conservations are considered for each component of the system as follows.

- Mass balance

$$0 = \sum \dot{m}_i - \sum \dot{m}_o \tag{1}$$

$$0 = \sum \dot{m}_i(1 - x_i) - \sum \dot{m}_o(1 - x_o) \tag{2}$$

- Energy balance

$$0 = \sum \dot{m}_i h_i - \sum \dot{m}_o h_o + \sum \dot{Q}_i - \sum \dot{Q}_o + \dot{W} \tag{3}$$

- Solution pump

$$h_o = h_i + \frac{\dot{W}_p}{\dot{m}_i} \tag{5}$$

- Expansion valve

For refrigerant and solution pump expansion valves, the isenthalpic processes are assumed.

$$h_o = h_i \tag{6}$$

2.3.2. COP

The heat recovered by the high temperature evaporator was excluded from the calculation. This is because the remaining heat is used instead of the heat source for operation.

$$COP_{cooling} = \frac{\dot{Q}_{evap}}{\dot{Q}_{gen} + \dot{W}_{pump}} \tag{7}$$

$$COP_{heating} = \frac{\dot{Q}_{abs,high}}{\dot{Q}_{gen} + \dot{W}_{pump}} \tag{8}$$

$$COP_{system} = \frac{\dot{Q}_{abs,high}+\dot{Q}_{evap}}{\dot{Q}_{gen}+\dot{W}_{pump}} \quad (9)$$

3. Results and discussion

The condenser outlet temperature(T_{cond}) and the low temperature absorber outlet temperature($T[1]$) are set to 30℃, respectively. The low temperature absorber outlet mass flow rate is set to 0.1(kg/s), and the split ratios of generator and condenser are 0.5, respectively as the base lines as summarized in Table 2.

Table 1 Characteristics of representative refrigerants for absorption refrigeration system

T_{gen}(℃)	T_{cond}(℃)	$T[1]$(℃)	$T[10]$(℃)	$m[1](kg/s)$	T_{16}(℃)	$r_g r_c$
66~70	30	30	75	0.1	45~50	0.5

3.1. Effect of the generator temperature on the cooling and heating performances

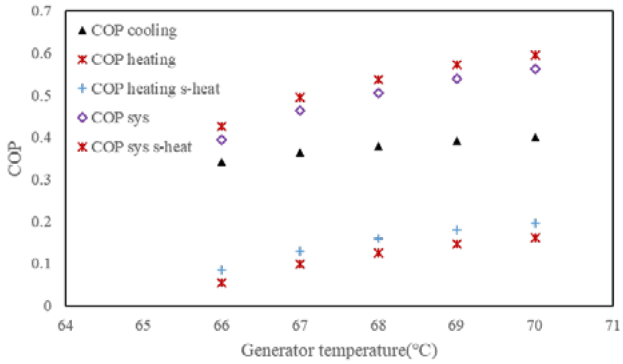

Figure. 2. Effect of generator temperature on COP

Figure 2 shows the COPs according to the generator temperature change. As the generator temperature increases, cooling COP($COP_{cooling}$) and heating COP($COP_{heating}$) increases. The maximum cooling COP and heating COP are calculated 0.400 and 0.161, respectively, at the generator temperature of 70℃. When heat is recycled in the high temperature evaporator, i.e., when the refrigerant passing through the high temperature evaporator is heated to 50℃, it always shows a higher performance and the maximum heating COP with superheat($COP_{heating\ s-heat}$) is calculated 0.196 which is 0.035 higher than the heating COP without superheat because the heat recycled in the high temperature evaporator is directly used to increase the heat capacity in the high temperature absorber. Maximum system COP without superheat consideration(COP_{sys}) is calculated 0.561 and COP with superheat consideration ($COP_{sys\ s-heat}$) is calculated 0.596 at the temperature of 70℃. When the generator temperature increases 4℃ from 66℃, cooling COP, heating COP, and heating COP with superheat increase 17.4%, 197.9%, and 134.0%, respectively. From this result, the heating COPs are more sensitive to the generator temperature than the cooling COP because as the generator temperature increases, the amount of heat delivered to the high temperature absorber by solution increases.

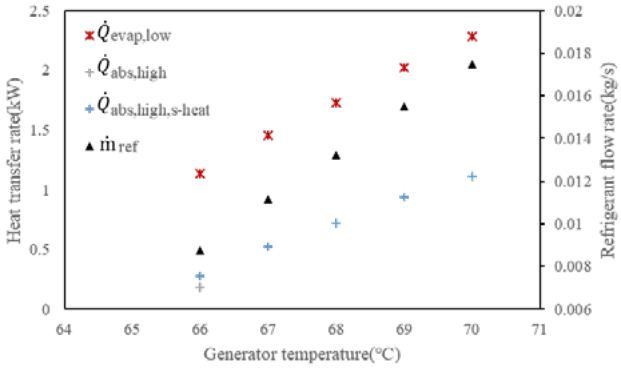

Figure 3. Effect of generator temperature on heat transfer rate and refrigerant generation

Figure 3 shows the heat transfer rate and refrigerant mass flow rate according to the generator temperature. As the generator temperature increases, the total generated refrigerant flow rate($\dot{m}_{ref}$) and heat transfer rate in low temperature evaporator and high temperature absorber increase. Maximum heat transfer rate of low temperature evaporator ($\dot{Q}_{evap,low}$), high temperature absorber ($\dot{Q}_{evap,low}$) without superheat and high temperature absorber with superheat($\dot{Q}_{abs,high,s-heat}$) are calculated 2.280kW, 0.9157kW and 1.114kW, respectively. Maximum generated refrigerant flow rate is calculated 0.0175kg/s. When the generator temperature increases from 66(℃) to 70(℃), the generator refrigerant flow rate increases 100.2% at the temperature of 70(℃). It is found that the heat transfer rates are improved, as the generator temperature increases, which makes refrigerant flow rate increase. The results for each state point are summarized in Table 3.

Table 3 Results for the state points of the cycle($T_e = 5℃, T_c = 30℃$)

[17]	30.0	1928.0	255.3	0.008743		0.000
[18]	5.0	951.5	255.3	0.008743		0.151
[19]	5.0	951.5	516.1	0.008743		1.000

4. Conclusions

The performance of the type 1 and type 2 combined sorption heat pump using the waste heat from the low temperature heat sources according to the change of generator outlet concentration and the split ratio at the

generator is analyzed. The working fluid pair is selected for the sorption heat pump using an alternative refrigerant R32 as refrigerant and organic liquid DMAC as absorbent. The following conclusions are drawn from the present study.

1. Between the generator temperature of 66℃ and 70℃, the maximum cooling COP, maximum heating COPs with and without superheat are calculated 0.400, 0.196, and 0.161, respectively when the generator temperature is 70℃. Heating COP is more sensitive to the generator temperature because as the temperature of the generator increases, heat supplied to the refrigerant of the high temperature absorber increases.

2. Heat transfer rate at the low temperature evaporator and high temperature absorber increases as the generator temperature increases because as the generator temperature increases, refrigerant flow rate increases due to the P-T-X equilibrium. Maximum heat transfer rates of low temperature evaporator, high temperature absorbers without and with superheat are calculated 2.280kW, 0.9157kW and 1.114kW, respectively.

Abstract

With growing demands of indoor air quality and thermal comfort, dedicated outdoor air system with dehumidification function is becoming more popular for residential use. However, due to limited air volume of outdoor air, dedicated outdoor air system often needs to supply air at very low humidity ratio for dehumidification, which decreases the system energy efficiency. In this work, by combining dedicated outdoor air system and small air-cooled chiller, a heat pump system for cooling, heating, dehumidification and outdoor air supply is proposed. In the system, a high temperature water coil is applied to precool the outdoor air for decreasing the energy consumption of dehumidification. Besides, dehumidification capacity of outdoor air system with precooling is enough to handle overall latent load. In the meantime, without the demand of dehumidification, the water supplying temperature of chiller can rise to 15°C or above, which is not only beneficial to energy efficiency improvement, but also available for dry terminal. Modeling results of the system indicate that the annual power consumption of the new system can be reduced by 16.9% relative to the combined operation of a dedicated outdoor air system and an individual small chiller.

1. Introduction

Since people pay more attention to indoor air quality today, residential dedicated outdoor air system (DOAS) become more popular in the market, and different types of DOAS have been widely researched, too. The basic type of DOAS is just in charge of fresh air supplying and purification. But considering energy saving and indoor thermal comfort, now DOAS usually has an additional dehumidification unit and can deal with partial or overall latent load.

For dehumidification DOAS, desiccant dehumidification and mechanical dehumidification are the two main approaches[1]. Desiccant dehumidification method transfers water from air to solid or liquid desiccant by adsorption or absorption process. It usually has better dehumidification efficiency, but it also has the problem of high cost, large volume and regeneration[2]. On the contrary, mechanical dehumidification method, which has relative lower dehumidification efficiency but lower cost and small volume, is more popular in residential DOAS market. Up to now, most of improved DOAS types were developed for better performance. Mumma et al. developed a novel DOAS to reduce humidification and reheating load, including a preheat coil, an enthalpy wheel, a deep cooling coil and a sensible heat exchanger[3]. Zhang et al. proposed a novel DOAS with total heat exchanger[4, 5]. Li et al. proposed a novel DOAS with multi-stage direct expansion coil and zero-energy heat pipe[6]. This system could reduce about 15.6% annual energy consumption according to the simulation results. Zhang et al. designed a frost-free exhaust air heat recovery DOAS[7]. Zhang et al. proposed a novel DOAS with two-stage direct-expansion dehumidification, subcooled reheating, and exhaust air heat recovery[8]. Coefficient of performance (COP) of this novel DOAS can reach 5.42 and 26% higher than the conventional one.

With the development of DOAS technology itself, the issue about how DOAS help air conditioning system save energy is also drawing much attention. A conventional solution is DOAS with the sensible heat load handling device. In this solution, a dehumidification DOAS deals with overall latent load, and the indoor terminal only deal with partial sensible load. This solution is a way to achieve temperature and humidity independent control, which can improve indoor thermal comfort effectively. Mumma et al. has shown that the combination of DOAS and radiant cooling system can reduce about 29% energy consumption compared to conventional variable air volume systems[9]. Saber et al. evaluated the performance of a decentralized DOAS with a radiant cooling system in the tropical climate[10]. Yin et al. analyze the energy saving potential of DOAS with radiant cooling system under different climate conditions in China[11]. Zhang et al. discussed the adaptability of the combined system with DOAS and radiant cooling panels in summer moist heat regions[12]. Li et al. developed a radiant air conditioning system with outdoor air dehumidifier for temperature and humidity independent control, and tested the performance of this system under variable operating conditions[13]. Lim et al. compared the performance of DOAS with thermoelectric module radiant cooling panel or hydraulic ceiling radiant cooling panels via a detailed energy simulation[14]. However, although the COP of chiller in this combination solution can be improved due to the high temperature of chilled water, COP of dehumidification DOAS in such solution is still relatively low. COP of the common mechanical dehumidification DOAS in the market is at most 3.5[6]. Due to the limited air volume of outdoor air, dehumidification DOAS often needs to supply air with very low humidity ratio and low temperature, which lead to low evaporating temperature and increase the energy consumption for dehumidification. Therefore, a higher efficiency solution for dehumidification DOAS is still needed to be explored.

In this work, we proposed a novel multi-function residential heat pump system, which included chiller subsystem and outdoor air subsystem. In the system, a high temperature water coil is applied to precool the outdoor air for decreasing the energy consumption of dehumidification. With an ingenious iterative design of two subsystems, the new system can achieve better performance than direct combination of chiller and DOAS. This paper is composed of five sections. Section 2 gives a system description of this new system. Section 3 presents a system model of the new system for performance analysis, and introduces the method of system modeling. Section 4 discusses the performance of new system under variable operating conditions, according to the simulation results. And section 5 gives some brief conclusions of this work.

2. System description

The new system is an integration of conventional chiller system and DOAS. Fig. 1 is the schematic of new system. It has 2 subsystems: chiller subsystems and outdoor air subsystem (OA subsystem), and the two subsystems are connected with each other by water pipes.

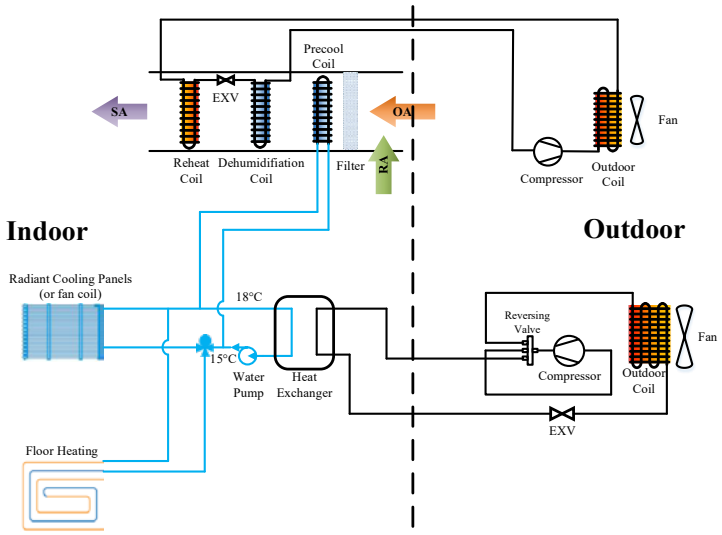

Fig. 1. Schematic of the new system

The chiller subsystem(below) is similar to a conventional residential chiller system. The difference is that water temperature of chilled water is 15°C in cooling season. And types of terminals are radiant cooling panels or dry fan coil. High temperature chilled water means better performance and less energy consumption of the chiller subsystem. But the chiller subsystem only deals with sensible load due to high temperature of chilled water.

The OA subsystem deal with the overall latent load and part of sensible load of rooms in cooling season. In order to increase the air volume, return air is mixed with outdoor air. Then the mixed air flow through three coils: precool coil, dehumidification coil and reheat coil. Precool coil is a water-air coil and water are from chiller subsystem. Dehumidification coil and reheat coil belong to a dedicated refrigeration cycle, driven by a dedicated compressor and an outdoor coil of OA subsystem. The mixed air is cooled, dehumidified and reheated by these three coils and sent to indoor finally.

In terms of the control strategy, temperature and humidity independent control is an important control target of this system. Therefore, compressors in both chiller subsystem and OA subsystem are variable speed compressor. The desired indoor dry bulb temperature is controlled by compressor of chiller subsystem, and the desired absolute humidity of supply air (SA) is controlled by compressor of OA subsystem. The suction superheat of these two refrigeration cycles is controlled by the EXV in respective cycle.

In heat pump mode, the dedicated refrigeration cycle of OA subsystem is turned off, and the precool coil change to preheat coil. To avoid unnecessary energy waste of mixing process, the RA inlet is turned off by an air valve in heat pump mode. Since there is no latent load in heating season, the overall load of OA subsystem is less than in cooling season. Therefore, the heating capacity of preheat coil is enough to heat the outdoor air to about 42°C.

There are three main advantages of this new system:

1) High chilled water temperature of chiller. Performance of chiller and thermal comfort of terminals are improved.
2) Outdoor air precooled by chilled water from chiller. Precooling process can reduce the cooling load of the dedicated refrigeration cycle, which means less energy consumption, smaller compressor and smaller outdoor unit of OA subsystem.
3) In heat pump mode, outdoor air can be effectively heated without dedicated heat pump cycle for OA subsystem.

3. System modeling

In order to analyze the performance of new system, a simulation model is developed using GREATLAB[15, 16]. GREATLAB is a general simulation software of refrigeration and air-conditioning system. The main methods of component and system simulation are briefly introduced below. More details about this model could be found in the references[15, 16].

Fin-tube coil is the main type of heat exchangers in this system. A tube-in-tube incremental model, which can account refrigerant and air distribution of the coil, is applied for fin-tube coil modeling. This model includes four levels: element level, tube level, circuit level and heat exchanger level. And the model is solved from inside to outside. First the equations at element level are solved. Then every tube is calculated by results at element level, and every circuit is calculated by results at tube level. Finally, all circuits are calculated and the mass flow rate is adjusted to balance pressure drop between circuits.

The equations at element level are as follows.

Refrigerant energy equation.

$$Q_{\mathrm{r}} = m_{\mathrm{r,in}} \left(h_{\mathrm{r,in}} - h_{\mathrm{r,out}} \right) \tag{1}$$

Refrigerant mass conservation equation:

$$m_{\mathrm{r,in}} = m_{\mathrm{r,out}} \tag{2}$$

Refrigerant momentum equation.

$$p_{\mathrm{r,in}} - p_{\mathrm{r,out}} = G^2 \left(v_{\mathrm{r,out}} - v_{\mathrm{r,in}} \right) + f \frac{G^2 v_{\mathrm{m}}}{2D} \tag{3}$$

Air energy equation.

$$Q_{\mathrm{a}} = m_{\mathrm{a}} \left(h_{\mathrm{a,in}} - h_{\mathrm{a,out}} \right) \tag{4}$$

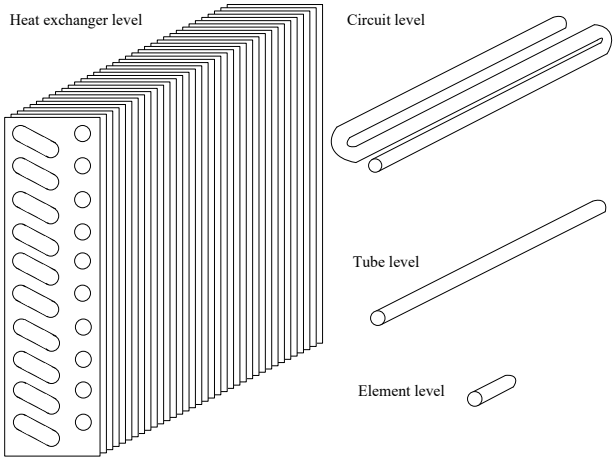

Fig. 2. Structure of the finned-tube heat exchanger model.

Where,

$$Q_{\mathrm{a,sens}} = \frac{A_{\mathrm{s}}}{1/\left(k_{\mathrm{a}}\eta_{\mathrm{s}}\right)+\left(R_{\mathrm{m}}+R_{\mathrm{fr}}\right)+\left(A_{\mathrm{s}}/A_{\mathrm{r}}\right)/k_{\mathrm{a}}}\left(T_{\mathrm{a}}-T_{\mathrm{r}}\right) \tag{5}$$

$$Q_{\mathrm{a,latent}} = m_{\mathrm{a,d}}\left(W_{\mathrm{a,in}}-W_{\mathrm{a,out}}\right)h_{\mathrm{latent}} \tag{6}$$

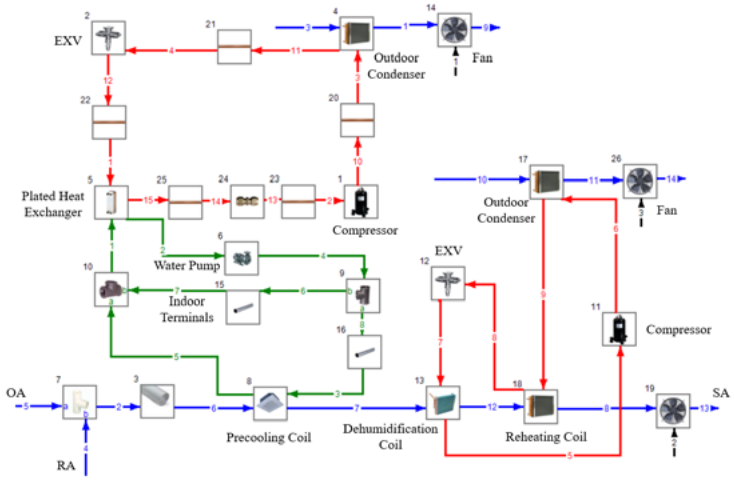

Fig. 3. System model of the new system in GREATLAB (cooling season).

Since the two compressors in this system are both variable-speed compressor, a multi-variable polynomial model[15] is applied for compressor simulation.

$$y = c_1 + c_2 T_e + c_3 T_c + c_4 f_r + c_5 T_e^2 + c_6 T_c^2 + c_7 f_r^2 + c_8 T_e T_c + c_9 T_e f_r + c_{10} T_c f_r + c_{11} T_e^2 f_r + c_{12} T_e f_r^2 + c_{13} T_c^2 f_r + c_{14} T_c f_r^2 + c_{15} T_e T_c f_r \quad (9)$$

where y can represent mass flow rate or power consumption of compressor. T_e and T_c represent evaporating temperature and condensing temperature, respectively. f_r represents compressor frequency. Coefficients c_1-c_{10} are curve-fitted according to compressor manufacturer's data.

Performance of expansion valves and fans are calculated according to the performance curves from manufacturers.

Based on all these component models, simulation model of the new system can be set up in GREATLAB, as shown in Fig. 3. System solver of this model is based on the Newton-Raphson algorithm. All fluid properties are calculated by REFPROP 9.0[22]. With the simulation model, we can analyze the performance of the new system under variable operating conditions. And the advantages of this new system will be discussed in detail in the next section.

4. System performance analysis and discussions

In this section, performance of the new system is numerically analyzed under different operating conditions. Firstly, a suitable baseline and some typical operating conditions are chosen in subsection 4.1. Then, an annual performance factor method is developed to analyze the annual performance of the new system in subsection 4.2. Finally, the results are presented and discussed in subsection 4.3.

4.1. Baseline and typical operating conditions.

To analyze performance of the new system, a comparison between the new system and conventional residential air-conditioning solution is necessary. In this study, a combination of chiller system and basic DOAS is chosen as the baseline of comparison and analysis. Schematic of baseline system is shown in Fig. 4.

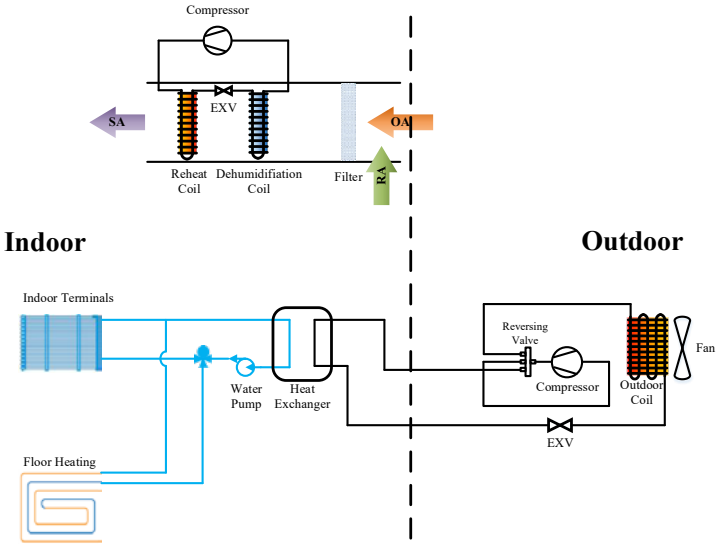

Fig. 4. Schematic of baseline system.

The chiller in both baseline system and improved new system is a practical chiller prototype, which has about 15kW design cooling capacity and is designed for about 150m^2 room. Some important design information of this chiller is shown in **오류! 참조 원본을 찾을 수 없습니다.**. And following the modeling method introduced in section 2, the simulation model of chiller was set up and well validated by experimental data. The comparison of some key performance parameters between simulation data and experimental data is presented in **오류! 참조 원본을 찾을 수 없습니다.**.

Table 2 Specifications of chiller

Name	Specification	Name	Specification
Refrigerant	R410A	Condenser	Fin-tube coil, 2 rows, 108 tubes, Tube length: 1000mm.
Design Cooling Capacity	15kW	Evaporator	Plated heat exchanger
Compressor	Rotary, variable-speed	Fan	Double axial fans, variable speed
Expansion device	EXV		

Table 3 Validation of chiller simulation model

Operating conditions	Cooling(heating) capacity/kW			Power/kW			Mass flow rate (water)/L·s^{-1}		
	Simulation	Test	Error	Simulation	Test	Error	Simulation	Test	Error
Cooling 100% load	15.11	14.93	**1.2%**	5.21	5.20	**0.2%**	0.69	0.68	**1.5%**
Cooling 75% load	11.20	11.29	**0.8%**	3.02	2.90	**4.1%**	0.68	0.68	**0.3%**
Cooling 50% load	8.02	7.58	**5.7%**	1.88	1.89	**0.5%**	0.71	0.68	**4.4%**
Cooling 25% load	5.52	5.29	**4.2%**	1.25	1.19	**5.0%**	0.70	0.68	**2.9%**
Heating 100% load	17.12	17.68	**3.2%**	5.84	5.80	**0.7%**	0.69	0.70	**1.4%**

The DOAS in baseline system is also a typical type of residential DOAS, prototype of this DOAS is shown in Fig. 5. The key design information of this DOAS is shown in Fig. 6. In this study, considering the demand of fresh air supplying and dehumidification for about 150m^2 room, one chiller needs to match 3 DOAS in the baseline system.

Table 4 Specification of DOAS

Name	Specification	Name	Specification
Refrigerant	R407C	Evaporator	Fin-tube coil, 4 rows, 36 tubes, Tube length: 420mm.
Design Dehumidification Capacity	26L/Day	Condenser	Fin-tube coil, 4 rows, 36 tubes, Tube length: 420mm.
Rotary	Rotary, constant speed	Fan	Single centrifugal fans, constant speed
Expansion device	Capillary tube		

As a multi-function heat pump system, it is necessary to analyze its system performance under variable operating conditions in cooling season, heating season and transitional season. Therefore, a variable operating conditions analysis is necessary for the new system. In this section, some typical operating conditions are chosen according to the typical meteorological year (TMY) data of Shanghai, as shown in Fig. 6. The TMY data are from DeST[23].

Fig. 6 shows the chosen 7 typical cooling operating conditions and 4 typical heating operating conditions. Point A is the rated cooling operating conditions (T_{DB}=35°C, T_{WB}=28°C). Point B and C are two 40°C+ extreme cooling operating conditions. Point D-F are three low temperature cooling operating conditions. Point G represents dehumidification operating conditions in transitional season. Point H-J are three different heating operating conditions. And point K represents heating operating conditions in transitional season.

Fig. 5. Photo of DOAS in baseline system.

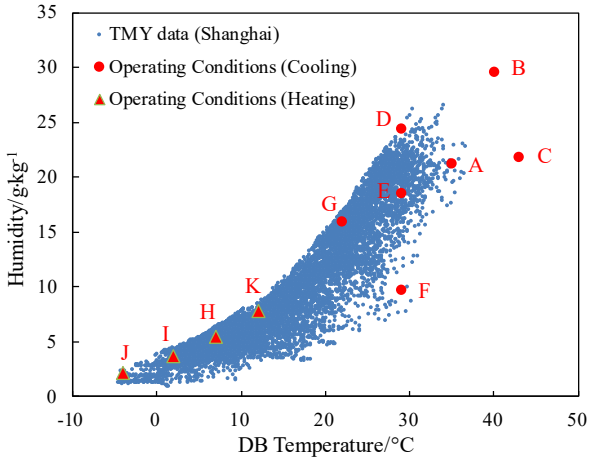

Fig. 6. Typical operating conditions in Shanghai.

4.2. Annual performance factor analysis

For further analysis, the annual performance factor (APF) of the new system is applied. In this study, APF is defined as:

$$\mathrm{APF} = \frac{Q_c + Q_h}{W_c + W_h} \tag{10}$$

where Q_c represents the total cooling capacity in cooling season and Q_h represents the total heating capacity in heating season. W_c and W_h represent the total power consumption in cooling season and heating season respectively.

APF is also calculated with TMY data of Shanghai, which is a typical region with hot moist summer and cold winter. In this work, APF is calculated as follows. Firstly, cooling season and heating season is divided into several temperature zones. The temperature and humidity interval of each zone is 1°C and 1g/kg respectively. Secondly the annual occurred time of each temperature zone is counted according to the TMY data. Then the energy consumption and cooling or heating capacity of system is calculated in every temperature zone, based on the simulation model. Finally, APF can be calculated in terms of the statistics of total energy consumption and total cooling or heating capacity within a year.

4.3. Results and discussions.

Based on the simulation model, performance of baseline system and the improved new system is calculated and compared with each other under variable operating conditions. The results in cooling season are shown in **오류! 참조 원본을 찾을 수 없습니다.**. Under rated operating conditions (A), COP of the new system is 3.94 and 46.5% higher than baseline system. Under the operating conditions B-F, the new system has about 23.7%-45% COP improvement compared to baseline system. Under the operating conditions G, which is a typical dehumidification operating conditions in transitional season, the new system has about 96.2% COP improvement compared to the baseline system. These results indicate better performance of the new system over the common combination of chiller and DOAS, especially under the operating conditions with large latent load.

Table 5 Performance comparison in cooling season

Operating Conditions	Outdoor Temperature (DB/WB)	Cooling Capacity /W	Latent Cooling Capacity /W	COP (Baseline)	COP (New System)	COP Improvement
A	35°C/28°C	14772	2275	2.69	3.94	**46.5%**
B	43°C/30°C	22162	2324	2.04	2.56	**25.5%**
C	40°C/33°C	20738	3654	2.15	3.01	**40.0%**
D	29°C/19°C	7525	522	3.76	4.65	**23.7%**
E	29°C/25°C	8799	1824	3.80	4.78	**25.8%**
F	29°C/28°C	9823	2848	3.31	4.80	**45.0%**
G	22°C/21°C	1898	1388	2.66	5.22	**96.2%**

Table 6 Contribution of different aspects to system performance improvement

System	Operating Conditions A		Operating Conditions F	
	COP	COP Improvement	COP	COP Improvement
Baseline	2.69	-	3.31	-
+ Outdoor Unit of DOAS	3.46	**28.6%**	3.81	**15.1%**
+ Precool coil	3.94	**46.5%**	4.80	**45.0%**

Performance improvement for the new system is mainly from two aspects: precooling process and heat rejecting to outdoor ambient. **오류! 참조 원본을 찾을 수 없습니다.** shows the contribution of different technology under operating conditions A and F. Both two aspects are important to the overall system performance improvement, and these two feature technology have different performance effect under different operating conditions. Under operating conditions A (T_{DB}=35°C, T_{WB}=28°C), adding outdoor unit of DOAS can bring 28.6% COP improvement, and adding precool coil can further increase COP improvement to 46.5%. But under operating conditions F (T_{DB}=29°C, T_{WB}=28°C), which is a low temperature dehumidification operating conditions, COP improvement from outdoor unit of DOAS is merely 15.1% while the overall COP improvement is nearly same to operating conditions A. The results indicate that precooling process is more effective for dehumidification operating conditions while heat rejecting is more important for those operating conditions with high cooling load.

Fig. 7 shows the detailed dehumidification process in OA subsystem under rated operating conditions according to the simulation results. It shows why the precool coil can reduce energy consumption of dehumidification. The precool coil, which handles about half cooling capacity, works with high temperature chilled water. Namely, half of cooling load for dehumidification process can be taken away in a more efficient way. And with this stepped cooling and dehumidification process, the uniformity of temperature difference in the whole duct is improved. Therefore, the overall COP of this system is higher than a conventional combined solution. Moreover, due to the cooling load of the dedicated cycle in OA subsystem is less than conventional DOAS, a smaller outdoor unit can be applied in OA subsystem of this multi-function system.

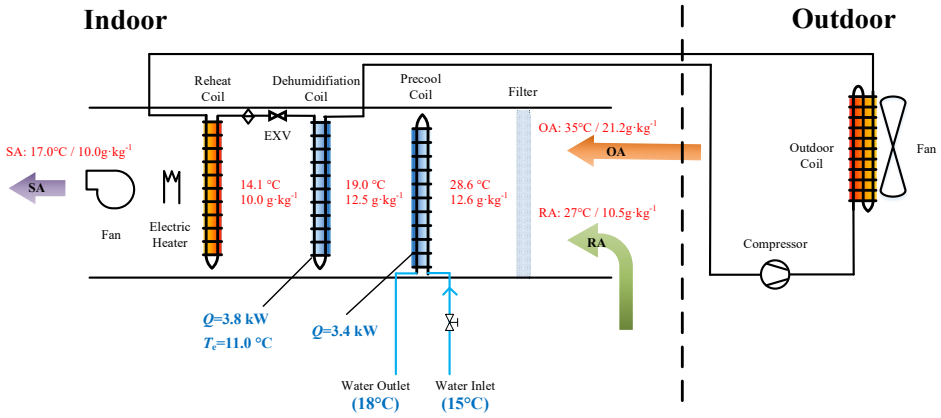

Fig. 7. Detailed schematic of dehumidification process in OA subsystem

The results in heating season are shown in 오류! 참조 원본을 찾을 수 없습니다.. In heat pump mode, compressor of OA subsystem is turned off in both baseline system and the new system. Since the improvement of the new system is mainly for cooling and dehumidification process, COP of the new system has little improvement compared to baseline system.

Fig. 8 shows the supply air temperature of OA subsystem under different heating operating conditions. This system can effectively heat outdoor air without dedicated heat pump cycle for OA subsystem. And the supply air temperature of OA subsystem can keep steadily under different operating conditions. In heat pump mode, the compressor of dedicated cycle in OA subsystem is turned off, only the water coil still works in OA subsystem. Even so, with the 45°C hot water supplied from chiller, the outdoor air can also be stably heated to about 42°C without mixing return air. And the indoor thermal comfort can be easily ensured under different operating conditions in winter.

Table 7 Performance comparison in heating season

Operating Conditions	Outdoor Temperature (DB/WB)	COP (Baseline)	COP (New System)	COP Improvement
H	7°C/6°C	2.82	2.76	**-2.1%**
I	2°C/1°C	2.06	2.06	**0.0%**
J	-4°C/-5°C	1.87	1.85	**-0.1%**
K	12°C/11°C	3.21	3.15	**-1.9%**

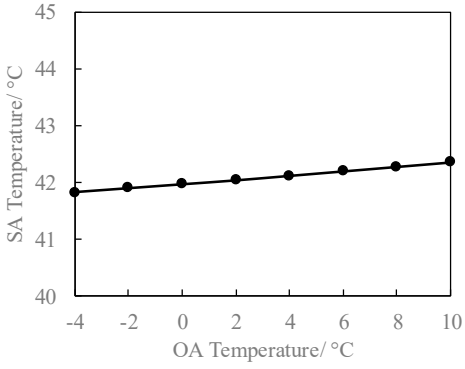

Fig. 8. Supply air temperature under different operating conditions in heating season

Table 8 APF of different system

Baseline	New System	APF Improvement
2.84	3.32	**16.9%**

Results of APF analysis are shown in **오류! 참조 원본을 찾을 수 없습니다.**. According to the simulation results, APF of the new system is 3.32 and 16.9% higher than baseline under the meteorological conditions of Shanghai. The results indicate that the new system has better performance and can reduce considerable energy consumption in annual operation especially in hot moist summer and cold winter region.

5. Conclusions

In this study, a novel multi-function residential heat pump system for cooling, heating, dehumidification and outdoor air supply is proposed. This system is composed by two subsystems: chiller subsystem and OA subsystem. In cooling season, the chiller subsystem only deals with sensible load and supply 15°C high temperature chilled water to sensible heat terminals. The OA subsystem has a dedicated refrigeration cycle and deals with overall latent load and partial sensible load. In order to decreasing the energy consumption of dehumidification and improve the performance of dehumidification, a precool water coil is added to precool outdoor air by high temperature chilled water. In heat pump mode, the outdoor air can be heated to over 40°C only by the water coil in OA subsystem.

A simulation model is developed and performance of this system is numerically analyzed based on modeling results. The overall COP of the new system can reach 3.94 under rated operating conditions, which is 46.5% higher than a conventional residential air-conditioning solution. And in terms of annual performance, APF of the new system is 3.32 and 16.9% higher than the conventional solution, under the meteorological conditions of Shanghai. Since the structure of this new system is complex and interactive, performance analysis in this work mainly focuses on the overall performance of whole system. In order to research the specific sources of energy conservation in this system, some other suitable analysis methods, such as uniformity analysis or second law analysis, are still worth to be applied for further analysis in future works.

Study on layer short mechanism and discharge pattern in refrigerant compressor for refrigerants with disproportionation reaction like HFO-1123

Mitsuhiro Fukuta[a,*], Hideyuki Fujimoto[b], Masaaki Motozawa[a]

[a]Shizuoka university, 3-5-1 Johoku, Naka-ku, Hamamatsu, 432-8561, Japan
[b]Shizuoka university, Graduate school of Integrated Science and Technology, 3-5-1 Johoku, Naka-ku, Hamamatsu, 432-8561, Japan

Abstract

HFO-1123, one of the low GWP refrigerants, will be decomposed with receiving large amounts of energy under high temperature and pressure condition. Short-circuit between motor winding wires caused by an insulation breakdown, i.e. layer short, in refrigerant compressors could be a trigger of the disproportionation reaction of HFO-1123.

In this study, the layer short mechanism and the electric energy discharged by the layer short of winding wire in the refrigerant compressor were investigated. A compressor equipped with a short-circuit generation mechanism in a compressor shell was used to measure the electric energy by the layer short during the compressor operation. Experiments were carried out mainly with the short-circuit between both ends of a main-winding as the worst case. There were several short-circuit patterns and the maximum current was observed to be 700 - 900 A and the electric energy was about 160 J. When the short-circuit occurred between terminals of the main-winding and an auxiliary-winding, the motor stopped while the electricity was continuously supplied, and temperature of the winding wire increased approximately 2.5℃/s.

Keywords: HFO1123, Disproportionation reaction, Compressor, Motor, Layer short, Electric energy

1. Introduction

From the viewpoint of preventing the global warming, the Kigali amendment to the Montreal protocol entered into force to phase-down the production and consumption of HFCs, and the use of the low GWP refrigerant is eagerly desired. HFO refrigerants have the low GWP, and application of the HFOs has been investigated in recent years. HFO-1123 is one of the low GWP refrigerants whose GWP is less than one and a mixture of HFO-1123 is considered as an alternative of R410A and R32. Although the GWP of the HFO-based mixed refrigerant can be reduced by increasing the mixing ratio of HFO-1123, a disproportionation reaction of HFO-1123 may occur when HFO-1123 gets high ignition energy under pressurized condition in refrigerant compressors [1,2]. If the disproportionation reaction occurs in the refrigerant compressor, the temperature and pressure in the compressor will rise steeply, and the refrigerant compressor might be destroyed. Since short-circuit between motor winding wires caused by an insulation breakdown, i.e. layer short, in the refrigerant compressors could be a trigger of the disproportionation reaction of HFO-1123, layer short mechanism and an electric energy caused by the layer short should be clarified [3].

In this study, the layer short mechanism and the electric energy discharged by the layer short of winding wire in the refrigerant compressor were investigated. A compressor equipped with a short-circuit generation mechanism in a compressor shell was used to measure the electric energy by the layer short during the compressor operation. The short-circuit between any two lead wires of the motor could be produced in the compressor with the short-circuit mechanism. As the first step of the study, experiments were carried out mainly with the short-circuit between both ends of a main-winding as the worst case. Current, voltage and

electric power when the short-circuit occurred were measured.

2. Experiment

Figure 1 shows a schematic diagram of the compressor for generating a layer short in the refrigerant compressor. A compression mechanism and a motor were assembled into a shell having a large space above the motor element. The short-circuit generation mechanism (Fig.1, right) was mounted at the upper space in the shell, and it could generate the short-circuit with two enamel wires in the motor winding by operating an external screw head during compressor operation. In addition, a glass window was installed on the shell, and the short-circuit generation could be observed from the outside.

Figure 2 shows a schematic diagram of the refrigeration cycle with the compressor shown in Fig.1.The refrigeration cycle was a gas cycle consisting of the compressor, a radiator, an expansion valve. The pressure condition was adjusted with the throttle valve and charge amount of refrigerant controlled using a small refrigerant cylinder connected to the cycle. The suction pressure and the discharge pressure were measured by Bourdon tube gauges. The temperature was measured by T-type thermocouple at suction and discharge pipe of the compressor, and before and after the throttle valve. Beside those, the temperature of stator windings inside the compressor were measured by the thermocouples at two points. The refrigerant used was R410A instead of HFO-1123 because of safety, and the oil used was PVE (VG68).

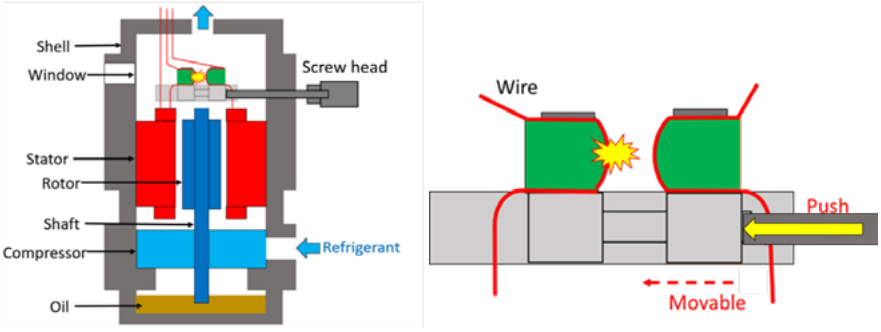

Fig. 1. Compressor for short-circuit experiment

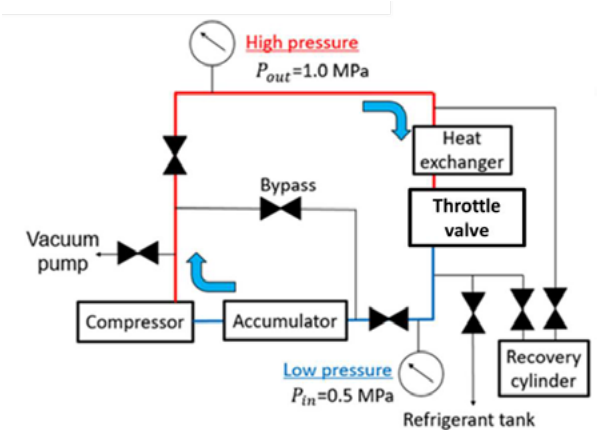

Fig. 2. Experimental gas cycle

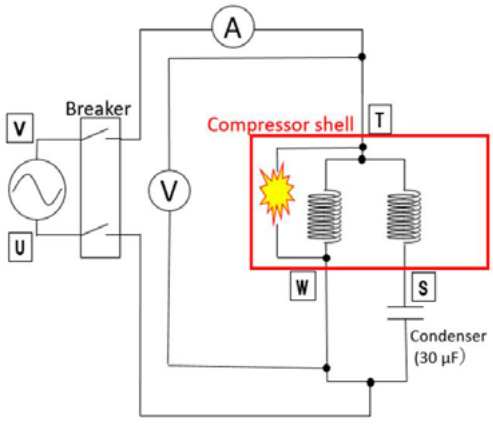

Fig. 3. Electric circuit (W-T short)

Figure 3 shows the motor driving circuit diagram. The motor was a 200 V single-phase permanent split type induction motor (rated output power is 750 W, outer diameter of motor stator is 112 mm, diameter of winding is 0.8 mm, resistance of winding is 35 Ω/km). A red square in Fig. 3 is the compressor shell and coils in the shell are the main-winding and the auxiliary-winding of the motor, respectively.

A breaker rated at 20 A was installed between the power source and the compressor. Over Load Protector (OLP) was not used at this time. Symbols W, T, and S represent the terminals of a glass terminal connected to the motor in the compressor. The short-circuit between W and T (W-T short) in the compressor shell is shown in Fig. 3. Enameled wires whose enamel coating was partially removed were inserted to lead wires of W and T, and these enameled wires were set at the layer short-circuit mechanism. When the short-circuit was produced, the voltage between the short-circuited terminals and the current flowing through the short-circuited enameled wire were measured using a high-voltage differential probe and a Rogowski coil, respectively. In addition to the W-T short, the short-circuit between W and S (W-S short) was conducted in this study.

After turning on the compressor, when the suction pressure and the discharge pressure reached 0.5 MPa (g) and 1.0 MPa (g), respectively, and became steady state, the short-circuit between two wires set at the short-circuit generation mechanism was yielded intentionally. The instantaneous electric power was calculated by the production of the current and the voltage. The electric energy due to the short-circuit was obtained by integrating the electric power with the time during which a large current was generated (short-circuit time). In addition, a high-speed camera was used to observe the sparks that occurred by the short-circuit generation.

3. Experimental result

3.1. Short-circuit at both ends of main-winding (W-T short)

The W-T short is shot-circuit between the both ends of the main-winding. Since it is equivalent to the short-circuit of the power source, this short-circuit is considered as the worst case discharging the maximum electric energy. When the W-T short occurred, a big spark rose, and the breaker was activated at that moment. Figure 4 shows the spark taken by the high-speed camera. The enamelled wire at the contact point after the short-circuit was fused as shown in Fig. 5 or welded. Figure 6 shows changes in current, voltage, and electric power against the time when the W-T short occurs. The zero point of the time on the horizontal axis is the time when the short-circuit occurred. Until the short- circuit occurred, the voltage waveform shows a sinusoidal one with an amplitude of 283 V. Although the current before the short-circuit is difficult to read from the figure because the full scale for the current is very large, it shows a sinusoidal wave with an amplitude of about 4 A. When the short-circuit occurred, the voltage between the W-T dropped to 0 V, and an instantaneous large current (maximum value of 784 A) flowed. The short-circuit time was 6 ms, and the electric energy due to the W-T short was 219 J.

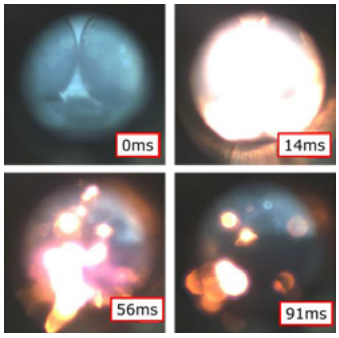

Fig. 4. Observation of the W-T short

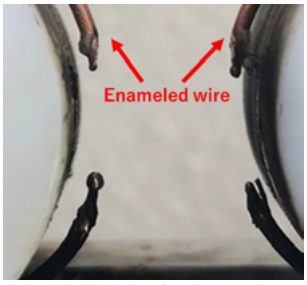

Fig. 5. Winding wire after the W-T short

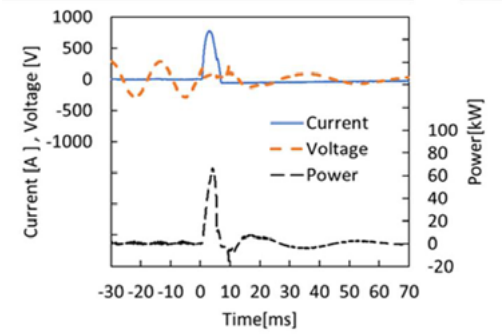

Fig. 6. Current, voltage, power (W-T short No.1)

Figure 7 shows another result when the W-T short generated under the same condition. As can be seen in Fig.7, once the voltage dropped to 0 V by the short-circuit, then increased and became 0 again. The instantaneous large current due to the short-circuit shows two peaks according to the voltage change. The short-circuit time was 6 ms in total for the two peaks. Electric energy generated was 168 J. In the case shown in Fig. 7, the two peaks were explained as that when the short-circuit occurred, only the contact part of the two enamel wires melted, the circuit temporarily recovered from the short-circuit to the normal state, and then the short-circuit occurred again.

In order to compare the results with the W-T short generated inside the compressor, W and T terminals were short-circuited at the outside of the compressor shell. No significant differences were observed in the current and voltage waveforms between them. Results for the W-T short generated both inside and outside of the compressor are summarized in Fig. 8 against phase angle θ of the voltage at the instant of the short-circuit generation.

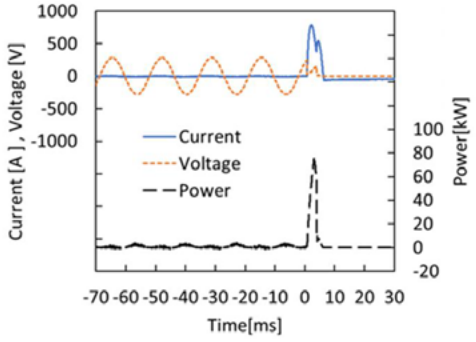

Fig. 7. Current, voltage, power (W-T short No.2)

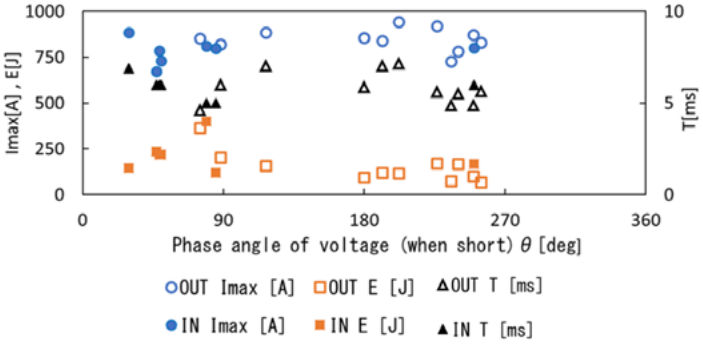

Fig. 8. Maximum current, short circuit time, and electric energy

The vertical axes of Fig. 8 represent the maximum current I_{max}, the electric energy E, and short-circuit time T. IN and OUT in Fig. 8 express the position where inside or outside of the compressor the short-circuit was generated. There was no significant influence of the voltage phase angle on the peak current, the electric energy, and short-circuit time. It can also be seen that the short-circuit often occurred at the range of phase angle 0-90°and 180 - 270°.The peak current was about 850 A, the electric energy was about 160 J, and the short-circuit time was about 7 ms. Since there was no difference between the short-circuit generated the inside and the outside of the compressor, the electric energy caused by the W-T short can be evaluated by the short-circuit between the W and T terminals outside the compressor. However, the layer short of the motor windings in the compressor accompanied by electric discharge should be examined in the compressor shell under the refrigerant atmosphere since the electric discharge is strongly affected by the refrigerant pressure [4], and an insulation of enamel deteriorates by high temperature [5].

3.2. Short-circuit between ends of the main-winding and auxiliary-winding (W-S short)

The W-S short is a short-circuit across the capacitor and makes the electric circuit of the motor into parallel two coils. When the W-S short occurred, the rotation of the motor stopped while the electricity was continuously supplied, and the motor temperature started to increase. Figure 9 shows the changes in the temperature of two positions of the upper coil end and the discharge pipe temperature when the W-S short occurred. When the motor temperature reached 150°C, the power was intentionally turned off to protect the motor. The temperature of Coil end (1) increased at 2.5°C/s after the short-circuit. If the temperature of the winding wire becomes so high that the enamel wire coating will deteriorate, the layer short may happen. This kind of risk is expected to be prevented by applying an over load protector in a power supply circuit.

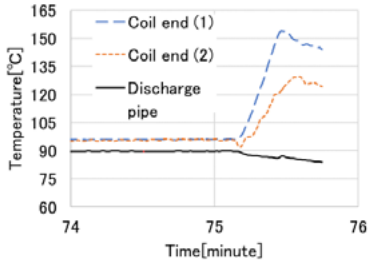

Fig. 9. Temperature change when the W-S short occurs

4. Future works

The following issues will be done to clarify the layer short mechanism and the discharge energy by the short-circuit in compressors.

1. Current and voltage measurement during the temperature rise by the W-S short
2. Investigation of the effect of over load protector
3. Short-circuit between both ends of auxiliary winding (T-S short)
4. Current, voltage and energy measurement in the case that the discharge occurs between wires with a certain minute gap.
5. Examination of degradation of enamelled wire due to short-circuit which occurs locally in the motor windings

5. Conclusion

Electric energy discharged by the short-circuit of winding wire in refrigerant compressors was investigated with a compressor equipped with a short-circuit generation mechanism in a compressor shell. The short-circuit between both ends of a main-winding (W-T short) was considered as the worst case. The maximum current was observed to be 700 - 900 A for about 7 ms, and the electric energy was about 160 J. When the short-circuit between both ends of a capacitor (W-S short), the motor stopped while the electricity was continuously supplied, and temperature of the winding wire increased approximately 2.5℃/s. Further study is needed to clarify the layer short mechanism in the refrigerant compressors.

Abstract

Aiming to save primary energy, reduce greenhouse gas, and save running cost, it is important to construct systems in industrial factories more efficient by utilizing heat from warm wastewater. To realize more efficient water heating system, it is essential to develop and evaluate affordable direct heat-recoverable heat pump which has direct recoverable evaporator. An experimental performance evaluation and an estimation based on the results have been conducted. According to the evaluation, developed heat pump achieved a COP of 4 or more, with an warm wastewater temperature of 35°C. Verification of the estimation was conducted by the field measurement. A problem, performance degradation according to fouling of the evaporator. A solution was developed, and availability was validated through the field measurement.

Keywords: wastet heat recovery, heat pump, direct recoverable evaporator, experimental performance evaluation, verification

1. Introduction

Heat pumps are expected to penetrate significantly due to their high energy conservation and greenhouse gas mitigation effects and have already established themselves as key components in air-conditioning equipment for residential and commercial buildings. Conversely, although penetration into the industrial sector is also now developing, due to exceptional energy conservation and greenhouse gas mitigation potential [1], some hindrances remain, for example, the high initial cost and the lack of awareness.

Heat recovery water-heating heat pumps capable of heating water up to high temperatures efficiently powered by waste heat from industrial processes are expected to spread because they use renewable energy (it is waste heat) efficiently, reduce primary energy input and offer high generality. Most conventional systems, however, were inefficient and involved high running costs because of their indirect construction, which meant an extra circulation loop was needed to recover heat from waste heat. Accordingly, commercialization of a “direct heat-recoverable heat pump”, capable of recovering heat directly in the evaporator (“direct heat-recoverable evaporator”) from waste heat, has been expected, which could conserve primary energy, reduce greenhouse gas, save on initial and running costs and reduce footprint. Many issues, however, remain when it comes to developing the “direct heat-recoverable evaporator”, for example, separating it from the heat pump, its ability to withstand various chemical species and impurities, anti-fouling performance and so on. Kuwabara et al. [2] reported the shell-and-coil type heat exchanger as a possible solution and a direct heat-recoverable heat pump is also being developed.

In this report, the direct heat-recoverable heat pump using a shell-and-coil type evaporator is evaluated in a performance evaluating facility and through field measurement. Degradation of heating capacity due to fouling accumulation and its fixing using self-cleaning found on the field measurement are also reported.

2. Experimental performance evaluation and modeling of efficiency

2.1. Heat pump to be tested

The direct heat-recoverable heat pump water heater is selected for testing, with specifications as in Table 1 and the following features [2]: (1) The evaporator can be settled separately from the main body (see Figure 1) and the maximum separation distance is 10 m, (2) it has a fixed speed compressor and (3) the outlet temperature can be controlled using a water-control valve.

Table 1. Specifications of heat pump to be tested

Heating capacity	50 kW
Refrigerant	R410A
Output temperature	50 – 65 °C
Upper limit of heat source temperature	53 °C
Maximum distance to evaporator	10 m

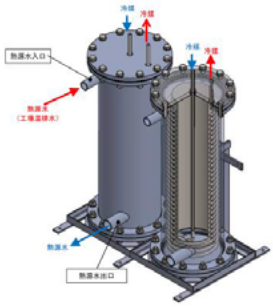

Figure 1 Schematic diagram of direct recoverable evaporator in the heat pump [2]

2.2. Performance evaluating facility

The performance evaluation facility is in the Central Research Institute of Electric Power Industry and Hashimoto et al. [3] reported on the design and performance of the facility, within which the heat pump to be tested is installed (see Figure 2). To measure performance, the hot water volumetric flow rate, hot water inlet and outlet temperature, heat source water volumetric flow rate, heat source water inlet and outlet temperatures and electricity consumption were measured highly accurate, with particular focus on ensuring accurate temperature measurement. A highly accurate resistance thermometer and highly accurate logger (NETSUSHIN NX1000) were used.

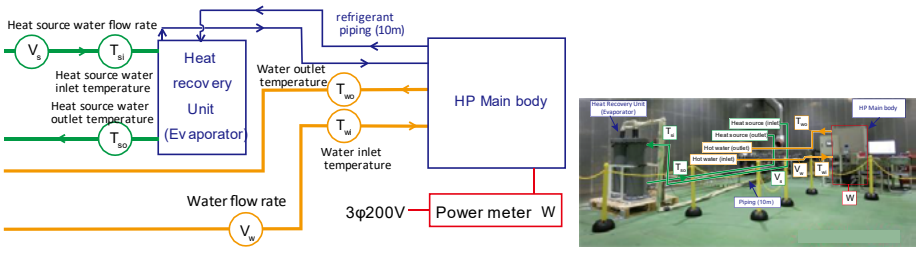

Figure 2 Photograph of the heat pump in the evaluating facility

2.3. Definitions of evaluation indexes

Water heating capacity, or Q_w, is defined as the following equation:

$$Q_w = \frac{60\, V_w (T_{wo} - T_{wi})}{860} \quad (1)$$

Here, V_w, T_{wi} and T_{wo} constitute the hot water volumetric flow rate (L/min), hot water inlet temperature (ºC) and hot water outlet temperature (ºC), respectively. And density of water assumed to be 1kg/L.

Coefficient of performance of water heating, or COP_w, is defined as the following equation:

$$COP_w = \frac{Q_w}{W} \quad (2)$$

Here, W is electricity consumption (kW).

2.4. Result of evaluation

(a)Rating condition

Table 2 shows the result of the performance in terms of the rating condition. Assuming that the heat pump is used for preheating boiler feedwater, that is inlet temperature T_{wi} is 17 ºC and target outlet temperature T_{wo} is 65 ºC, and using warm waste water as a heat source, that is heat sink inlet temperature T_{si} is 30 ºC, the conditions shown in the notation were used as rated conditions. As a result of the measurement, A was 64.89 ºC, that is almost equal to the target of 65 ºC, and the heating capacity was 53.59kW and COP_w was 3.84.

Table 2 Performance in rating condition. (Run 65-1-1)

Title	Setpoint	Title	Results
T_{wi} (ºC)	17	Q_w (kW)	53.59
T_{si} (ºC)	30	V_w (L/min)	16.09
		W (kW)	13.95
		COP_w (-)	3.84
T_{wo} (°C)	65	T_{wo} (°C)	64.89

(b)Performance map

The water-heating capacity map (Figure 3) is obtained using the hot water inlet temperature and the heat source water inlet temperature as parameters.

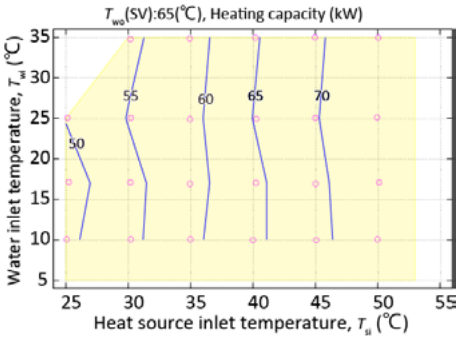

Figure 3 Performance map (T_{wo} (SV) =: 65 ºC)

2.5. Modeling of efficiency

Performance measurements are used to obtain a modeling equation. Assuming a hot water outlet temperature of 65 ºC, the water heating COP is modeled as per Equation (3).

$$COP_w = 0.065\,T_{si} + 1.95 \quad (3)$$

Here, T_{si} is heat source water inlet temperature. Since the influence of T_{wi} is very weak, it is ignored.

3. Verification by field measurement

3.1. Outline of the field measurement

A field measurement is conducted in a cleaning factory located near Sendai City, Miyagi prefecture (in the Tohoku region of Japan). Figure 4 shows a schematic diagram of the field measurement. This factory uses about 70 tons of steam per day, and all of which is supplied by a steam boiler fueled with A-type heavy oil.

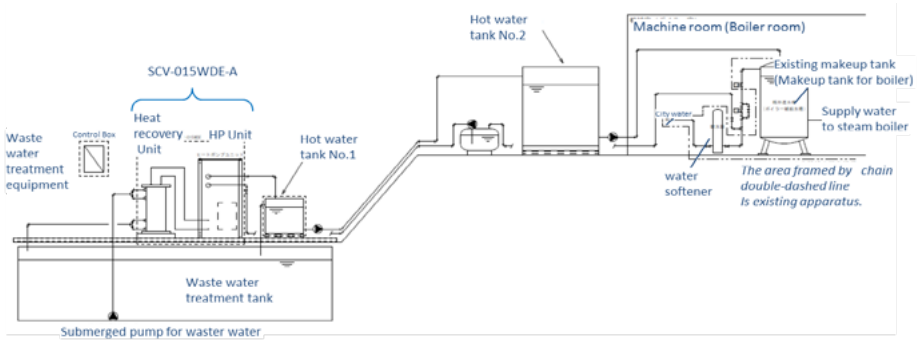

Figure 4 Schematic diagram of the field performance evaluation.

The overall amount of warm effluent wasted from all the cleaning processes in the factory constitutes about 300 tons per day, which is collected in a waste water treatment tank and then discarded as sewage after purification and pH adjustment. The warm wastewater contains fiber waste, dust, detergent components, soap scum and so on.

The heat pump to be tested is installed on top of the wastewater treatment tank and the warm wastewater is propelled to the heat pump by the pump, whereupon heat is recovered from the same and the wastewater is returned to the wastewater treatment tank.

The standard specification of the evaporator shell is made of PVC, but was made of acrylic for the field measurement to visualize the fouling inside the evaporator. The distance between the heat pump main body ("HP Unit") and the heat-recoverable evaporator ("Heat Recovery Unit") is set at 5 m.

There are two hot water tanks. Tank 1, volume of $2m^3$, is located on the wastewater treatment tank, while Tank 2 is located near the steam supplying boiler in the mechanical room. The distance between the two tanks is 140m and they are connected by well-insulated hot water piping. The existing replenishing tank (makeup tank) and Tank 2 are also connected by piping.

In the field measurement, the following two type of tests are conducted:

1. Non-load test:
   Heat is recovered from warm wastewater to generate hot water, and the hot water is discharged into a wastewater treatment tank.
2. Full-scale load test:
   Hot water generated by recovering heat from warm wastewater is supplied to the replenishing tank to be used for preheating replenishing water.

Field measurements are conducted from July 2017 to February 2018. The no-load test lasted for about 6 months from July 2017 to January 2018, while the full-scale load test lasted for two weeks from February 5 to 16, 2018. The factory does not operate at weekends.

Well water (temperature 12 - 16 ºC) is used as a heated medium to generate hot water, and the target hot water outlet temperature was set to 65 ºC.

3.2. Field measurement result and the verification of the modeling

The heating capacity is degraded due to cumulative fouling in the field measurement, which is mitigated by daily self-cleaning. Details will be described in Section 4 and the following description is based on the result after conducting self-cleaning.

Figure 5 shows the daily average heating COP by field measurement (hereinafter referred to as heating COP (field), indicated as "Field test" in figure 5) from February 5 to 16 and heating COP (lab) calculated from Equation (3). The heated COP (field) on February 5 is about 10% higher than the heated COP (lab), which is presumably attributable to the length of the refrigerant pipe between the evaporator and main body.

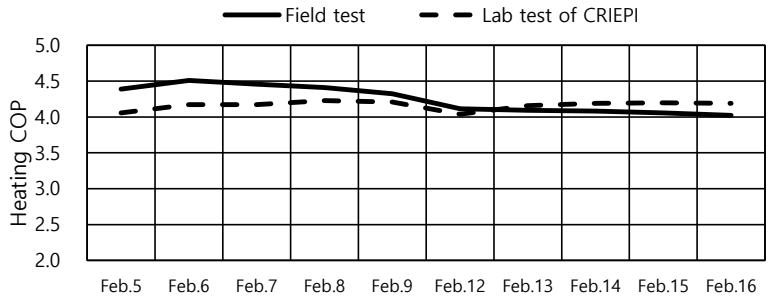

Figure 5 Performance comparison between field measurement and modeling by lab evaluation

From February 6 to 12, the heating COP (field) is on a downward trend, which implies that daily self-cleaning cannot completely remove the fouling from the coil surface of the evaporator. Conversely, since the decreasing trend of heated COP (field) after February 12 has been alleviated, self-cleaning is considered effective in preventing any reduction in heated COP.

3.3. Estimation of the installation effect

Figure 6 shows the estimated reduction in daily A-type heavy oil and increase in daily electricity consumption based on the field measurement. The average reduction in A-type heavy oil was about 88L, and the average increase in electricity was about 194kWh.

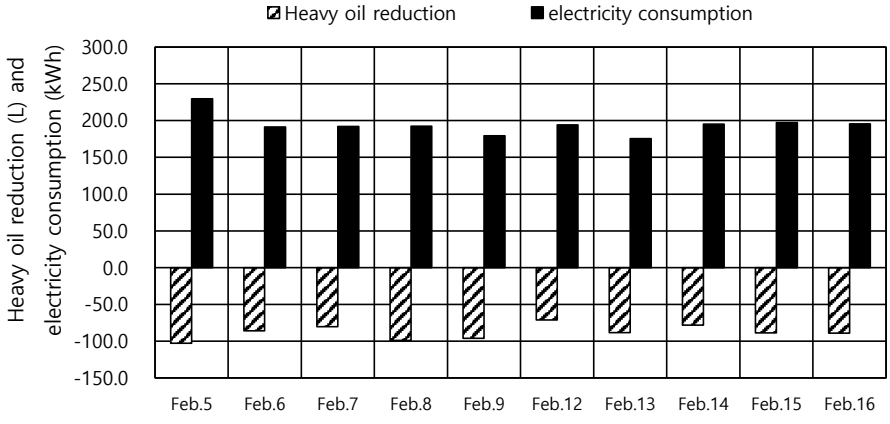

Figure 6 Daily variation of estimated electricity consumption and A-type heavy oil reduction effects.

The annual introduction effect is estimated based on this result. Assuming 262 working days per year, a primary energy reduction effect of 395 GJ and a CO_2 emission-reduction effect of 36 ton- CO_2 can be expected. Here, the grid power primary energy conversion factor, A-type heavy oil calorific value, grid power CO_2 emission intensity (2015) and A-type heavy oil CO_2 emission intensity are assumed at 9.97 MJ / kWh, 39.1 MJ / L, 0.53 kg- CO_2 / kWh and 2.71 kg- CO_2 / L, respectively.

With regard to the CO_2 emission-reduction effect, further intensification can be expected as the decarbonization of grid power progresses.

4. The cumulative fouling on the coil of evaporator and the effect of self-cleaning

Figure 7 shows the water-heating-capacity and heat source temperature at the inlet of the evaporator (denoted as “draining temp”) under operation. A decline in heating capacity is observed as shown in the graph denoted as “no cleaning” (from February 14 to 16), at a rate estimated at 094 MJ/h. Based on the virtually constant heat source temperature and the accumulation of cotton-lint fouling observed, it was suggested that the latter fouling may explain the deterioration, something supported by the significant fouling adhesion on the first day and the concurrent significant decline.

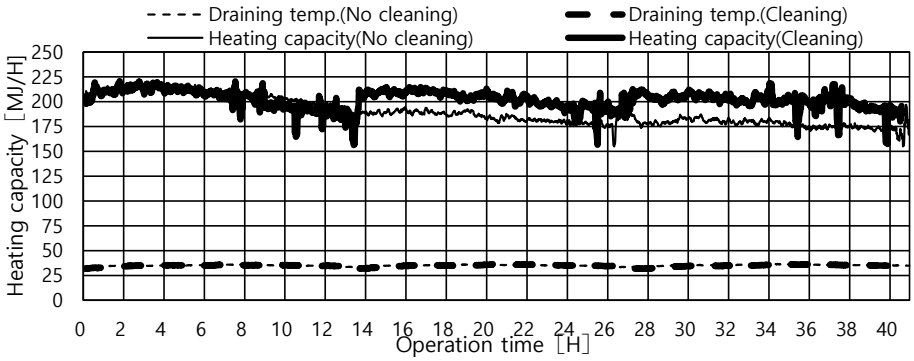

Figure 7 Decreasing heating capacity with adherence onto coil surface and recovery by the self-cleaning

There has been concern about the decline in the evaporator heating capacity due to cumulative fouling on the evaporator coil surface since the project started. Annual chemical cleaning and disassembly cleaning (once every two to three years) are being considered and urgent measure to counter daily performance degradation are required due to cumulative fouling beyond expectations.

Self-cleaning using discharge heat source water from the evaporator is carried out as an urgent measure. To realize the self-cleaning, a discharge valve is installed on the piping on the evaporator outlet. Random bubbling from the discharge valve helps to clean more effectively.

Figure 7 also shows the heating capacity and heat source temperature at the evaporator inlet after self-cleaning, the results of which are shown as “cleaning” (from February 14 to 16). The self-cleaning is conducted daily just after stopping operation. It is confirmed that the visual impact of the cumulative fouling was eased and the heating capacity recovered after the self-cleaning.

5. Conclusion

A heat-recoverable water heating heat pump is evaluated in two ways, via a performance measurement facility and field measurements and its high performance due to a direct heat-recoverable evaporator was confirmed, despite being designed as an affordable heat pump.

In addition, a problem of fouling on the surface of the evaporator coil is solved by using a new heat exchanger cleaning method (daily self-cleaning) and it was confirmed that performance recovered after this cleaning. It is also understood that the length of the separation pipe between the main body and evaporator impacted on performance.

Aiming to conserve more primary energy in the industrial sector, it is important not only to improve heat pump efficiency but also to improve the total design of the hot water supply system and system operation. We will continue to challenge these improvements.

Nomenclature

COP	: Coefficient of Performance, -	W	: Electricity consumption, kJ・s^{-1}

Abstract

In this article possibilities and constraints of grid flexible control of heat pumps for domestic heating are investigated. By creating dynamic coalitions of heat pumps and control their power consumption, demand response can be offered to the power grid. For a functional power grid, the heat pumps electrical power consumption needs to follow the electrical grids needs accurately.

Possibilities to externally control the power consumption of a ground source heat pump has been investigated. Both direct control, where the compressor speed is set directly, and indirect control, achieved with outdoor temperature sensor override, has been evaluated. For the evaluation a test cycle for laboratory testing of a heat pumps grid flexibility has been developed.

Based on the test cycle, the heat pumps possibilities to follow the load profile using both direct and indirect control was tested in laboratory. Both control methods were possible to use, with the direct control being significantly more accurate. Using direct control, the power consumption of the compressor managed to be within ±10% of the stated power consumption for 97% of the time.

Keywords: Grid flexible heat pump; Heat Pump control; Smart grid; Demand response; Heat Pump

1. Introduction

The European power system undergoes a major transformation driven by a steadily increasing share of power from renewable intermittent energy sources, such as wind power and solar energy. When the production of electric power from intermittent sources increases, the need to control the variations in the power system increases as well [1][2]. Heat pumps, with their possibility to convert power to heat, can support the transformation of the power system. Making use of the building's thermal inertia in combination with controlling the heat pump´s power consumption makes it possible to use the heat pump to provide demand response [1]. Historically heat pump design has focused on providing a good indoor climate and domestic hot water (DHW) with as high efficiency as possible. In the future with more and more variable power production it will likely be of greater importance to provide comfort with low impact on global warming rather than with as high efficiency as possibility.

By external control of the heat pumps and their power consumption, demand response can be offered to the power grid. The term "demand response" includes controlling the power consumption to better match the consumption with the power supply. Demand response can be used to avoid power peaks, balance the power consumption, avoiding curtailment of power production from intermittent renewable sources etc. One way to

offer a larger flexibility in electric power is to make dynamic clusters of heat pumps, giving higher flexibility when controlled together [1][3].

1.1. Scope

The objective with the article is to evaluate different strategies for indirect and direct control of a grid flexible heat pump and give recommendation of the best way to externally control a heat pump with variable speed compressor for offering grid flexibility. A grid flexible heat pump is defined as a heat pump that can adjust its electrical power use to external demands.

1.2. Method

Two different strategies for heat pump control have been evaluated by laboratory tests of a ground source heat pump with a variable speed compressor. The strategies evaluated are indirect control via temperature sensor override and direct control of the heat pumps compressor speed. In addition, other possibilities and constrains of heat pump control have been evaluated using a literature survey and a questionnaire sent out to four Swedish heat pump manufacturers.

1.3. Delimitations

The article focuses on how to control the heat pumps power consumption externally. How the power profile for offering demand response is calculated and distributed to the individual heat pumps are out of the scope of the article and only briefly described. The article studies the control of the heat pumps power consumption and heat production related to space heating, production of domestic hot water is not included.

1.4. Background

The benefit with heat pumps, when it comes to demand response, is their possibility to transform power to heat. In combination with the thermal inertia in buildings, or thermal storages, it gives a possibility to control, within certain limits, when the building needs to be heated and still keep a good indoor climate. By controlling the power consumption of the heat pump, it is possible to help balancing the power systems variations in supply and demand. But controlling the power output from a single heat pump gives low flexibility to the grid, in order to provide a useful size of power to use for demand response a coalition of heat pumps needs to be controlled together. In the EU project Flexible Heat and Power (FHP) [4], which work the article is based on, this is done in several steps. First the available thermal flexibility from the individual buildings is calculated, followed by aggregating the flexibility from all individual buildings for a neighborhood or a community. Then the aggregated plan can be used to offer balancing services to the local distribution system operator (DSO) or the balance responsible party (BRP). Finally, the decided control of the heat pump coalition will be disaggregated and dispatched to the individual heat pumps, where each heat pump is given a power profile to follow. This article focuses on the last step, how to control the heat pumps power consumption and follow a decided power profile given by an external party.

1.4.1. Heat pump control

There have been other projects during the last years investigating the use of heat pumps to offer demand response in different ways. How the heat pumps power consumption is controlled varies. In some projects an off-signal is sent to the heat pump. One example is the EU project EcoGrid [5], the project demonstrated the operation of a power system with high amount of renewable and variable energy resources on the Danish island of Bornholm. The operating tools for heat pumps developed in the project had the possibility to send an off signal to the heat pump for a certain time period.

Another way to control the heat pump is based on the German “Smart grid ready” or “SG ready” standard. It is a standard for smart control defined by the German Bundesverband Wärmepumpe e.V. [6]. The standard makes it possible to send a signal to the heat pump that activates one of the four defined modes. The activation of each mode is done based on how two terminals are open (0) or closed (1). The setting of the terminals activates different setting of the heat pump control. When one of the modes is activated, the heat pump is programmed to respond in a certain way. The exact response for each mode is not defined by the standard and can vary from one heat pump model to another.

The four defined heat pump working modes are [7]:

1. Blocking mode: HP is switched off, until storage reaches its lower allowed temperature level. (1:0)
2. Normal mode: HP operates with normal set-points. (0:0)
3. Low price mode: HP is switched on. (0:1)
4. Over capacity mode: HP is switched on, storage temperatures increased to the maximum temperature allowed by the HP. (1:1)

2. Strategies for heat pump control

One important step in the chain to provide demand response is to be able to control the heat pump based on external signals in order to make the heat pump consume the amount of electricity asked for. Both sending an off signal to the heat pump or using the SG ready standard gives a very rough control of the heat pumps power consumption. In order to make the heat pump follow a defined power profile a method with higher accuracy is needed. Two alternative methods are evaluated in order to find a way with higher accuracy. External control of a heat pump can be divided into two main categories, direct- and indirect control.

2.1. Indirect control

The heating demand of a building is dependent on the outdoor temperature and a heat pump is programmed to adjust its heat production based on the outdoor temperature. Most heat pumps are equipped with an outdoor temperature sensor, giving information about actual temperate, used to estimate the heating demand of the building. At low winter temperatures the auxiliary heater may need to start to cover the total heating demand of the building. Manipulating the temperature sensor and sending a fake outdoor temperature to the heat pump is a possible way to indirect control the heat pumps heat production and power demand. An alternative way to control the heat pump indirect is to adjust the heat pumps heating curve. In the tests related to this project the outdoor temperature sensor was replaced with an adjustable precision potentiometer making it possible to manually set the outdoor temperature wanted.

2.2. Direct control

At direct control the heat pumps ordinary, internal control to set the compressor speed and switch between space heating and production of DHW is bypassed and the compressor is controlled directly. This makes it possible to control the heat pumps power consumption fast and with higher accuracy. To make this work it is necessary that the heat pumps is prepared for external control and that it is possible to communicate with it. No heat pump on the market has this functionality today.

During the laboratory tests with direct control a software developed by the heat pump manufacturer of the tested heat pump was used. The software is normally used for internal testing by the manufacturer. Via a computer connected to the heat pump, the software made it possible to set the compressor frequency directly. As a complement to the software an add-on was created. The add-on makes it possible to set the frequency profile asked for via a csv-file. This made it possible to create a test sequence that automatically changes the compressor speed at desired times, making it easier to test longer sequences with changing compressor speed or to make fast changes.

2.3. Constrains in compressor speed change

The heat pumps on the market today are developed to give high comfort with as high efficiency as possible. But in order to be flexible, the heat pump needs to handle fast changes in compressor speed. A survey sent out to four Swedish heat pump manufacturers showed that different manufacturers have different approaches, comparing the time inverter heat pumps took from off mode to maximal heat production or from the lowest compressor speed to the highest. Figure 1 shows large differences in time going from minimum to maximum speed depending on the choice of heat pump model. Note that for the laboratory test presented in this article “HP A” has been used.

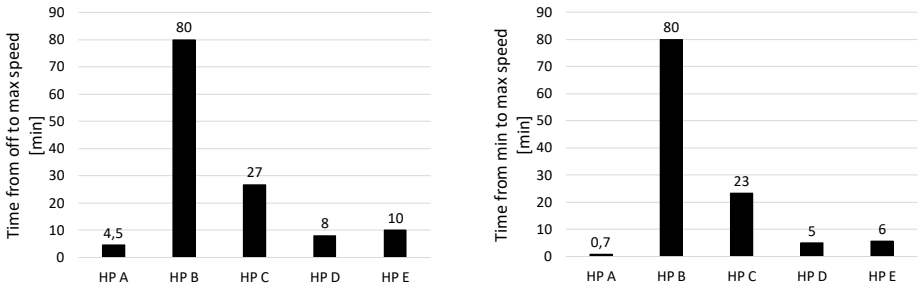

Figure 1. Time from compressor off to full speed (left) and from running at lowest compressor speed to highest compressor speed (right).

Another constraint is the start-up phase, where the compressor typically needs to run at a fixed, midrange speed for minutes, to secure lubrication before the speed asked for can be set. The speed control also varies between different manufacturers, not all use stepless speed control, but instead use fixed speed in steps to alter between. The reason is to have better control of the performance, as stepwise means most operation modes can be tested and optimised, and since the heating system and building has high inertia, there is little point of controlling speed exactly.

3. Test method

The performance using both indirect and direct control of a ground source heat pump was tested in laboratory based on a standardized test cycle for evaluating the possibilities to control a grid flexible heat pump. In addition, a number of 24h test profiles were developed and tested using direct control.

3.1. Test cycle

In order to standardise testing and evaluation of the control of a grid flexible heat pump an eight-hour long test cycle for laboratory testing was developed. The purpose with the test cycle is partly to evaluate how close the heat pump in combination with the external control manage to follow the specified test profile. Partly to test if the heat pump control manages a number of functions, such as start and stop of the compressor, changing the compressor speed and start and stop the auxiliary heater, se Figure 2.

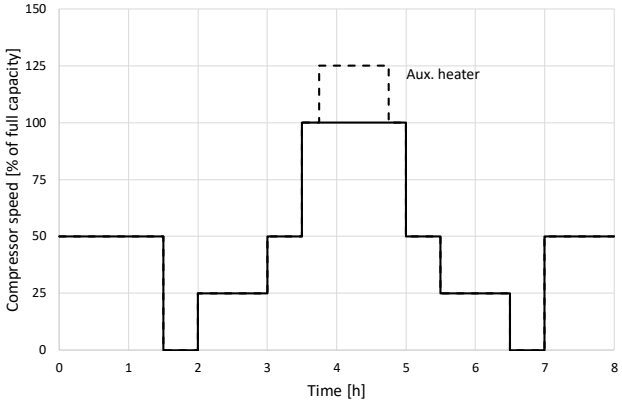

Figure 2. Test cycle for laboratory testing of a grid flexible heat pump

3.2. Key performance indicators

Four key performance indicators (KPI) for the flex function was identified in order to evaluate the results. KPI_1 - KPI_3 expresses how well the heat pump can follow the test cycle, while KPI_4 expresses how the flex function affects the heat pumps coefficient of performance, COP. In Table 1 below each KPI is defined:

Table 1. Definition of key performance indicators for evaluation of grid flexible heat pump control

Key Performance Indicators	
$KPI_{1, a \text{ and } b}$	Average deviation between the measured compressor speed, heat production or power consumption compared to stated value by the test cycle. The result for KPI_1 is expressed in revolutions per second (rps) or in watt (W). With a: auxiliary heater included and b: auxiliary heater excluded.
$KPI_{2, a \text{ and } b}$	Percentage of the time the compressor speed, heat production or power consumption is within ±3% of the value given by the test cycle, where the interval, ±3%, is defined at maximum compressor speed. With a: auxiliary heater included and b: auxiliary heater excluded.
$KPI_{3, a \text{ and } b}$	Percentage of the time the compressor speed, heat production or power consumption is within ±10% of the value given by the test cycle, where the interval, ±10%, is defined at maximum compressor speed. With a: auxiliary heater included and b: auxiliary heater excluded.
$KPI_{4, a \text{ and } b}$	KPI_4 gives the impact on the heat pump efficiency, COP, related to making the heat pump follow the test cycles variations instead of working on stable conditions. KPI_4 is calculated as the average COP during the whole test cycle (time 0h to 8h) divided by average COP during test time 0.5h to 1.25h (when the compressor is working on stable conditions at 50% of maximum speed). With a: auxiliary heater included and b: auxiliary heater excluded.

4. Results

The results from the laboratory tests with indirect and direct control are presented below, followed by a comparison of the results from the two tests.

4.1. Test cycle, indirect control

During the test a manipulated outdoor temperature was sent to the heat pump making the heat pump change the compressor speed in order to follow the test sequence in Figure 2. This was done manually using a potentiometer. The results from the test is presented in Figure 3 below. The figure shows that the test cycle is followed relatively well, but not perfect. It also shows that the compressor follows the test cycle better than the auxiliary heater does. An additional outcome from the test was that it is easier to follow the profile going up in compressor speed than going down with high accuracy.

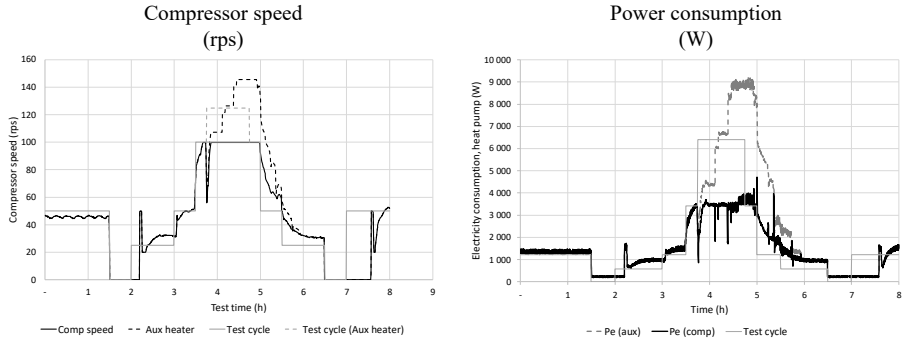

Figure 3. Results indirect control of compressor speed and auxiliary heater via temperature sensor override. Compressor speed (left) and power consumption (right)

The outdoor temperature corresponding to a specific compressor speed and thus a specific heating capacity and electricity consumption is individual for each heat pump, depending on the heat pump model, the heating demand of the building and the heat curve chosen.

4.2. Test cycle, direct control

During the test with direct control, changes to the compressor speed were made manually by a test engineer using the software described in chapter 2.2 and following the test sequence in Figure 2. The results from the test is presented in Figure 4 below. The figure shows that the heat pump compressor follows the test cycle with high accuracy, but it was not possible to activate the auxiliary heater using this version of the program for direct control. The largest deviation of the compressor speed compared to the test cycle occurs after two hours, when the compressor needs to start at 50% before it can reduce the speed to 25% to follow the test cycle. Otherwise the compressor speed follows the test sequence very well.

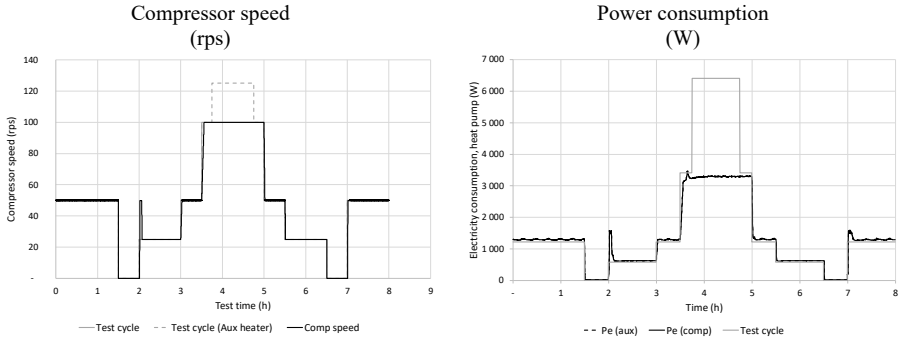

Figure 4. Results for direct control of compressor speed and auxiliary heater. Compressor speed (left) and power consumption (right)

4.3. Comparison results indirect and direct control

Comparing the results from the two laboratory tests shows that the direct control follows the test cycle much better. Looking at the compressor only, the direct control is in average 1rps from the set value compared to 9rps for indirect control. For the total, also including the auxiliary heater, the direct control is approximately 10rps better, even though the direct control function couldn't start the auxiliary heater.

Table 2. Summary of test results, results for KPI_{1-3} based on compressor speed.

	Total (Auxiliary heater included)		**Compressor only** (Auxiliary heater excluded)	
	Indirect control	Direct control	Indirect control	Direct control
KPI_1 Average deviation from test cycle	14rps	4rps	9rps	1rps
KPI_2 Time share within ±3% of the test cycle	24%	85%	36%	97%
KPI_3 Time share within ±10% of the test cycle	62%	85%	75%	98%
KPI_4 Decrease COP			-13%	-11%

Looking at KPI_2, the time within ±3% of the set value, there is a large difference between direct and indirect control, but looking at KPI_3, the time within ±10% of the set value, the differences has decreased. This indicates that the indirect control can follow the cycle roughly, but if high accuracy is needed direct control is much better. KPI_4 shows how COP is affected by using the heat pump for flexibility services following the test cycle in Figure 2. In this test COP decreased with approximately 10-15% following the flexible test cycle instead of running the heat pump at stable condition with a compressor speed at 50rps. Additional tests show that the impact on COP depends on the shape of the power profile asked for, see chapter 4.4. Since neither the direct control nor the indirect control managed to start the auxiliary heater correctly, the results on how COP is affected for the total is not included in the results but starting the auxiliary heater will make COP decrease further.

Table 3. Summary of test results, results for KPI_{1-3} based on power consumption.

	Total (Auxiliary heater included)		**Compressor only** (Auxiliary heater excluded)	
	Indirect control	Direct control	Indirect control	Direct control
KPI_1 Average deviation from test cycle	900W	470W	370W	100W
KPI_2 Time share within ±3% of the test cycle	12%	76%	19%	76%
KPI_3 Time share within ±10% of the test cycle	54%	85%	64%	97%
KPI_4 Decrease COP			-13%	-11%

The heat pump power consumption can be followed within ±100W with direct control, roughly four times better than with indirect control. Comparing $KPI_{2 \text{ and } 3}$ in Table 2 and Table 3 shows that with the control methods used in the test it is easier to set the correct compressor speed, translating the compressor speed to power consumption will make the accuracy decrees.

4.4. 24 h test profiles with direct control

In order to further evaluate direct control of the heat pump a number of 24h test profiles were developed and tested in laboratory as a complement to the test cycle. The profiles were based on different scenarios and the purpose with the test was to evaluate how well a heat pump can follow a specified profile using direct control and how the heat pump´s COP, will be affected by following an external profile instead of working in more stable conditions. Below two examples of profiles are presented.

For each test profile a csv-file was created including information about time and compressor speed for every change in speed. Data for the conversion was based on performance tests in the laboratory. The general settings of the heat pump are based on test condition B in table 14 in the test standard for heat pumps, EN14825:2018 [8], representing the conditions at an outdoor temperature of +2°C, for a medium temperature application (typical radiator system) in cold climate.

4.4.1. Profile for peak shaving

A 24h profile for peak shaving has been developed for a theoretic model house with radiator heating. The outdoor temperature is assumed to be +3°C all day, in this case leading to a constant heating demand of 5kW. In the profile the heat pump is assumed to be switched off from 07:00 to 10:00 and from 17:00 to 20:00, it is also assumed that the building has an thermal inertia that makes it possible to switch off the heat pump for three hours and still keep a good indoor climate. To compensate for the period when it is switched off the heat pump produces more heat during other hours. In this case it is assumed that the heat pump will compensate by producing the heat needed at maximum capacity. In the morning this is done before the heat pump is switched of and in the afternoon, it is done after. The result from the test is presented in Figure 5.

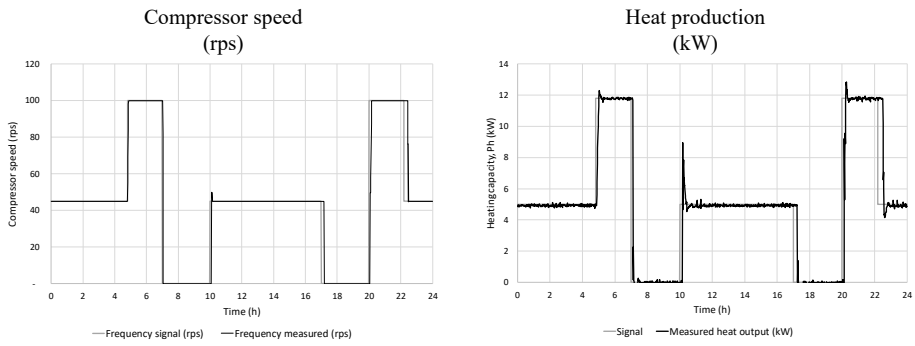

Figure 5. Control signal vs. measured compressor speed (left) and vs. measured heat production (right), profile from peak shaving at +3°C.

The average deviation in heat production between the profile and the measured values from the heat pump test is about 460W. Using a peak shaving profile, as described in Figure 5, instead of working in stable conditions at 5kW heating will decrease COP with 8%, based on data from the laboratory test. Note that the test cannot fully simulate a real installation. In the laboratory tests the return temperature to the heat pump as well as the brine inlet temperature is kept constant independent on how the heat pumps is operated. In a real installation it is a risk that COP will decrease further.

4.4.2. Profile for cost minimization, Aahus Nov 26th

The purpose with the cost minimization profile used for testing is to make a test profile with hourly changes of the heat pumps power consumption in order to minimize the heating cost. For this a simple cost minimization algorithm has been developed for a theoretical model house, based on Excels solver function, with focus on the creation of a relevant test profile. The cost minimization is based on historical climate data in Aarhus, Denmark in combination with historically hourly electricity prices. Nord Pool [9] and DMI [10] are used as a data sources. Aarhus, Denmark November 26th, 2018 was chosen as an example of a day due to its large variations in the hourly electricity prices. This was a day with large changes in electricity prices and a moderate variation in outdoor temperature, from -4°C to +2°C, see Figure 6 below.

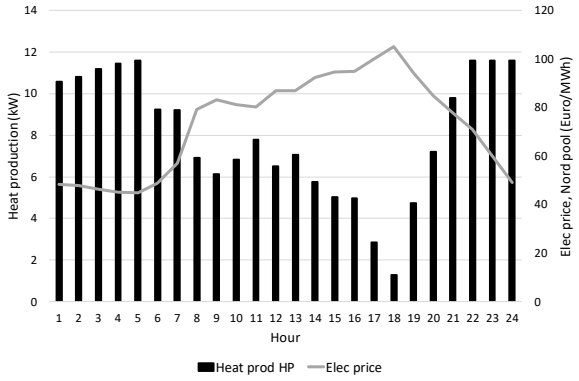

Figure 6. Load profile for heating 26 Nov. 2018 in Aarhus, based on cost minimization in relation to hourly variations in electricity price from Nord Pool [9]

The results from the test is summarized in Figure 7. The average deviation in heat production between the profile and the measured values from the heat pump test is about 380W. Despite a lower COP (-4%) the heating costs decreases with 6%, following the cost minimization profile instead of producing heat based on the actual outdoor temeprature (based on Nord Pool prices, no other costs included).

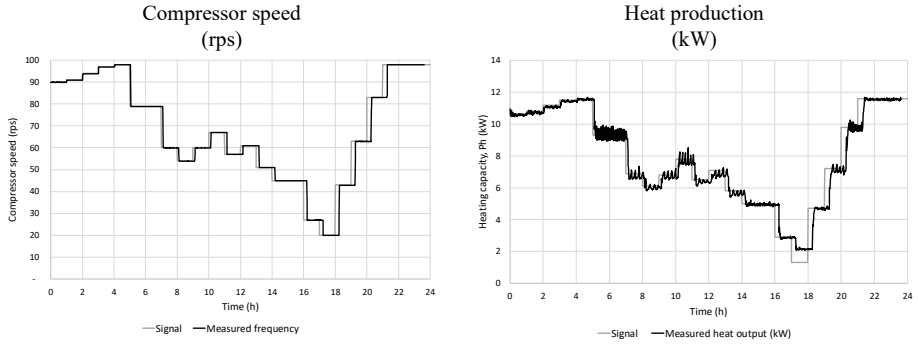

Figure 7. Control signal vs. measured compressor frequency (left) and vs. measured heating capacity (right), profile from cost minimization in Aarhus Nov. 26th, 2018.

5. Discussion

The overall aim with controlling the heat pump performance is to be able to externally control the power consumption and thereby be able to offer demand response. The electricity consumption can be controlled in different ways, which can be divided into two main groups; via indirect or direct control of the heat pump.

The results from laboratory tests with indirect control shows that it is possible to follow changes in a test cycle by using indirect control via temperature sensor override. The heat pump cannot follow the cycle in detail, but the general trend is followed relatively well. A benefit with using outdoor temperature sensor override is that the same software and equipment will work on most heat pump models. The disadvantage is that the equipment must be physically installed at the heat pump and the temperature sensor must be replaced.

A direct control of the heat pump compressor speed or its electricity consumption gives better possibilities to control the heat pump performance with high accuracy. At present day an individual software, overriding manufacturers internal control circuits, will be needed for each heat pump model to use direct control. To make this solution come true, the option needs to be part of manufacturers standardized protocol for controlling the heat pump as a complement to today´s temperature control.

The results from the different 24h-profiles tested in the heat pump laboratory shows that in general the profiles can be followed with high accuracy using direct control. The compressor speed in the profile can be followed with ±1-2rps and the heat pumps total power consumption with approximately ±100W. The evaluation of the results from the laboratory tests show that COP decreases with 0-10% depending on the shape of the profile, if the auxiliary heater is started COP decreases further. In real installations COP might decrease further, since the test rig cannot fully simulate a real heat pump installation. In the laboratory the return temperature to the heat pump is kept at a constant temperature, independent on how the heat pumps is operated. How the return temperature in a building will be affected depending on how the heat pump is controlled is hard to simulate in lab. This can lead to both higher and lower COP. In the same way, as for the return temperature, the brine inlet temperature to the heat pump is kept constant in the laboratory tests. In a real installation the brine inlet temperature will drop if the heat pump works on high compressor speed for a while. This will cause a decrease in COP.

6. Conclusions

Recommendations for external control of the heat pumps electricity consumption can be summarized as:

1. For older heat pumps or non-premium heat pumps sold today:
   Outdoor temperature sensor override: This is a solution that will work on more or less all heat pumps, but the accuracy of the heat pumps electricity consumption is not as good as for other alternatives. There is also a need for a physical installation on the heat pump which is costly.
2. For premium heat pumps sold today and future heat pumps:
   Indirect control of the temperature settings by adjustments of the heating curve or similar via web-API. Many premium heat pumps sold today are connected to the internet and a web interface or an app makes it possible for the owner to make changes related to the heat pump settings at a distance.
3. For future heat pumps:
   Direct control of the heat pump will give the fastest control of the power consumption and have the best accuracy. To make this happening it needs to be part of the manufacturers standardized protocol for controlling the heat pump.
4. Chose a heat pump with a fast response variable speed compressor. A survey to a few manufacturers shows a built-in limit between 4.5 and 80 minutes to go from compressor off to maximum capacity for heat pumps with variable speed compressors.

Abstract

Space and DHW heating appliances play a major role in increasing energy efficiency and reducing greenhouse gas emissions. A number of recent publications identified fuel driven sorption heat pumps (FSHP) as a promising technology which can considerably contribute to these goals, compared with current state-of-the-art gas appliances. The EU Ecodesign Regulation and the Implementing Regulations for different groups of energy-related products have highlighted the need for unbiased and transparent testing and performance evaluation methods. Although the technology is not new, the market is still developing and the current standards have yet to be evaluated regarding their applicability, unambiguousness and comprehensiveness. Within the IEA HPT Annex 43 and the EcoTest Projects round robin tests on gas driven sorption heat pumps have been performed based on the current European standards. In this paper, the results of the test will be presented with an emphasis on the assessment of the test and evaluation methods and their comparison. As one of the results, shortcomings of the methods and possible improvements have been detected and provided to the relevant CEN Technical Committees for further consideration.

Keywords: gas heat pump; test methods; quality assurance; energy label

1. Introduction

A proclaimed goal of the EU energy policy is to reduce the greenhouse emissions to 80-95 % below the levels of 1990 by 2050. As around 40 % of the final energy consumption in the EU countries can be attributed to the building sector (85 % thereof for space heating and domestic hot water (DHW) preparation), a fast deployment of energy-efficient solutions is crucial to reach this target. The EU addressed this issue in a number of directives regulations, most notably within the Ecodesign and EPBD directives, in which the standards for the energy efficiency of the buildings and HVAC equipment are defined.

The energy consumption for space heating per square meter heated area has been decreasing steadily in the EU countries since 2000. As new dwellings are being built at a rate of about 1,1 % of the total dwelling stock annually, the main contribution to the decrease of specific energy consumption can be attributed to the boiler retrofit and energy efficiency measurements on building envelope. This shows that the retrofit market is the main key to reaching the goals in the given time frames under current market development in the building sector. Therefore, efficient and affordable technologies targeting this market are needed to meet the proclaimed targets of the environmental policy. A number of recent publications (e.g. [1], [2]) on future energy market see fuel driven sorption heat pumps (FSHP) as a promising technology in that respect. The technology is seen by many as the next step in the development of fossil fuel heating systems. It can considerably increase the energy efficiency and usage of renewable energy sources while decreasing greenhouse gas emissions, compared with current state-of-the-art fossil fuel boilers. With expected net decarbonisation of gas grid by increasing biogas

production, development of power-to-gas concepts and evolution towards the usage of hydrogen, the FSHP, especially gas-fired heat pumps, may further gain in importance.

Calculations to identify the optimal technology mixtures both on the energy production and demand sides in terms of overall annual costs until 2050 were reported in [1]. The simulations were based on a comprehensive model of the overall German energy sector which takes into account the geographical, political, social, economic and technological characteristics of the location and forecasts their development in the upcoming decades. Having the minimum cumulative cost of the transition from the current energy system to an energy system with a substantial reduction of CO_2 emissions as the target function, the simulations yielded the optimal technology mix for a number of different target values.

Figure 1 shows the projected development of the share of heating systems for the buildings by 2050 for the assumed 85 % CO_2 emission reduction compared to 1990 values. This scenario seems to be slightly optimistic since the proclaimed policy of the German government sees an emission reduction of 80 % for the same time period. However, it shows the potential of the heat pump not only as a highly efficient technology, but also as the most cost-effective one in the decades to come. According to the scenario, most of the electricity will be produced by solar and wind power plants by 2050. Fluctuating electricity production will require considerable storage capacities to ensure a reliable energy supply. In that context, production of combustibles by power-to-gas processes and usage of current gas grid and its storage potentials will play a very important role in the future. This means that, even in an electricity-dominated energy system, the need for efficient gas fired energy conversion appliances using existing gas infrastructure will most probably exist.

The scenario sees a domination of heat pumps as heating systems in buildings by 2035 and a complete takeover by late 2040s. GHPs would reach a share of around a quarter of the total market. The technology should experience its first major break-through around 2026-2027 when a threshold of 1 million installed units should be reached. Although this estimation seems to be rather enthusiastic considering just a couple of thousands of currently installed units and not more than a handful of products available on the market, it shows the potential of the technology if the presumed cost and efficiency targets are met and a decarbonisation of energy system is pushed at projected pace. Needless to say, this estimation is highly dependable on a number of factors, including further technology development and acceptance, future energy system configuration, development of energy prices, incentive policy and development of competing technologies, among many others.

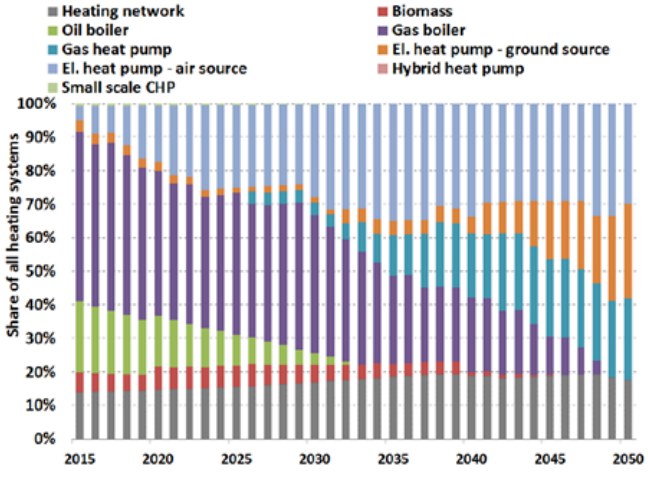

Figure 1. Development of heat supply technologies in buildings until 2050. Source: [1]

2. Market and appliances

Since its market entry in the mid-2000s and until 2010, only one manufacturer (Robur S.p.A.) of gas driven heat pumps was active on the European market. With heating capacities of around 40 kW the appliances were used mainly in small commercial installations. From 2010 onwards, a number of products aiming at single

family house market – both new and retrofit – were introduced by major heating equipment manufacturers. All available products were built using sorption technologies. However, almost all these products have been removed from the market in the last 2-3 years leaving Robur to be the sole provider of this technology once again.

Two main concepts were being pursued by the manufacturers: bivalent appliances with an adsorption heat pump using water as refrigerant supported by a modulating condensing boiler. These units need a heat source above 0 °C to avoid freezing – a ground heat source or solar collectors are needed. The adsorption heat pumps were sized to cover only one part of the nominal load up to ca. 4-5 kW. The concept did not prove to be interesting for the market and these appliances were withdrawn by the manufacturers. Absorption appliances are monovalent machines and run with ammonia-water working pair. Due to a lower freezing point of ammonia, they can operate with ambient air as heat source at temperatures well below 0 °C. These units can modulate their output capacities in the range of ca. 30 to 100 % of nominal thermal power.

Figure 2. Overview of available and withdrawn GHPs in the European market with main characteristics

In 2019, a start-up company BOOSTHEAT SA brought up their heat pump to the market after eight years of development. Unlike all other gas driven appliances for heating, it is not based on sorption technology but uses an own-developed mechanical compression system.

It is expected that the main market, due to its size, availability of gas mains and technology characteristics will be boiler replacement, especially in countries which are traditionally dominated by this fuel. Figure 2 gives an overview of currently available and withdrawn products with their main characteristics.

Despite a rather slow market development, a number of development activities have been reported in the recent years, both in the EU and in the USA. The main driver in Europe is to find an efficient solution for retrofit for heating in countries with well-developed gas grid. In the USA, the legislation on the minimum efficiency of sanitary water heaters created a need for more efficient gas-fired appliances. Figure 3 gives an overview of some of the reported appliances / concepts under development.

3. Standardised test methods and quality assurance

The Ecodesign Regulation and the corresponding Implementing Regulations for different groups of energy-related products have highlighted the need for unbiased and transparent testing and performance evaluation methods for all technologies. In the Communication of the European Commission 2014/C 207/02 [3], a list of harmonised standards for testing and performance evaluation of different heating appliances is provided. For gas fired sorption heat pumps EN 12309 [4] is referred to as the reference document for space heating application. The current version of EN 12309, Parts 1 and 3 to 7 have been published in December 2014. Part 2 "Safety" was published a year later in April 2016. The standard has been developed to be compatible with the corresponding methodologies used for electrically driven heat pumps in EN 14511 [5] and EN 14825 [6] and, thus, uses the same basic methodology for the testing and calculation of the seasonal performance figures. A basic description of the methodology can be found e.g. in [7]. For non-sorption units, no standards are currently available on the European level.

Table 1. Main features and differences between EN 12309-7 and VDI 4650-2

EN 12309	VDI 4650-2
Part load conditions related to the declared heating/cooling load	Part load conditions related to the declared HP capacity
Electrical and thermal energies are consequently separated, PER is used for an overall energy consumption	Electrical and thermal energies are put together in some figures; electrical efficiency not provided as a separate figure
Data for three different climates available, adaption to other climates possible	Part load data based on only one climate, adaption to other climates rather difficult
Performance evaluation for bivalent (hybrid) units possible (gas boiler and solar thermal)	Calculation of bivalent operation possible (only solar)
Heating and cooling considered, DHW is missing	Cooling not considered
Electrical power input during idle time considered for the calculation of seasonal performance	Electrical power input in standby mode not considered in performance figures

Due to a lack of suitable EN standards at the time, a VDI guideline for calculation of the seasonal efficiency of gas driven heat pumps was developed – the VDI 4650-2 [8] for the purpose of granting subsidies for the appliances in Germany. Similarly to the corresponding EN standards, the calculation method is strongly based on the VDI 4650-1 [9] which applies to electrically driven units. It inherited the operating conditions, including the part load rations, but was extended with new features to suit the needs of the products. These extensions include solar thermal collectors as heat source, direct solar DHW production, a performance figure to take into account dual driving energy and so forth. An overview of the main features of both standards is given in Table 1. Despite the availability of the EN 12309 and its current harmonisation with the EU Ecodesign and Energy

label Directives, the VDI 4650-2 is still used for product assessment within the German federal subsidy program for heating with renewable energies.

In 2018, a new standard (EN 13203-6 [10]) for the energy consumption evaluation of sorption gas heat pumps for sanitary hot water production was introduced as part of a series of similar standards for a variety of gas driven appliances, including hybrid heat pumps (combination of a gas boiler and an electrically driven heat pump).

Both the EN 12309 and the EN 13203-6 have been scrutinised in round robin tests organised within the IEA HPT Annex 43 [11] and the EcoTest [12] projects. The findings have been reported to the relevant Technical Committees (TCs) and will be considered within the current revision processes which aim to harmonise these standards with the Ecodesign and Energy Labelling Directives.

The main European independent and voluntary certification mark, the Heat Pump Keymark, has added gas driven heat pumps to its scope in 2019.

4. Round Robin Test on a hybrid adsorption heat pump (IEA HPT Annex 43)

The project IEA HPP Annex 43, among other objectives, aimed at investigating the applicability, unambiguousness and comprehensiveness of the relevant existing standards used for assessing fuel sorption heat pumps. For the purpose, a round robin test on a gas-driven hybrid heat pump was carried out according to the standard EN 12309:2014.

The choice to test this kind of appliance was dictated mainly by its operational complexity. In hybrid heat pumps, the combination of two technologies in one appliance, such as a condensing boiler for the peak load and a sorption module for the base load, generates a discontinuous operation of the appliance.

In this specific case, the tested machine was a geothermal hybrid heat pump consisting of a condensing boiler and a zeolite (adsorption) heat pump module. The presence of the adsorption module caused a cyclical machine's operation.

The tests were carried out at two different temperature applications: low temperature application (28 °C - 35 °C) and medium temperature application (35°C – 45 °C), both for "average" climate conditions. The method used was the "inlet temperature method" while, for results' reproducibility reasons, water was employed as heat transfer medium at the outdoor heat exchanger.

Analysing an operation cycle (see Figure 4), it's possible to distinguish four different phases: adsorption phase, during which only the sorption module is working; adsorption plus boiler phase, where both the condensing boiler and the sorption module are working; boiler phase, where only the condensing boiler is working and, finally, desorption phase, where only the sorption module is working and no heating energy is delivered.

These four phases and their alternation affect the applicability of several requirements of the analysed test procedure such as the limits on the permissible deviations of the quantities of interest. For example, the evaporator (i.e. the "outdoor" heat exchanger) and the internal circulation liquid pump, responsible for the circulation of the heat transfer medium between the machine and the geothermal probes, work only when the sorption module is adsorbing. This means that the monitored quantities at this component such as the inlet and outlet temperatures, flow rate and the differential external static pressure will have an unsteady behaviour (see Figure 5). It's easy to understand that it's not possible to respect the limits on permissible deviations prescribed in Table 4 of the standard EN 12309:2014, Part4.

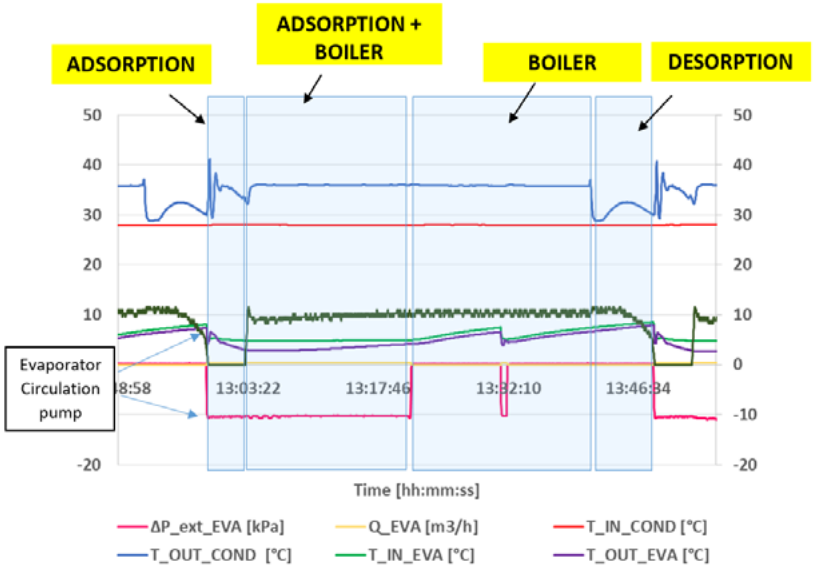

Figure 4. Operation cycle of the hybrid heat pump under test (ΔP_ext_EVA – external pressure difference over the evaporator; T_OUT_COND – outlet water temperature from the condenser; Q_EVA – water volume flow rate through the evaporator; T_IN_EVA – inlet water temperature to the evaporator; T_IN_COND – inlet water temperature to the condenser; T_OUT_EVA – outlet water temperature from the evaporator)

The same can be said for the condenser (i.e. the "indoor" heat exchanger), where the only two parameters that can respect the limits of permissible deviations are the inlet temperature (red line in Figure 5) and the flow rate since, after a certain time, their behaviour depend only on the control of the test rig. The only parameter that, in this case, is influenced by the hybrid heat pump's operation and, therefore, has an unsteady behaviour, is the outlet temperature (see Figure 5, dark blue line). Nevertheless, no requirements are foreseen on this parameter even if it is crucial for the distribution system. With this regard, it could be useful to have a requirement (a permissible deviation) on that.

Concerning the permissible deviations of the inlet temperatures, they vary (the amplitude) based on machine's load: i.e. as the load decreases, the deviation increases. This is not necessary since the fluctuation of the inlet temperatures depend only on the test rig control and not on the machine.

Another remark concerns the duration of the test (equilibrium phase plus data collection phase): From the executed tests, it emerged that some "special" cycles occur (see Figure 5, light red rectangles). This means that the choice of the test duration shall be done in order to consider all operational peculiarities of the hybrid heat pump under test. According to the prescription given in the paragraph 4.5.2.1 of EN 12309-4:2014, the equilibrium period and the data collection period shall be at least 40 minutes and 30 minutes, respectively.

It's clear that, for this kind of machines, the definition of these periods in terms of minutes is not representative but it shall be done in terms of complete operational cycles instead. From the tests carried out, it was concluded that minimum appropriate number of operational cycles that can also allowed to collect a significant number of samples could be eight. This number is also high enough to include all possible strange or peculiar cycles.

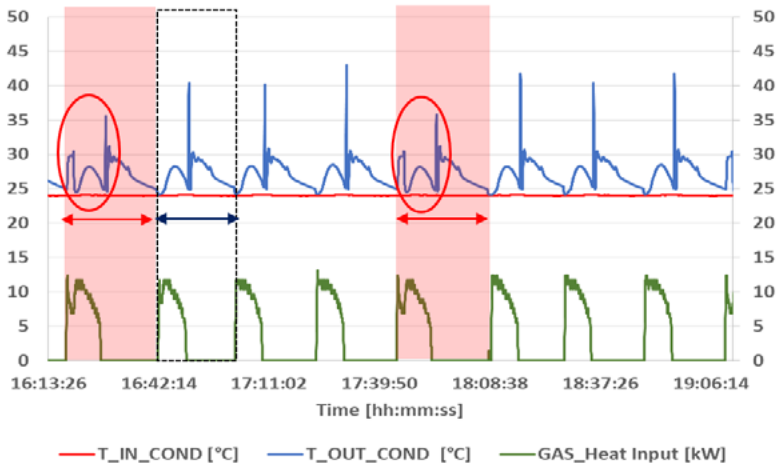

Figure 5. Operational cycles: definition of test duration (T_IN_COND – inlet water temperature to the condenser; T_OUT_COND – outlet water temperature from the condenser; GAS_Heat Input – energy input from the gas calculated with the lower heating value)

A final remark concerning the reduced capacity tests: according to the standard, when the minimum heating capacity provided by the machine is higher than the required part load ("target"), on-off tests shall be performed, i.e. tests where periods when the machine is "on" and works at the minimum allowed capacity alternate with periods when the machine is "off". The duration of these periods are calculated using a given formula. From the round robin test it emerged that these tests are not only being far away from the real operation conditions, but they are also quite time consuming.

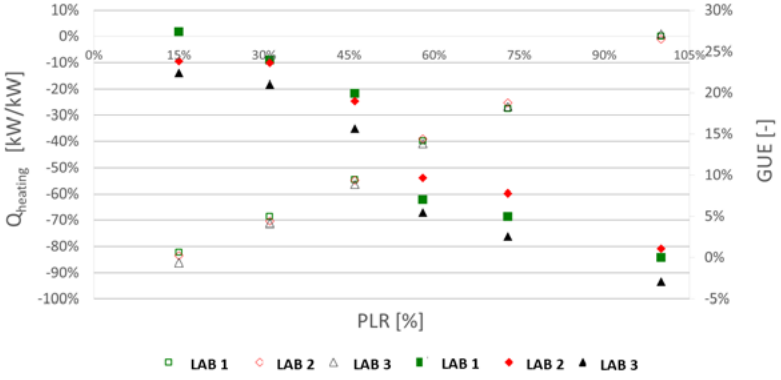

Figure 6. Dimensionless test results: measured heating capacities (left axis, filled marks) and GUE for each laboratory (right axis, hollow marks)

The round robin test involved three laboratories, two of them being also in the consortium of the EcoTest Project for performing round robin tests on fuel absorption heat pumps, as described in the next chapter.

Figure 6 shows the (dimensionless) results obtained during the round robin test. As it is possible to observe, even if there is the necessity to revise some parts of the test procedure, the achieved results showed a high grade of consistency among them especially in terms of Gas Utilisation Efficiency (GUE).

While concerning the heating capacity, due to a wrong flow rate at source side used by the laboratory 3, the difference between the highest and the lowest value on the average vary from 3 % to 7 %.

5. Round Robin Test on a water-to-water absorption heat pump (EcoTest)

Within the EcoTest project, a water-to-water absorption heat pump was tested according to EN 12309 and EN 13203-6. The aim of the project was to assess the inter-laboratory reproducibility, intra-laboratory repeatability and variability required to be used for the application of the regulations by evaluating the standards implementing those regulations. The work also aimed at commenting on the applicability and understandability of the relevant standards and their applicability in the light of market surveillance, minimise the room for different interpretations and to suggest improvements to the CEN/TCs.

5.1. Space heating efficiency according to EN 12309

The measurements according to EN 12309 were conducted by four participating laboratories. The appliance was tested for high temperature application (supply temperature of 55 °C), constant water volume flow rates at both the heat source and the heat sink. The appliance was a continuously operated water-to-water absorption unit with a nominal capacity of 40 kW.

The laboratories showed an overall high level of common understanding regarding the testing and test data evaluation methodology. Only a small number of questions in this regard were raised during the test cycle.

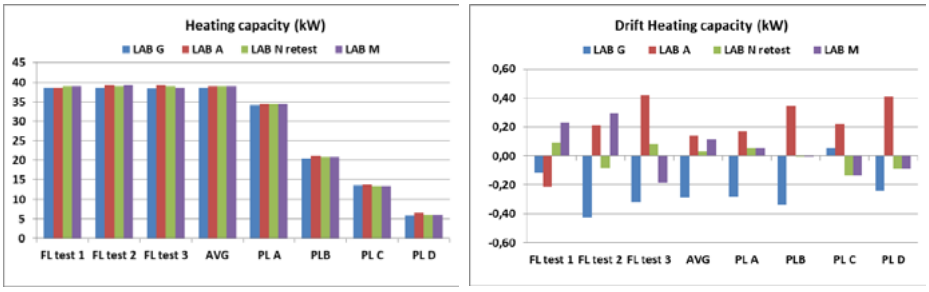

Figure 7. Measured heating capacities (left) and absolute deviation from the average value for each laboratory (right)

As shown in Figure 7, the measured heating capacities by each of the laboratory were very close to each other with a highest absolute deviation from the arithmetic mean value of 400 W or about 1 % of the nominal heating load for full load test (FL) or around 7 % for part load (PL) D (6 kW).

The test at full load was performed three times at each lab to assess the intra-laboratory repeatability of the measurement. The arithmetic average values from all three tests are shown in column “AVG”. It can be seen from Figure 7 that the intra-laboratory repeatability of the measurements did not differ in its magnitude from the inter-laboratory reproducibility, which is a positive indication for the robustness of the methodology as well as for the high level of the measurement quality by the participating laboratories.

In Figure 8, the calculated seasonal space heating efficiency η_s (left) and the deviations of the results for each laboratory from the arithmetic mean value of the round robin test (right) are shown. The difference between the highest and the lowest reported value is 3,5 %, as can be seen also in Table 2. The maximum deviation from any single reported value from the overall average is less than 2 %. Taking into account the complexity of the method and the characteristics of the appliance under test, these results can be considered to be very good and show that the provisions of the methodology described in EN 12309 are in line with the requirements of the Ecodesign and Eco Labelling Regulations in this respect. However, as only four laboratories took part in the testing, a final conclusion based on a full statistical evaluation cannot be drawn.

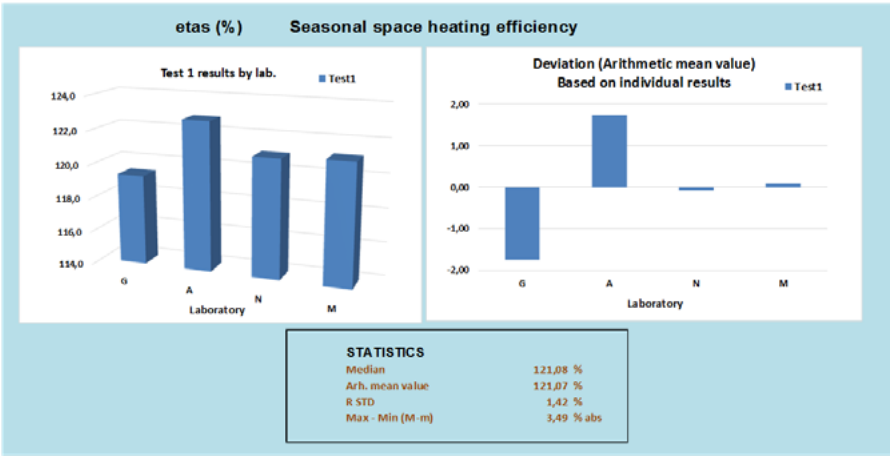

Figure 8. Calculated η_s (left) and absolute deviation from the average value for each laboratory(right)

Other reported significant efficiency parameters such as Seasonal Auxiliary Energy Factor (SAEF) and Seasonal Gas Utilisation Efficiency (SGUE) also showed very good agreement among the laboratories. In Table 2, the median, arithmetic mean, standard deviation, difference between the maximum and the minimum reported values (max-min) and its relative difference ((max-min/avg) are shown for SAEF, SGUE and seasonal space heating efficiency η_s.

Table 2. Statistical values obtained for the seasonal performance parameters for space heating

Parameter	Median	Arithmetic average	Standard deviation (σ_R)	max-min	(max-min) / avg [%]
SAEF	20,73	20,62	0,83	1,87	**9,0**
SGUE	1,48	1,48	0,02	0,04	**2,7**
η_s	121,08	121,07	1,42	3,49	**2,9**

5.2. Energy consumption for the domestic hot water production according to EN 13203-6

At the time of the testing, the EN 13203-6 was still not officially published. While scrutinising the final draft, some inconsistencies of the method compared to the methodology described in the EU Regulations and in a methodologically similar standard for electrically driven heat pumps (EN 16147:2017) were detected. Therefore, it was decided to adapt the methodology and to perform two tapping cycles for comparison: one according to EN 13203-6 and one according to EN 16147. The resulting overall test protocol is shown in Figure 9.

After the common heating-up and standby measurements, the EN 16147 tapping cycle was initiated right after the end of the standby period with the first draw-off at 07:00. After the 24 hours' cycle and after the heat pump was switched off by the controls when the set hot water tank temperature was reached, the two tapping cycles of EN 13203-6 starting with the first draw off at 21:30 were performed.

The system used consisted of the appliance described in Chapter 5.1 with an additional 1000 l tank. As the unit is not declared by the manufacturer for the DHW production, hydraulic connections and controls had to be adapted to enable the laboratories to perform the tests. Thus, the results were used only to discuss the applicability of the standard itself and not to conclude on the reproducibility or repeatability of the methodology. Already while preparing the measurement and discussing the methodology, a number of remarks on EN 13203-6 was made. Obvious mistakes and inconsistencies were fixed for the test protocol and were reported to the relevant CEN Technical Committee.

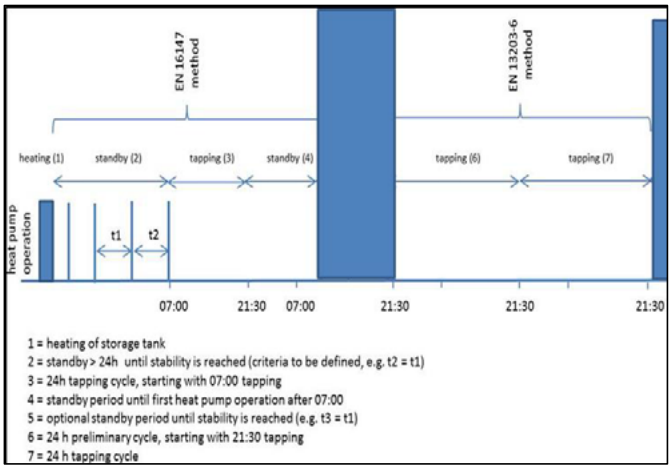

Figure 9. Test protocol for the evaluation of EN 13203-6

Table 3 shows the results for gas (Q_{gas}) and electricity (Q_{elec}) consumptions, as well as for the seasonal water heating efficiency (η_{wh}). Compared to the results for space heating, the variability of the reported results is much higher for all parameters. This lies partly in the lack of the experience with the newly developed standard, partly in the methodology description itself, but partly also in the tested system itself, since it was only adapted to the water heating function. Therefore, as stated before, the results below cannot be taken for any final conclusion regarding the measurement quality or the methodology itself.

Table 3. Statistical values obtained for the seasonal performance parameters for domestic hot water

Parameter	Arithmetic average	Standard deviation (σ_R)	max-min	(max-min) / avg [%]
Q_{gas}	24,80	2,71	5,42	**21,85**
Q_{elec}	1,32	0,12	0,12	**9,09**
η_{wh}	68,70	8,11	15,87	**23,10**

6. Conclusions

Even though there are only a few products on the market for residential heating and sanitary hot water application, a considerable amount of R&D activity is reported from many countries. The current EU legislative, including the Ecodesign and the Energy Labelling Regulations include the technology, which is a very important market drive. Further, gas heat pumps are explicitly eligible to obtain the Heat Pump Keymark, the main voluntary quality scheme in Europe – also a very important signal for the end consumers, as well as governmental subsidies, which are available for gas heat pumps in most of the principal European markets. There are testing and performance standards available – both on the CEN and national levels. The CEN standards are currently in the process of harmonisation with the Energy Labelling directive. Within two recent projects, the CEN standards EN 12309 and EN 13203 were evaluated in round robin tests. The results showed that the methodology is yielding very good results regarding applicability, repeatability and reproducibility. For the continuously operated absorption heat pump the reported seasonal efficiency values lie within 3,5 percent points for the heating application. For the water heating application, the reported values were not homogenous, mainly due to the novelty and some shortcomings of the described methodology in the standard, as well as due to the system used for the test. Further, a more in-depth analysis by the expert community pointed out some weak points of both standards and proposed improvements which will be considered by the relevant technical committees.

It has to be pointed out that the results shown above were obtained on only two products (one of which has been removed from the market) and by a rather small number of participating laboratories. As the market

develops and more products enter the market, similar trials will have to be performed in order to ensure that the testing and evaluation methodology is transparent and fair for all stakeholders.

With current primary energy efficiencies, gas heat pumps can deliver heat with 30 % higher efficiency than condensing gas boilers. If applied on a large scale as a replacement product for the gas boiler, they can considerably reduce the CO_2 emissions in short time period without the need of further investments in supply grids or building envelopes.

A large scale monitoring campaign to investigate the full potential of the technology and supply reliable information for the policy and customers would be needed. It would also send a message to hesitant manufacturers, that the investment in the technology can pay off in the future.

Abstract

As a part of the review process of the EU Ecodesign and Eco Labelling Regulations, project EcoTest was carried out in order to evaluate the standards used for assessing the efficiency of space, combination and sanitary hot water heaters and to issue recommendations to the relevant CEN Technical Committees. Within the project, all technologies with their respective standards covered by the Regulations for the aforementioned products, including some emerging technologies, were assessed in a series of round robin tests performed by accredited laboratories Europe wide. Heat pumps, as one of the acknowledged key technologies in the process of decarbonisation of heat generation in buildings, had a prominent place within the project. Four different electrically driven heat pumps were tested in a series of round robin tests following the latest versions of the relevant standards. In the present paper, selected findings of the project regarding the methodology of the standards, the reproducibility itself and influence of different parameters on the reproducibility of the methods are shown and discussed.

Keywords: Ecodesign; standards; heat pumps; comparison; round robin test

1. Introduction

In order to reduce the greenhouse gas emissions from space, combination and domestic hot water (DHW) heaters, which are responsible for 82 % of the overall final energy consumption in the residential sector within the EU [1], the European Commission introduced requirements for the energy efficiency and labelling of these products with Regulations 813/2013 and 814/2013 and Delegated Regulations 811/2013 and 812/2013 [2-5]. The regulations aim at setting minimum efficiency requirements regarding the seasonal efficiency of the products and obligatory information for the end users on the product efficiency with a labelling system using standardized, reproducible testing and efficiency evaluation methods. The described test and evaluation methods were mostly based on relevant EN standards, with some differences, which were taken into account by issuing mandates to the relevant EN technical committees to harmonise the standards with the regulations [6-7]. The implementation of these regulations started on September 26th, 2015.

Following Article 7 of the aforementioned Commission Regulation and Commission Delegated Regulation, these documents are currently in the process of revision taking into account the advancements in the market products and the applicability of the current testing methodology. In order to evaluate the applicability of the test standards, which are the basis for the performance evaluation of the products covered by the Regulations, the European Commission in cooperation with CEN asked for an action to evaluate and improve, if necessary, the relevant standards.

A group of 22 accredited laboratories gathered in a consortium won an open tender with their proposal for the project EcoTest with the aim to evaluate the standards and formulate recommendation for the CEN TCs regarding possible improvements.

2. Project EcoTest

Project EcoTest started in October 2017 and finished in July 2019. It gathered 22 accredited laboratories covering all technologies in the scope of the Ecodesign and Eco Labelling Regulations for space, combination and DHW heaters. The aim was to assess the inter-laboratory reproducibility, intra-laboratory repeatability and variability by evaluating the testing and evaluation methodology used for the implementation of those regulations. The work also aimed at commenting on the applicability and understandability of the relevant standards and their applicability in the light of market surveillance, minimise the room for different interpretations and to suggest improvements to the CEN/TCs. The structure of the project is shown in Figure 1 (left).

The work programme consisted in a series of round robin tests based on the latest versions of the relevant standards that were followed by a detailed analysis of the results for each of the technologies (product groups) in scope, **오류! 참조 원본을 찾을 수 없습니다.** (right).

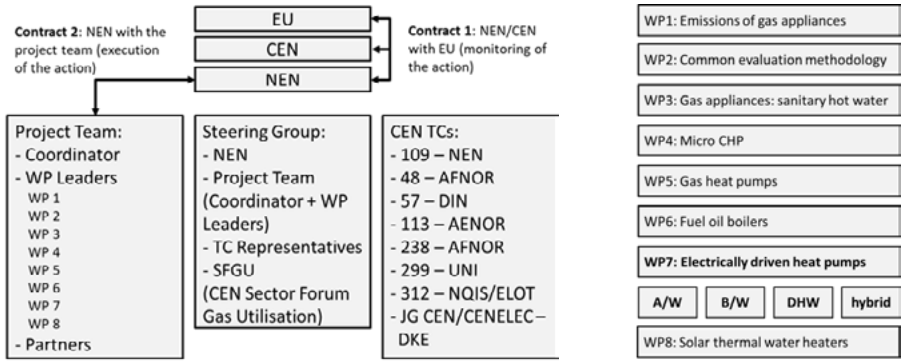

Figure 1: Structure of the EcoTest Project (left) and technologies covered within the Work Packages (right)

Besides the execution of the test and analysis of the results, the participating experts were scrutinising and commenting all applied standards. CEN/TCs were directly involved in the project work through liaisons, which facilitated a first-hand, continuous communication between the project and the CEN experts.

The outcome of the project was put into a series of reports. The main findings were collated in the Project Report. All documents were sent to the EC for approval. The publication is expected by the end of 2019.

3. Execution of the tests on electrically driven heat pumps and methodology evaluation

Within the Work Package 7 for electrically driven heat pumps, four round robin tests (RRTs) on four different appliances were executed. An overview of the main appliance data, applied test conditions and standards used is given in Table 1. A total of 8 laboratories took part in the testing. However, not all laboratories participated in all RRTs which negatively influenced the possibilities for statistical evaluation of the results in some cases.

As three out of four standards were in the process of revision at the beginning of the project, CEN/TC 113 provided the final versions of the revised standards, which had some differences in comparison to the versions in use at the time. This ensured the up-to-dateness of the results and comments, but also imposed a challenge for the participating laboratories, since some of the procedures were new (e.g. for hybrid heat pumps) and executed for the first time by most of the laboratories. This had as a consequence that the focus of RRT4 (hybrid) was rather on providing feedback on the applicability of the newly developed method and the understandability of the method description than on the repeatability or reproducibility.

All laboratories reported their values using templates which were created and distributed for each of the round robin test. A generic template for all appliances within the EcoTest project was common to ensure comparability of the results. However, this document had to be adapted to the specific needs and features of each of the appliances.

Table 1: Overview of the main appliance data, applied test conditions and standards for all four round robin tests

	RRT1	RRT2	RRT3	RRT4
Main appliance data				
HP type (source/sink)	outdoor air / water	water / water	indoor air / DHW	outdoor air / water
Capacity control	inverter	staged (2)	no	only gas burner
Indoor liquid pump	integrated	integrated	-	integrated
Outdoor liquid pump	-	not integrated	-	-
$P_{designh}$ [kW]	12	32.2	-	7 (whole unit)
Installation	outdoor	indoor	indoor	indoor
Water tank capacity [l]	-	-	300	-
DHW set temperature	-	-	55 °C	-
Profile / smart control	-	-	XL / no	-
Acoustic tests	yes	no	no	no
Test conditions and standards used				
Climate	average, "A"	average, "A"	average, "A"	average, "A"
Water flow indoor HX	fixed	fixed	-	fixed
Temperature indoor HX	variable outlet	variable outlet	-	variable outlet
Water flow outdoor HX	-	fixed	-	-
Temperature application	low (35 °C)	medium (55 °C)	-	medium (55 °C)
Liquid pump indoor	integrated	-	-	-
Standards implemented	EN 14511 [8], EN14825 [9], EN 12102-1 [10]	EN 14511, EN14825	EN 16147 [11]	EN 14511, EN14825

After completing a test, a laboratory first sent preliminary data to the work package leader (WPL) who checked them and gave his consent to the reporting lab to send the appliance to the next laboratory. Final results and selected measurement data were reported to the WPL using the templates, as described above. The WPL processed the received data in the following steps:

1. All received data were first checked for plausibility and reporting errors like signs, units, syntax errors etc. Obvious errors were corrected by the WPL.
2. The data sets were compared to each other and outliers and stragglers were detected using a common analysis procedure, as described below.
3. The key performance values were recalculated from the provided data in order to detect inconsistencies and errors in the calculations.
4. A check of the compliance of relevant values with the permissible deviations defined in the standard was carried out.

All deviations, inconsistencies – obvious or assumed – were protocolled for all round robin tests. The reported data and the found inconsistencies were discussed within the group or in telephone calls or emails between the WPL and the respective laboratory in order to find the cause and to decide whether the whole test or a part of it needed to be repeated or a calculation procedure used revised.

A number of corrections were made in the course of the data evaluation. All corrections have been added to the protocols and the most important ones – influencing the final result – were reported in the Final Report which gives a detailed analysis of the specific results from each of the round robin tests.

4. Main results for electrically driven heat pumps

4.1. Compliance with the procedures

In general, all the laboratories showed a very high level of knowledge regarding the implementation of standardised test methods to different kinds off appliances. Some deviations from the described methodology

or the common practice in some laboratories were detected but they could be attributed mostly to the imprecise formulation within the standards and also to translation issues. In this respect, a number of comments to the TC113 consider clarification in the methodology description.

Most issues regarding the compliance with the procedures were observed during the testing of the hybrid appliance since the methods were used for the first time by all laboratories except one. Discussions prior to, during and after the measurements delivered valuable input to the TC 113 and ad hoc JWG TC 113/WG7 – TC 109/WG1 which has the mandate to develop testing procedures for this type of appliances.

4.2. Compliance with the requirements regarding permissible deviations

The laboratories showed a very high level of maintaining the operating conditions within the permissible deviation ranges throughout the measurements. However, some laboratories did exceed the limits in a small number of cases, both for mean as well as for single measured values.

Table 2 shows the deviations of measured values to the operation conditions' target values for RRT1 and Table 3 the same quantities for RRT2. The biggest problem for the laboratories, as expected, was to reach and maintain the relative humidity of the outdoor air within the required tolerances (RRT1, Table 2). Interestingly, all laboratories managed to keep the single measured vales within the tolerance band of ± 1 K. However, the maximum allowed deviation of the mean from the target value was in one case (one laboratory, one operating condition) outside the tolerance band of ± 0.4 K.

Table 2: Deviations of measured to the operation conditions' target values for RRT1 (impermissible deviations marked in bold)

RRT1: A/W Heat Pump					
		deviation of mean values		*deviation of single measured values*	
		permissible deviation	*max*	*permissible deviation*	*max*
Outdoor heat exchanger					
Inlet air temperature (dry bulb)	*°C*	±0.3	0.19	±1.0	0.71
Inlet air temperature (wet bulb)	*°C*	±0.4	**-0.43**	±1.0	-0.83
Temperature difference (db-wb), deviation from 1 K	*K*	±0.3	**-0.41**	-	0.49
Indoor heat exchanger					
Outlet temperature	*°C*	±0.3	0.11	±0.6	0.40
Inlet temperature	*°C*	±0.2	-0.12	±0.5	-0.37
Mass flow	*%*	±1.0	**-1.03**	±2.5	-1.53
Voltage	*%*	±4.0	2.34	±4.0	3.49

All water temperatures, both at the inlet and at the outlet of the appliances, could be kept well within the respective permissible deviation bands, as well as the voltage. Keeping the mass flow rate constant seems to be a challenge for some laboratories. In RRT2, one laboratory exceeded permissible deviation for the mass flow rate mean value by far in case of one operating condition, which, however, did not significantly influence the final result of the measurement.

Table 3: Deviations of measured to the operation conditions' target values for RRT2 (impermissible deviations marked in bold)

RRT2: W/W Heat Pump				
	deviation of mean values		*deviation of single measured values*	
	permissible deviation	*max*	*permissible deviation*	*max*

Outdoor heat exchanger					
Outdoor HX inlet temperature	*°C*	±0.2	0.1	±0.5	-0.3
Outdoor HX outlet temperature	*°C*	±0.3	0.09	±0.6	0.21
Indoor heat exchanger					
Indoor HX inlet temperature	*°C*	±0.2	0.1	±0.5	0.35
Indoor HX outlet temperature	*°C*	±0.3	0.15	±0.6	0.39
Mass flow rate indoor HX	*%*	±1.0	**-1.08**	±2.5	1.99
Mass flow rate outdoor HX	*%*	±1.0	**1.99**	±2.5	**-4.21**
Voltage	*%*	±4.0	2.24	±4.0	2.79

In Table 4, the deviations of measured to the operation conditions' target values for the indoor-air DHW heat pump during the draw-off test are shown. The provided values are considering only the periods with draw-offs and not the entire 24 h test. Even though the arithmetic mean values were very well within the permissible deviation range, the single measured values of the indoor air were well outside the range at one laboratory. The temperature of the cold water at the inlet was not always within the permissible ±1 K at two laboratories.

Table 4: Deviations of measured to the operation conditions' target values for RRT3 during Stage E (EN 16147). Impermissible deviations marked in bold

RRT3: DHW Heat Pump (draw-offs)						
			arithmetic mean values for the entire tapping cycle		*individually measured values*	
			deviation of mean values		*deviation from target*	
		target value	*permissible deviation*	*max*	*permissible deviation*	*max*
$T_{air,dry\ bulb}$	*°C*	20	±0.6	0.27	max. ±1.5	**2.49**
$T_{air,wet\ bulb}$	*°C*	15	±0.4	0.18	max. ±1.0	**3.45**
$T_{cold\ water,inlet}$	*°C*	10	±1.0	-0.72	±1.0	**1.74**

4.3. Reproducibility of the methods

One of the key aims of the project was to evaluate the reproducibility of the standardised test methods and to investigate possible improvements, especially regarding the key performance factors such as seasonal efficiency $\eta_{s,h}$ for heating appliances and η_{wh} for DHW appliances.

After the initial inspection of the data received from the participating laboratories, a number of errors was discovered. In order to evaluate their influence on the final result ($\eta_{s,h}$ or η_{wh}), all errors were divided into five categories:

1. Syntax error or wrong units, no influence on the final result;
2. Problem with the measurement or data acquisition / post processing, no correction possible but no influence on the final result;
3. Problem with the measurement / data post processing, influence on the final result. Corrected by the laboratory;
4. Problem with the measurement or data acquisition / post processing, no correction possible, influence on the final result;
5. Procedure not followed, influence on the final result.

Many small errors occurred in the course of transferring data into the provided templates. These errors were mostly corrected by the work package leader and were not further considered since they are not likely to happen in circumstances outside of this project (category 1). Some errors were attributed to e.g. the wrong setting of the measurement equipment, but did not influence the result such as setting of the voltmeter for one instead of three phase measurement (category 2). In quite a number of cases, the laboratory reported a wrong value or made a mistake in the calculation. These values were then corrected by the laboratory itself and put into protocol (category 3). In a small number of cases, the laboratories did not comply with the procedures or acquired wrong measurement values which did influence the final result (categories 4 and 5). These errors were, however, rather isolated and could be attributed to the novelty of the method (as for hybrid units) or alternative understanding of the procedure. In cases where errors of categories 4 or 5 happened and the measurement could not be repeated, the results were mostly not taken into account for statistical evaluation (if very obvious) or detected as outliers / stragglers during the statistical analysis.

Table 5: Analysis of the error types encountered in the analysis of the reported data

	RRT1	RRT2	RRT3	RRT4
Category 1	47%	31%	60%	48%
Category 2	0%	0%	0%	14%
Category 3	51%	29%	40%	21%
Category 4	1%	0%	0%	4%
Category 5	0%	40%	0%	12%
# Errors	78	48	10	188

Table 5 shows the number of different error types found in the reported data from the four RRTs. The number of errors is taking into account each single value that was affected, including error propagation up to the final figure. It can be seen that most errors were found in RRT4 for the test on the hybrid appliance. That was expected, since the test methods applied were new and the staff performing the tests had no previous experience. Also interesting, that quite a number of errors of category 5 (procedure not followed) were found in RRT2 for the test of a staged water-to-water heat pump. The reason was the same as for RRT4 – these appliances are not so commonly tested in most laboratories.

Quite a large absolute number of errors of category 3 found, especially in RRT1 and RRT2, could be attributed to the issues connected to the measurement of the electricity consumption in non-active operation modes and calculation errors in the data post-processing. These issues were specifically addressed in the recommendations to the TC 113.

The impact of the detected errors in the initially reported values can be seen from Table 6. It shows the differences between the highest and the lowest reported values by all laboratories for $\eta_{s,h}$ and η_{wh} (RRT3) before and after all corrections have been made. In case of RRT1, the difference slightly increased, in most cases, however, it could be considerably reduced.

Table 6: Difference between the maximum and minimum reported values for $\eta_{s,h}$ or η_{wh} from initially reported values and after corrections

max-min	RRT1	RRT2	RRT3	RRT4 separated	RRT4 combined
initial	24.10	33.30	8.09	51.70	19.27
final, after corrections	25.20	14.10 (2.00)	8.09	2.30	7.20

High difference for RRT1 can be explained with different behavior patterns of the unit in some of the laboratories. In one case, the unit performed a defrost cycle at 7 °C outdoor air temperature, which considerably lowered the calculated seasonal efficiency. If these results are removed from the analysis, the max-min value drops from 25.2 to 16.8. Another factor which had a considerable influence on the results in RRT1 and RRT2 was the measurement of the electricity consumption in non-active operation modes. It was found, that the if

the standby mode was reached by lowering the thermostat on one hand or by setting the operation mode to "summer" on the other, substantially different electricity consumptions were measured. This influence can be seen in

Table 6: Difference between the maximum and minimum reported values for $\eta_{s,h}$ or η_{wh} from initially reported values and after corrections

in the RRT2 column. In the first case, the final value for max-min is 14.10, in the second it drops to 2.00.

In Table 7, the statistics on the main parameters from all RRTs are shown. The main quantities shown in the table are the following:

- median: median value from all reported values;
- average: arithmetic mean value from all reported values;
- sR: standard deviation;
- minmax: difference between the highest and the lowest reported value for the parameter;
- **minmax/avg**: difference between the highest and the lowest reported value for the parameter, divided by the arithmetic mean value in %. **This quantity was chosen as the main parameter to conclude on the reproducibility**;
- R1 (abs): reproducibility calculated by multiplying the standard deviation by a factor of 2.83;
- R2 (abs): reproducibility calculated by multiplying the standard deviation by a factor of 4.00;
- R1 (%avg) and R2 (%avg): reproducibility calculated as a percentage of the average;
- N test-lab: the number of reported, valid test results. For each laboratory only one result is considered;
- stragglers and outliers: indication whether there are stragglers (an unusual data point which, when examined using e.g. Grubbs' test, Cochran's test or KSD has the probability between 1 % and 5 % of being valid) and outliers (an unusual data point which, when examined using e.g. Grubbs' test, Cochran's test or KSD has the probability of less than 1 % of being valid) and how many.

However, the number of reported values, i.e. participating laboratories in the RRTs was in the context of statistic evaluation relatively low. Thus, the statistic evaluation of the results can be taken rather as a guide to address some of the issues that were found during the tests than as a hard fact in order to finally conclude on the reproducibility of the methods or to provide recommendations for e.g. adjustment of the market surveillance tolerances.

For a number of parameters taken into account a straggler or an outlier were found. The data were then evaluated again without the straggler or the outlier. These values are indicated with (w/o straggler) or (w/o outlier). In presented data sets, not more than one straggler or one outlier per parameter were found, if any. When excluded, the reproducibility improved significantly. However, in some cases a new straggler or outlier have been detected (indicated with "one new straggler / outlier"). The data were not repeatedly evaluated without the indicated straggler or outlier.

The variation of the reported efficiency figures for the air-to-water capacity controlled heat pump (RRT1) was rather high. The main reason for that was the difference in the appliance behaviour during the testing and presumably influence of the control setting during the measurements of electricity consumption during non-active operation modes as well as different possibilities to account for the efficiency losses during on-off operation of the heat pump (C_d factor). If excluded from the analysis, the reproducibility of the results increases considerably. The same observations were made for the water-to-water two-stage heat pump (RRT2).

The sound power measurements showed relatively good agreement of the results among the laboratories. However, the variability of the results is higher than the market surveillance verification tolerance defined by the European Commission of 2 dB. However, if a straggler is removed, the difference between the highest and the lowest reported values drops down to 1.32 dB. Also here, some differences in the appliance behaviour could be observed regarding the fan speed, which has the largest single influence on the overall sound power level. No direct correlation between the applied measurement methods and the obtained sound power could be observed.

A considerably lower variability in the reported efficiencies was observed for the DHW heat pump. The minmax/avg value was 4 % after removing a straggler. Also the values for the reference hot water temperature θ'_{wh} showed a very good agreement for all laboratories. The reported volumes of mixed water (V_{40}), however, showed much higher deviations. One laboratory reported a volume smaller by 36 l or around 10 % from the arithmetic mean of the whole measurement series, which was detected as an outlier. The reason for such a measurement outcome could not be found during the discussion of the results with the laboratory. If removed from the statistical evaluation, the minmax/avg value drops to the same level as for other reported parameters.

The two newly developed test methods for hybrid heat pumps (RRT4) showed a very good agreement of calculated efficiencies among themselves. For the separated method, being the simpler one between the two, the difference between the maximum and the minimum reported efficiency figures was very low – around 2 %. Results from the combined method show a much higher variability, at levels comparable to RRT1 and RRT2. These relatively high values could be reduced by half after removing a straggler.

4.4. Brainstorming on standards

The standards used in Work Package 7 have been repeatedly discussed and revised in the past years. At the time when the round robin tests began, all but one standard were under revision and new versions just about

to be published. Meanwhile, all versions of the standards used in the project have been published but most of them are already in a new revision process which will consider the outcome of the EcoTest project.

The cause for an almost on-going revision process is that the heat pump market is developing very fast and the emerging products are increasingly complex with more sophisticated controls and rising application diversity. Therefore, many features of the newly published standards were applied by most of the laboratories for the first time and the comments were collected until the end of the testing period. This gave the group less time to discuss the issues reported and search for possible solutions or investigate them within the round robin tests. A considerable number of comments was handed over to TC113 for further discussion.

5. Conclusions and further steps

There are many different types of heat pump appliances on the market win a variety of different configurations using different heat sources. Not all could be covered by the project. Through the choice of the appliances for the round robin tests, an attempt was made to cover as much features of the standards as possible.

From the analysis of the reported data, certain conclusions, some of which can be generally applied to all conducted round robin tests, can be made. In the WP7 Final Report, a more detailed analysis is provided for each of the tested appliances and used test procedures.

- Very good general understanding of the rather complicated test methods by the laboratories, even for appliances which were not easy to test. However, in certain points the reading of the standards differs among the laboratories. As the complexity of the appliances increases, as well as the type of applications covered, it gets harder to follow all the requirements of the standards.
- The specifications for some procedures in certain measurement cases are quite scattered around the standards and can be hard to understand and to follow by laboratories / engineers with less experience. This is especially the case if in a new, revised standard some changes in formulae, coefficients etc. are made.
- All laboratories have shown a high level of accuracy regarding reaching and keeping all test conditions constant throughout the measurements. In just a few cases, minor deviations outside of the permissible range have been found which in most cases did not significantly influence the final result. The parameters, for which outliers could be found, are in areas which are quite well controllable. A better real-time control of these parameters could be implemented to avoid exceeding the permissible deviations.
- In general, the settings on the appliance may quite vary from one laboratory to the other if no or insufficient information from the manufacturer is available. As the controls get more complicated, the variety of possibilities to reach a certain test condition rises. Thus, with current test methods, the support from the manufacturer has an influence on the reproducibility of the results.
- Differences in the measured values for the electricity consumptions in non-active operation modes have been observed. It has not been completely clarified in all cases whether the laboratories used different settings to reach the operation mode or the appliances behaved differently. It was shown that with alternative settings on the controller different values were measured by the same laboratory, which had a considerable influence on the seasonal efficiency (RRT2: 16 % for $\eta_{s,h}$).
- Quite large reported differences between the highest and the lowest values for seasonal efficiencies ($\eta_{s,h}$) for air-to-water capacity controlled (25.2 %) and water-to-water staged (14.1 %) unit. However, the difference could be diminished by:

    a. calculative elimination of the appliance behaviour influence, influence of the freedoms in calculation of seasonal efficiencies;
    b. using an alternative method for the measurement of the electricity consumption in non-active operation mode (influence of the manufacturer's support).

Even though valuable conclusions and recommendations for the improvement of the relevant standards could be made from the project, many issues – some of which were found in the course of testing and discussions – still remain unsolved. In order to solve some of these issues, further experimental investigation on a broader basis is needed. Therefore, a clear commitment regarding the importance of the standardisation work, followed by financial support for similar joint actions, from both the industry and the policy is needed.

Acknowledgements

The project EcoTest was financed by the EU, agreement number A/CEN/GROW/EFTA/534/535/2015-14

The authors would like to thank all participants of the EcoTest Project for good cooperation and commitment without which this publication would not have been possible.

The influence of different water-injection methods on water vapor high temperature heat pump

Di Wu[a], Bin Hu[a*], R.Z. Wang[a]

[a]Institute of Refrigeration and Cryogenics, Shanghai Jiao Tong University, Shanghai 200240, China

Abstract

To yield higher temperature output and better performance, a high temperature heat pump with water refrigerant is developed and the corresponding prototype is established. Water-injection is adopted to reduce the discharge superheat. The theoretical results show that compared with HFO and HC refrigerants and traditional HFC refrigerant, water has better performance when the condensation temperature is above 100°C. With the increase of the condensation temperature, the simulation performance of water vapor heat pump is better, which means water is more suitable for higher temperature application fields. Based on the experimental investigation, the system performance with different injection lines and ports are compared. Its start-up and dynamic performance present that this heat pump reaches steady-state in 10 minutes and water-injection can effectively decrease the discharge temperature. The internal injection line can realize the self-adjustment of injected-water and discharge temperature. The coefficient of performance of this heat pump with internal water-injection is better than that of external.

Keywords: Water refrigerant; High temperature heat pump; COP; Internal water-injection;

1. Introduction

Global warming has always been a major environmental issue of concern to the whole world, which has brought a huge and disastrous impact on global biodiversity and the stability of the ecological environment. In order to curb global warming, effective methods must be adopted to reduce the consumption of fossil fuels and the emission of greenhouse gases. Heat pumps are an energy-saving technology with significant potential for industrial applications. Especially, vapor compression heat pumps are the most widely used and are available in a wide variety of sizes for different applications [1].

As shown in Fig. 1, the heat pumps can be classified as low-temperature heat pumps (LTHPs), medium-temperature heat pumps (MTHPs), high-temperature heat pumps (HTHPs), and ultra-high-temperature heat pumps (UHTHPs). In this classification, the different kinds of heat pumps are strictly defined by the output temperature and loosely defined by the heat source temperature. Based on the above classification, the vapor compression heat pump with output temperature ranging from 100℃ to 160℃ is regarded as the HTHP. Many researchers are studying the HTHP with different working fluids, including natural refrigerants [2, 3], HCs [4, 5] and HFOs [6, 7]. Bamigbetan O et al. [8, 9] experimentally investigated an R600 HTHP with a prototype compressor for industrial waste heat recovery from 50℃ to heat delivery at 115℃. Kondou C et al. [10] designed different cycle configurations with R1234ze(Z) refrigerant to supply the output temperature of 160℃ as the waste heat was 80℃. Arpagaus C et al. [11] examined the experimental performance of R1336mzz(Z) in a laboratory single-stage HTHP with 5~10 kW heating capacity using a variable speed piston compressor. When the heat source is 60℃ and output is 110℃, the coefficient of performance (COP) of this R1336mzz(Z) heat pump with an internal heat exchanger is 3.0 with a 24% increment compared with

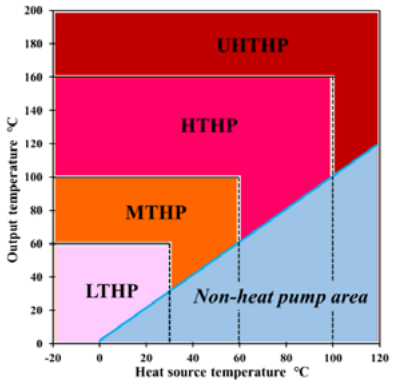

Fig. 1. The classification of vapor compression heat pump

it. By comparing with other HFO and HCFO refrigerants theoretically, they also found that R1336mzz(Z) achieves the highest COP in the temperature range from 120℃ to 10℃ [12]. Wu D et al. [13, 14] presented a novel water vapor HTHP system with 80~90℃ waste heat recovery and above 100℃ hot water supply. When the evaporation temperature was 85℃, the COP decreased from 6.10 to 1.96 with condensation temperature increasing from 110℃ to 150℃.

In this work, based on the existing experimental investigation on water vapor HTHP, preliminary experimental investigation of the water vapor HTHP system performance with different injection lines and injection ports is carried out to find the effect of different injection methods on the heat pump performance.

2. Working fluid

Nowadays, the selection principle of refrigerant takes ozone depletion potential (ODP) and global warming potential (GWP) into consideration and considers them as the main indexes on environmental protection, which limits that ODP is 0 and GWP is below 150 [15]. In Table.1, five kinds of refrigerants (GWP<150)-R718, R600, R601, R1234ze(Z) and R1336mzz(Z)-are chosen to be used in HTHP systems as working fluids. A high GWP HFC refrigerant, R245fa, is added as the representative of traditional HTHP refrigerants.

Table.1 The properties of HTHP refrigerants [1, 16]

Refrigerant	Chemical formula	T_{crit} /℃	P_{crit} /bar	ODP	GWP	SG	NBP/℃
R718	H_2O	373.9	220.6	0	0	A1	100.0
R600	$CH_3CH_2CH_2CH_3$	152.0	38.0	0	20	A3	-0.5
R601	$CH_3CH_2CH_2CH_2CH_3$	196.6	33.7	0	20	A3	36.1
R1234ze(Z)	$CHF=CHCF_3$	150.1	35.3	0	1	A2	9.8
R1336mzz(Z)	$CF_3CH=CHCF_3$	171.3	29.0	0	2	A1	33.4
R245fa	$CHF_2CH_2CF_3$	154.0	36.5	0	858	B1	14.9

The theoretical performance of HTHPs with these selected refrigerants are calculated in an idealized single-stage heat pump cycle with the following assumptions: (1). the condensation and evaporation processes are isobaric; (2). the expansion process is isenthalpic; (3). the suction temperature of the compressor has 20℃ superheat for R601 and R1336mzz(Z) and has 5℃ superheat for the left refrigerants; (4). compression process with a constant isentropic efficiency of 0.7; (5). the condensation temperature increases from 100℃ to the critical temperature with a constant 40℃ temperature lift.

The calculation results and comparison at 40℃ temperature differences are illustrated in the following pictures, including the COP (Fig. 2), the compression ratio (Fig. 3) and the volumetric heating capacity (Fig. 4).

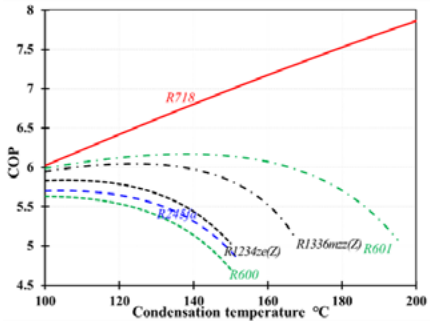

Fig. 2. The COP of the HTHPs with selected refrigerants

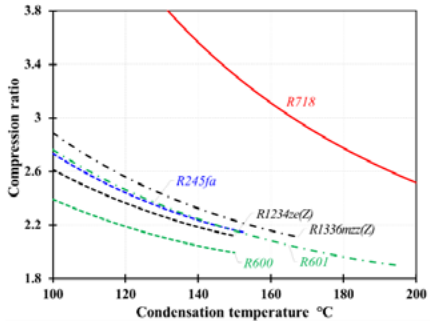

Fig. 3. The compression ratio of the HTHPs with selected refrigerants

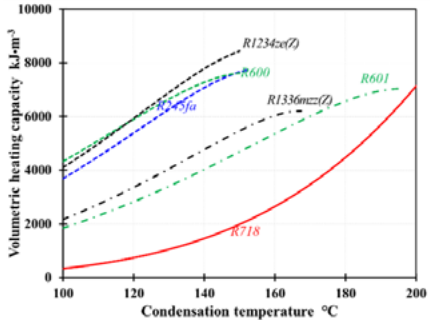

Fig. 4. The volumetric heating capacity of the HTHPs with selected refrigerants

Based on the above table and calculation results, compared with the other five refrigerants, water has many advantages in HTHP applications, especially in ultra-high-temperature output fields. Water has the highest critical temperature, the best environmental protection performance, and the safest property. The calculation COP, shown in Fig.2, also presented that water has the best theoretical performance when the condensation temperature is above 100℃. However, Fig.3 and 4 also illustrated the disadvantages of water refrigerant in heat pump systems. Compared with the other kind of refrigerants, water has the biggest compression ratio and the smallest volumetric heating capacity in the simulation conditions. So the application of water in the HTHP field needs an appropriate compressor with a bigger compression ratio to satisfy high temperature lift and a bigger volume flow rate to overcome its small volumetric heating capacity.

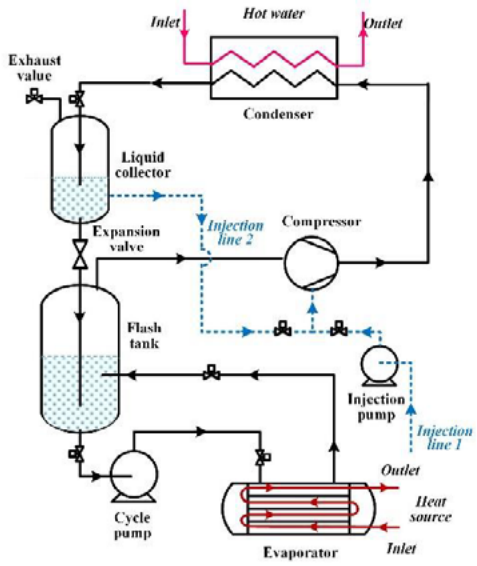

Fig. 5. The schematic diagram of the R718 HTHP with two injection lines

Furthermore, the big compression ratio of water will also lead greatly high discharge superheat and temperature in the heat pump system. So the discharge superheat and temperature must be lowed to promise the safety application of water in HTHP systems. What's more, with the increasing of the condensation temperature, the simulation COP and volumetric heating capacity of water vapor HTHP increases and the compression ratio of the heat pump decreases, which means water vapor HTHP has better performance in higher temperature application fields.

3. Water vapor HTHP

As shown in Fig.5, the schematic diagram of the water vapor HTHP has two different injection lines: external injection line (injection line 1) and the internal injection line (injection line 2). The external injection line is used to inject water from the outside with constant pressure and low temperature, and the internal injection line is used to inject condensed water from the liquid collector with various pressure and high temperature. There are also two injection ports in the water vapor HTHP prototype: the suction side injection port and the compression chamber injection port. These different injection lines and ports may have different effects on the performance of the water vapor HTHP.

4. Experimental results

Based on the schematic diagram of the water vapor HTHP, a prototype of this heat pump with two different injection lines and two different injection ports were set up. Experimental investigations were carried out to study the performance of the water vapor HTHP, including the start-up and dynamic performance, the influence of different injection ports and the injection lines.

4.1. Start-up and dynamic performance

As shown in Fig. 6(a), (b), and (c), the start-up and dynamic performance of the water vapor HTHP is presented with internal water injection in the compression chamber. With the rotate speed increasing from 0 to 5000 rpm in 8 minutes, the system reached steady-state in 10 minutes as the evaporation pressure was uncharged near 0.4 bar and other working properties were steady. In the start-up process, with the increase of the rotate speed, more water vapor was suctioned from the evaporator and the evaporation pressure decreased directly. At first, the condensation pressure increased and then decreased with the increase of the rotate speed,

which is mainly due to the accumulation of the discharge steam and the flow rate of the condensation water. With the increase of the rotate speed, the discharge temperature and superheat temperature increased rapidly as the rotate speed was above 2400 rpm. In order to control the discharge temperature in the start-up process, the injected-water was injected into the compressor with a much higher flow rate when the rotate speed was 2400 rpm. After the rotate speed reaching the highest value, 5000 rpm, the flow rate of the injected-water was adjusted to control the discharge temperature near the saturation temperature.

After the start-up process, by adjusting the opening of the expansion valve to control the condensation temperature, the dynamic performance of the water vapor HTHP was illustrated as the rotate speed and the evaporation pressure were invariant. With the increase of the condensation temperature, more power consumption was demanded to protect the larger compression ratio and enthalpy lift in the compression process. Larger compression ratio and enthalpy lift mean higher discharge temperature and more injected-water, so the flow rate of the injected-water also increased. However, the flow rate of the injected-water is not only controlled by the opening of the injection valve but also adjusted by the pressure of liquid collector. As shown in Fig. 6(c), when the opening of the injection valve is fixed, with the increasing of the condensation pressure, the flow rate of injected-water also increased to control the discharge temperature. When the pressure adjustment of the injected-water was failure and the discharge temperature was higher than the saturation temperature, the opening of injection valve will permit more injected-water to control the discharge temperature.

4.2. The influence of injection ports

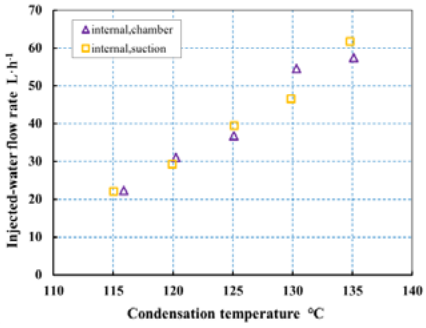

Fig. 7(a) Injected-water flow rate comparison

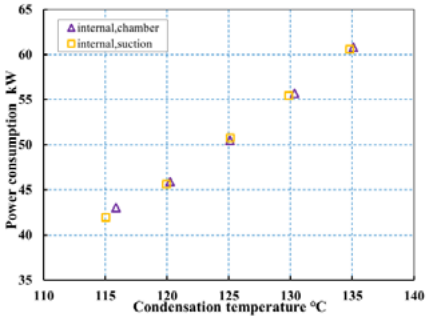

Fig. 7(b) Power consumption comparison

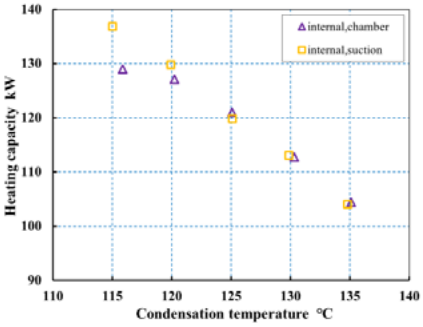

Fig. 7(c) Heating capacity comparison

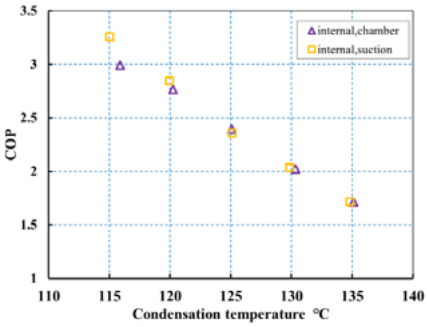

Fig. 7(d) COP comparison

Fig. 7. The performance comparison of the water vapor HTHP with different injection ports

There are two different injection ports designed in the water vapor HTHP. One is in the compressor chamber with water directly injected into the compression process to lower the discharge temperature. The other is in the suction side with water injected into the suction side of the compressor and then mixed with water vapor and suctioned into the compression chamber. When the water is injected into the system, different injection ports may have different effects on the system performance, especially on the control of the discharge temperature. When the water is injected into the compressor chamber, it can directly absorb the superheat of the compressed water vapor and lower the temperature timely. However, when the water is injected into the suction side, it can separate and mix uniformly with the water vapor, which is better for absorbing heat in the compression process. The control of the discharge temperature has a delay as the water is injected into the suction side.

To compare the influence of different injection ports, an experimental investigation is carried out with internal water injection at 73°C evaporation temperature. The result comparison is shown in Fig. 7(a) to (d), including the injected-water flow rate, power consumption, heating capacity, and COP. The result presented that the difference in system performance with different injection ports is not obvious and the injection ports have little influence on the system performance. This may due to that the compression process is faster than the heat transfer in the compression chamber, and most of the injected-water has not evaporated into steam when it was discharged from the compressor. So the separate and fogging degree of the injected-water has little influence, and the flow rate of the injected-water plays the most important role. However, more experimental investigations are needed to prove the results.

4.3. The influence of injection channels

To provide the steady of the injected water and keep the mass conversation of the water in the system, two injection lines are designed in the water vapor HTHP, external water injection from the outside and internal

water injection from the liquid collector. When the injected-water is from the outside, the temperature, pressure

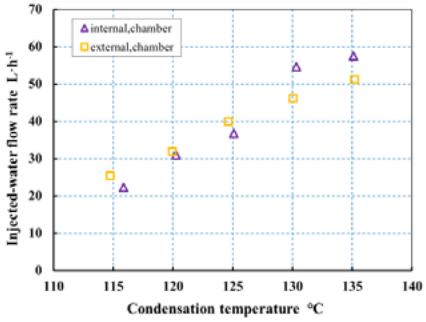

Fig. 8(a) Injected-water flow rate comparison

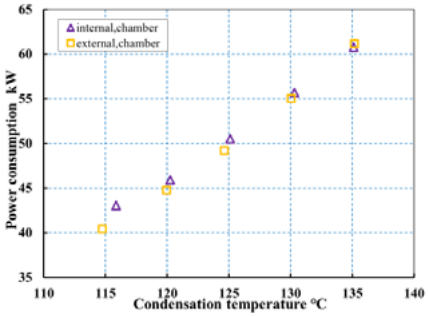

Fig. 8(b) Power consumption comparison

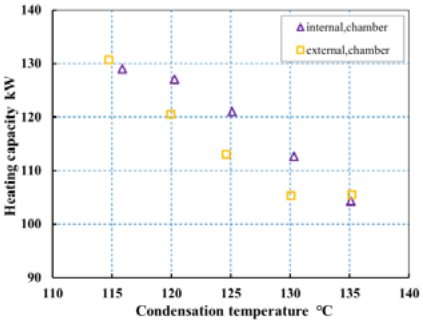

Fig. 8(c) Heating capacity comparison

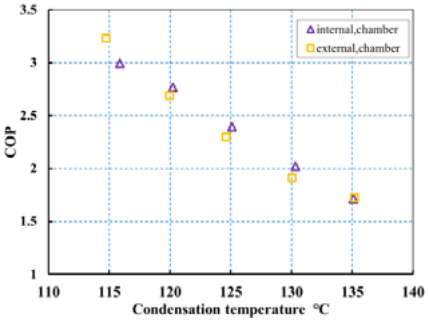

Fig. 8(d) COP comparison

Fig. 8. The performance comparison of the water vapor HTHP with different injection channels

and flow rate of the injected-water are controlled easily, which is good for the steady operation of the heat pump. However, external water injection will lead to an increase in the working fluid in the system, and destroy the balance of long-time operation. In this experimental investigation, to keep the balance of the water refrigerant in the system with the external water injection, some water will be discharged from the liquid collector. When the injected-water is from the liquid collector, the system working fluid is conversation and the flow rate of injected-water will increase simultaneously with the increase of the condensation temperature. It can realize the self-adjustment of injected-water and discharge temperature of the system. However, the temperature and pressure of the injected-water are changed with the condensation temperature.

The experimental investigation is carried out with different injection channel at 73℃ evaporation temperature. The result comparison is shown in Fig. 8(a) to (d), including the injected-water flow rate, power consumption, heating capacity, and COP. The result presented that the difference of injected-water flow rate and power consumption with different injection lines is not obvious. However, the heating capacity and COP of the two injection line systems are different. The internal injection system has better heating capacity and COP, which may due to the higher temperature of the injected-water.

5. Conclusions

Water vapor HTHP is a significant vapor compression heat pump with a high output temperature. The theoretical simulation results show that compared with new HFO and HC refrigerant and traditional HFC refrigerant, R718 has better performance when the condensation temperature is above 100oC. What's more, with the increasing of the condensation temperature, the simulation COP and volumetric heating capacity of water vapor HTHP increases and the compression ratio of the heat pump decreases, which means water vapor HTHP is more suitable for higher temperature application fields. Its start-up and dynamic performance

present that this heat pump can reach steady-state in 10 minutes and water injection can effectively decrease the discharge temperature. The internal injection line can realize the self-adjustment of injected-water and discharge temperature. When the opening of the injection valve is fixed, with the increasing of the condensation pressure, the flow rate of injected-water also increased to control the discharge temperature. When the pressure adjustment of the injected-water was failure and the discharge temperature was higher than the saturation temperature, the opening of the injection valve will permit more injected-water to control the discharge temperature. Different injection ports have little influence on heat pump performance. However, the different injection channels have influence on the heat pump performance, especially on the heating capacity. So it is very significant to design a suitable water vapor heat pump cycle with the best injection method.

Abstract

To yield higher temperature output and better performance, a high temperature heat pump with water refrigerant is developed and the corresponding prototype is established. Water-injection is adopted to reduce the discharge superheat. The theoretical results show that compared with HFO and HC refrigerants and traditional HFC refrigerant, water has better performance when the condensation temperature is above 100°C. With the increase of the condensation temperature, the simulation performance of water vapor heat pump is better, which means water is more suitable for higher temperature application fields. Based on the experimental investigation, the system performance with different injection lines and ports are compared. Its start-up and dynamic performance present that this heat pump reaches steady-state in 10 minutes and water-injection can effectively decrease the discharge temperature. The internal injection line can realize the self-adjustment of injected-water and discharge temperature. The coefficient of performance of this heat pump with internal water-injection is better than that of external.

1. Introduction

Global warming has always been a major environmental issue of concern to the whole world, which has brought a huge and disastrous impact on global biodiversity and the stability of the ecological environment. In order to curb global warming, effective methods must be adopted to reduce the consumption of fossil fuels and the emission of greenhouse gases. Heat pumps are an energy-saving technology with significant potential for industrial applications. Especially, vapor compression heat pumps are the most widely used and are available in a wide variety of sizes for different applications [1].

As shown in Fig. 1, the heat pumps can be classified as low-temperature heat pumps (LTHPs), medium-temperature heat pumps (MTHPs), high-temperature heat pumps (HTHPs), and ultra-high-temperature heat pumps (UHTHPs). In this classification, the different kinds of heat pumps are strictly defined by the output temperature and loosely defined by the heat source temperature. Based on the above classification, the vapor compression heat pump with output temperature ranging from 100℃ to 160℃ is regarded as the HTHP. Many researchers are studying the HTHP with different working fluids, including natural refrigerants [2, 3], HCs [4, 5] and HFOs [6, 7]. Bamigbetan O et al. [8, 9] experimentally investigated an R600 HTHP with a prototype compressor for industrial waste heat recovery from 50℃ to heat delivery at 115℃. Kondou C et al. [10] designed different cycle configurations with R1234ze(Z) refrigerant to supply the output temperature of 160℃ as the waste heat was 80℃. Arpagaus C et al. [11] examined the experimental performance of R1336mzz(Z) in a laboratory single-stage HTHP with 5~10 kW heating capacity using a variable speed piston compressor. When the heat source is 60℃ and output is 110℃, the coefficient of performance (COP) of this R1336mzz(Z) heat pump with an internal heat exchanger is 3.0 with a 24% increment compared with

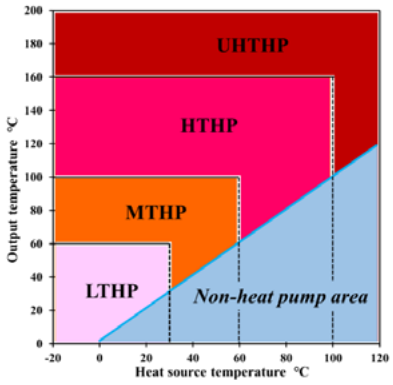

Fig. 1. The classification of vapor compression heat pump

it. By comparing with other HFO and HCFO refrigerants theoretically, they also found that R1336mzz(Z) achieves the highest COP in the temperature range from 120℃ to 10℃ [12]. Wu D et al. [13, 14] presented a novel water vapor HTHP system with 80~90℃ waste heat recovery and above 100℃ hot water supply. When the evaporation temperature was 85℃, the COP decreased from 6.10 to 1.96 with condensation temperature increasing from 110℃ to 150℃.

In this work, based on the existing experimental investigation on water vapor HTHP, preliminary experimental investigation of the water vapor HTHP system performance with different injection lines and injection ports is carried out to find the effect of different injection methods on the heat pump performance.

2. Working fluid

Nowadays, the selection principle of refrigerant takes ozone depletion potential (ODP) and global warming potential (GWP) into consideration and considers them as the main indexes on environmental protection, which limits that ODP is 0 and GWP is below 150 [15]. In Table.1, five kinds of refrigerants (GWP<150)-R718, R600, R601, R1234ze(Z) and R1336mzz(Z)-are chosen to be used in HTHP systems as working fluids. A high GWP HFC refrigerant, R245fa, is added as the representative of traditional HTHP refrigerants.

Table.1 The properties of HTHP refrigerants [1, 16]

Refrigerant	Chemical formula	T_{crit} /℃	P_{crit} /bar	ODP	GWP	SG	NBP/℃
R718	H_2O	373.9	220.6	0	0	A1	100.0
R600	$CH_3CH_2CH_2CH_3$	152.0	38.0	0	20	A3	-0.5
R601	$CH_3CH_2CH_2CH_2CH_3$	196.6	33.7	0	20	A3	36.1
R1234ze(Z)	$CHF=CHCF_3$	150.1	35.3	0	1	A2	9.8
R1336mzz(Z)	$CF_3CH=CHCF_3$	171.3	29.0	0	2	A1	33.4
R245fa	$CHF_2CH_2CF_3$	154.0	36.5	0	858	B1	14.9

The theoretical performance of HTHPs with these selected refrigerants are calculated in an idealized single-stage heat pump cycle with the following assumptions: (1). the condensation and evaporation processes are isobaric; (2). the expansion process is isenthalpic; (3). the suction temperature of the compressor has 20℃ superheat for R601 and R1336mzz(Z) and has 5℃ superheat for the left refrigerants; (4). compression process with a constant isentropic efficiency of 0.7; (5). the condensation temperature increases from 100℃ to the critical temperature with a constant 40℃ temperature lift.

The calculation results and comparison at 40℃ temperature differences are illustrated in the following pictures, including the COP (Fig. 2), the compression ratio (Fig. 3) and the volumetric heating capacity (Fig. 4).

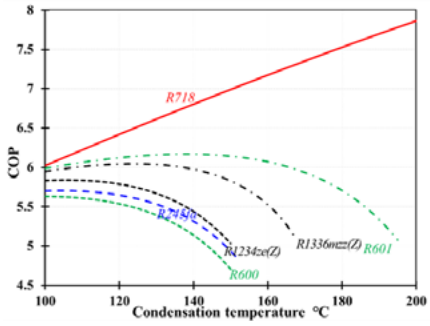

Fig. 2. The COP of the HTHPs with selected refrigerants

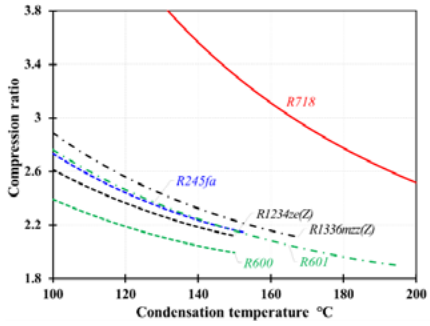

Fig. 3. The compression ratio of the HTHPs with selected refrigerants

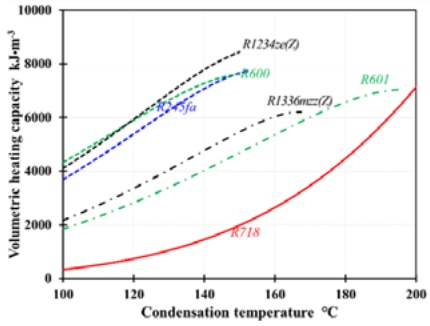

Fig. 4. The volumetric heating capacity of the HTHPs with selected refrigerants

Based on the above table and calculation results, compared with the other five refrigerants, water has many advantages in HTHP applications, especially in ultra-high-temperature output fields. Water has the highest critical temperature, the best environmental protection performance, and the safest property. The calculation COP, shown in Fig.2, also presented that water has the best theoretical performance when the condensation temperature is above 100℃. However, Fig.3 and 4 also illustrated the disadvantages of water refrigerant in heat pump systems. Compared with the other kind of refrigerants, water has the biggest compression ratio and the smallest volumetric heating capacity in the simulation conditions. So the application of water in the HTHP field needs an appropriate compressor with a bigger compression ratio to satisfy high temperature lift and a bigger volume flow rate to overcome its small volumetric heating capacity.

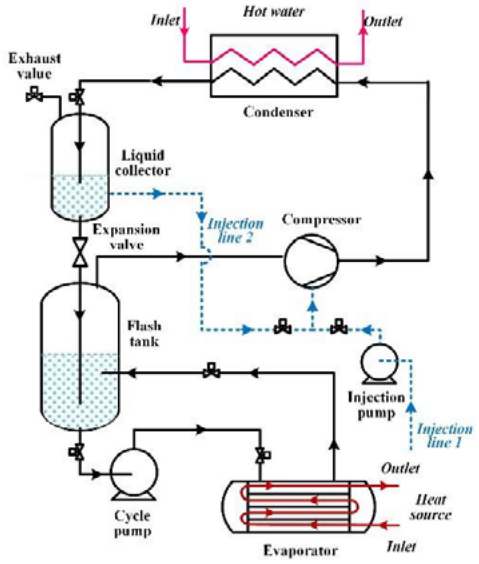

Fig. 5. The schematic diagram of the R718 HTHP with two injection lines

Furthermore, the big compression ratio of water will also lead greatly high discharge superheat and temperature in the heat pump system. So the discharge superheat and temperature must be lowed to promise the safety application of water in HTHP systems. What's more, with the increasing of the condensation temperature, the simulation COP and volumetric heating capacity of water vapor HTHP increases and the compression ratio of the heat pump decreases, which means water vapor HTHP has better performance in higher temperature application fields.

3. Water vapor HTHP

As shown in Fig.5, the schematic diagram of the water vapor HTHP has two different injection lines: external injection line (injection line 1) and the internal injection line (injection line 2). The external injection line is used to inject water from the outside with constant pressure and low temperature, and the internal injection line is used to inject condensed water from the liquid collector with various pressure and high temperature. There are also two injection ports in the water vapor HTHP prototype: the suction side injection port and the compression chamber injection port. These different injection lines and ports may have different effects on the performance of the water vapor HTHP.

4. Experimental results

Based on the schematic diagram of the water vapor HTHP, a prototype of this heat pump with two different injection lines and two different injection ports were set up. Experimental investigations were carried out to study the performance of the water vapor HTHP, including the start-up and dynamic performance, the influence of different injection ports and the injection lines.

4.1. Start-up and dynamic performance

As shown in Fig. 6(a), (b), and (c), the start-up and dynamic performance of the water vapor HTHP is presented with internal water injection in the compression chamber. With the rotate speed increasing from 0 to 5000 rpm in 8 minutes, the system reached steady-state in 10 minutes as the evaporation pressure was uncharged near 0.4 bar and other working properties were steady. In the start-up process, with the increase of the rotate speed, more water vapor was suctioned from the evaporator and the evaporation pressure decreased directly. At first, the condensation pressure increased and then decreased with the increase of the rotate speed,

which is mainly due to the accumulation of the discharge steam and the flow rate of the condensation water. With the increase of the rotate speed, the discharge temperature and superheat temperature increased rapidly as the rotate speed was above 2400 rpm. In order to control the discharge temperature in the start-up process, the injected-water was injected into the compressor with a much higher flow rate when the rotate speed was 2400 rpm. After the rotate speed reaching the highest value, 5000 rpm, the flow rate of the injected-water was adjusted to control the discharge temperature near the saturation temperature.

After the start-up process, by adjusting the opening of the expansion valve to control the condensation temperature, the dynamic performance of the water vapor HTHP was illustrated as the rotate speed and the evaporation pressure were invariant. With the increase of the condensation temperature, more power consumption was demanded to protect the larger compression ratio and enthalpy lift in the compression process. Larger compression ratio and enthalpy lift mean higher discharge temperature and more injected-water, so the flow rate of the injected-water also increased. However, the flow rate of the injected-water is not only controlled by the opening of the injection valve but also adjusted by the pressure of liquid collector. As shown in Fig. 6(c), when the opening of the injection valve is fixed, with the increasing of the condensation pressure, the flow rate of injected-water also increased to control the discharge temperature. When the pressure adjustment of the injected-water was failure and the discharge temperature was higher than the saturation temperature, the opening of injection valve will permit more injected-water to control the discharge temperature.

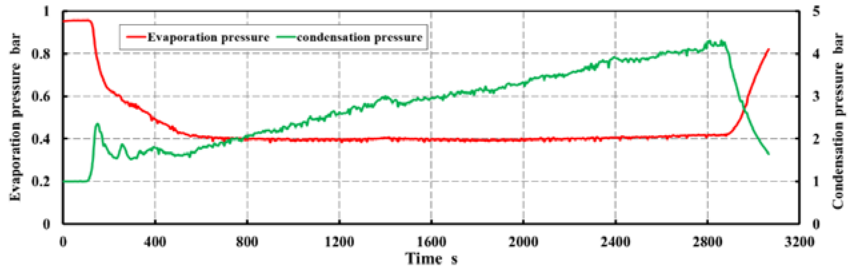

Fig. 6(b). The start-up and dynamic performance of evaporation and condensation pressure

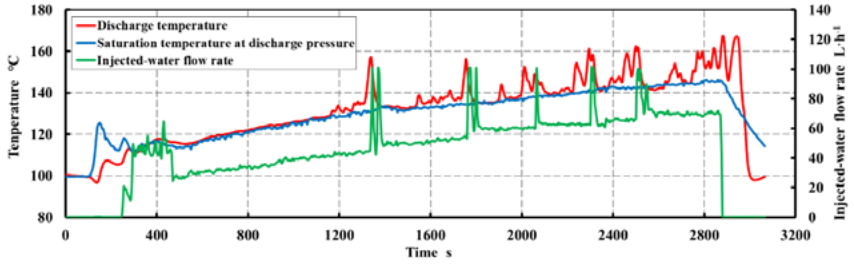

Fig. 6(c). The start-up and dynamic performance of discharge temperature and injected-water flow rate

4.2. The influence of injection ports

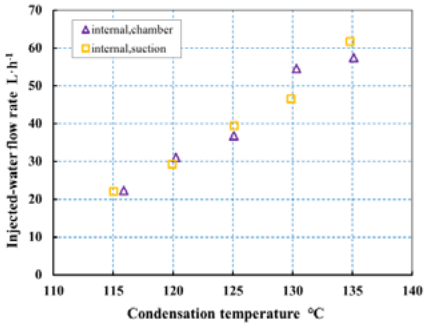

Fig. 7(a) Injected-water flow rate comparison

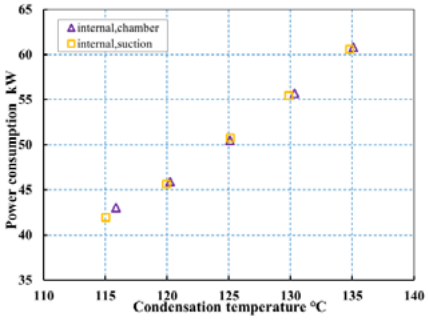

Fig. 7(b) Power consumption comparison

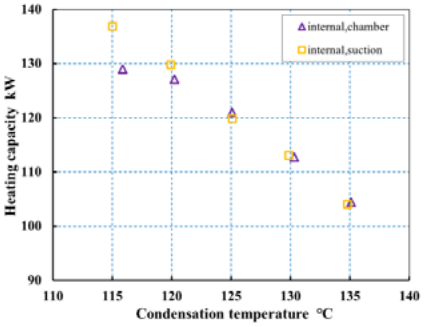

Fig. 7(c) Heating capacity comparison

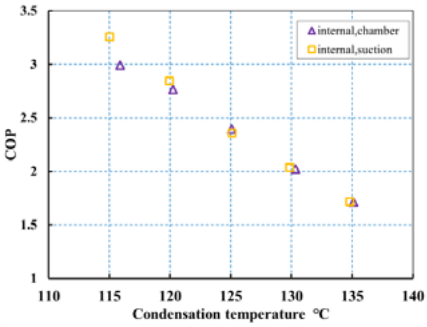

Fig. 7(d) COP comparison

Fig. 7. The performance comparison of the water vapor HTHP with different injection ports

There are two different injection ports designed in the water vapor HTHP. One is in the compressor chamber with water directly injected into the compression process to lower the discharge temperature. The other is in the suction side with water injected into the suction side of the compressor and then mixed with water vapor and suctioned into the compression chamber. When the water is injected into the system, different injection ports may have different effects on the system performance, especially on the control of the discharge temperature. When the water is injected into the compressor chamber, it can directly absorb the superheat of the compressed water vapor and lower the temperature timely. However, when the water is injected into the suction side, it can separate and mix uniformly with the water vapor, which is better for absorbing heat in the compression process. The control of the discharge temperature has a delay as the water is injected into the suction side.

To compare the influence of different injection ports, an experimental investigation is carried out with internal water injection at 73℃ evaporation temperature. The result comparison is shown in Fig. 7(a) to (d), including the injected-water flow rate, power consumption, heating capacity, and COP. The result presented that the difference in system performance with different injection ports is not obvious and the injection ports have little influence on the system performance. This may due to that the compression process is faster than the heat transfer in the compression chamber, and most of the injected-water has not evaporated into steam when it was discharged from the compressor. So the separate and fogging degree of the injected-water has little influence, and the flow rate of the injected-water plays the most important role. However, more experimental investigations are needed to prove the results.

4.3. The influence of injection channels

To provide the steady of the injected water and keep the mass conversation of the water in the system, two injection lines are designed in the water vapor HTHP, external water injection from the outside and internal

water injection from the liquid collector. When the injected-water is from the outside, the temperature, pressure

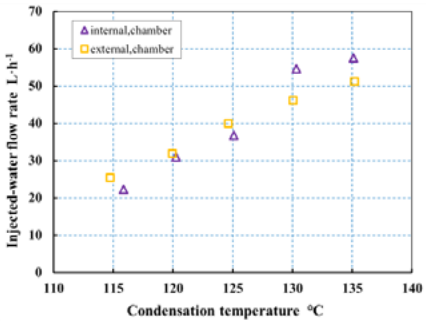

Fig. 8(a) Injected-water flow rate comparison

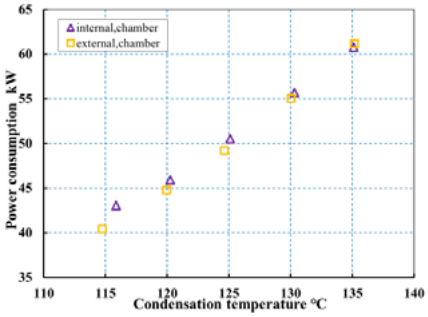

Fig. 8(b) Power consumption comparison

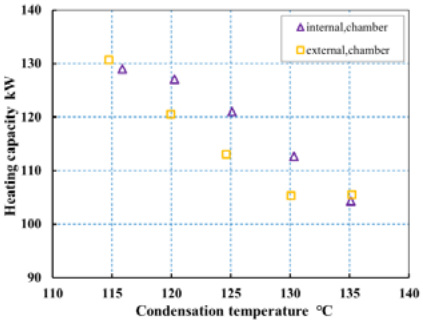

Fig. 8(c) Heating capacity comparison

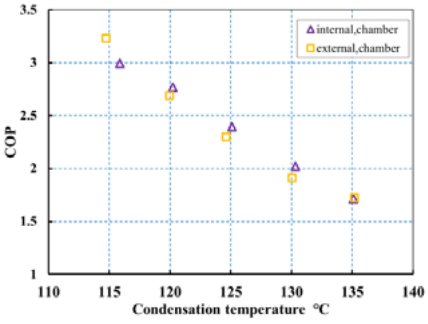

Fig. 8(d) COP comparison

Fig. 8. The performance comparison of the water vapor HTHP with different injection channels

and flow rate of the injected-water are controlled easily, which is good for the steady operation of the heat pump. However, external water injection will lead to an increase in the working fluid in the system, and destroy the balance of long-time operation. In this experimental investigation, to keep the balance of the water refrigerant in the system with the external water injection, some water will be discharged from the liquid collector. When the injected-water is from the liquid collector, the system working fluid is conversation and the flow rate of injected-water will increase simultaneously with the increase of the condensation temperature. It can realize the self-adjustment of injected-water and discharge temperature of the system. However, the temperature and pressure of the injected-water are changed with the condensation temperature.

The experimental investigation is carried out with different injection channel at 73℃ evaporation temperature. The result comparison is shown in Fig. 8(a) to (d), including the injected-water flow rate, power consumption, heating capacity, and COP. The result presented that the difference of injected-water flow rate and power consumption with different injection lines is not obvious. However, the heating capacity and COP of the two injection line systems are different. The internal injection system has better heating capacity and COP, which may due to the higher temperature of the injected-water.

5. Conclusions

Water vapor HTHP is a significant vapor compression heat pump with a high output temperature. The theoretical simulation results show that compared with new HFO and HC refrigerant and traditional HFC refrigerant, R718 has better performance when the condensation temperature is above 100oC. What's more, with the increasing of the condensation temperature, the simulation COP and volumetric heating capacity of water vapor HTHP increases and the compression ratio of the heat pump decreases, which means water vapor HTHP is more suitable for higher temperature application fields. Its start-up and dynamic performance

present that this heat pump can reach steady-state in 10 minutes and water injection can effectively decrease the discharge temperature. The internal injection line can realize the self-adjustment of injected-water and discharge temperature. When the opening of the injection valve is fixed, with the increasing of the condensation pressure, the flow rate of injected-water also increased to control the discharge temperature. When the pressure adjustment of the injected-water was failure and the discharge temperature was higher than the saturation temperature, the opening of the injection valve will permit more injected-water to control the discharge temperature. Different injection ports have little influence on heat pump performance. However, the different injection channels have influence on the heat pump performance, especially on the heating capacity. So it is very significant to design a suitable water vapor heat pump cycle with the best injection method.

Benefits and reliability of air-to-water heat pumps in residential applications, using R-290 refrigerant and an alternative design solution to guarantee high safety with standard components.

Sergio Maria Capanelli*

Carel Industries S.p.A., Via dell'Industria 11, 35020 Brugine (PD), Italy

Abstract

The optimisation of energy consumption, the search for higher system efficiency and the need to reduce CO_2 emissions are driving the heat pump market, especially in residential applications. In EMEA especially, the need to switch to alternative refrigerants is changing the criteria for selecting components and developing projects. Most of the market trends have already identified flammable refrigerants as the way to solve compliance issues, while at the same time raising new issues regarding usability and reliability of potentially explosive devices in residential systems. Unit and component manufacturers are starting to work together in order to develop affordable and reliable solutions, not only improving component technologies and their mounting in the unit, but working closely together right from the start of the project.
Here below we describe an example of a fruitful collaboration for the development of an R-290 air-to-water heat pump, where accurate unit design, experience as HVAC component and heat pump manufacturers, have led to the development of a product with the highest performance in terms of efficiency and reliability, meeting all the standards for the use of flammable refrigerants on the European residential heating market.

Keywords: heat pumps; R-290; safety; DC; EEV;efficiency

1. Introduction

The Kigali amendment to the Montreal Protocol [1] entered into force on 1 January 2019, and was aimed at phasing down hydrofluorocarbons (HFCs) by cutting their production and consumption, so as to reduce so-called direct CO_2 emissions. However, actions to reduce the use of HFC refrigerants had already started in most developed countries. In the European Union, F-gas regulations [2] were published in 2014, establishing restrictions to the use of HFC refrigerants according to their global warming potential (GWP) and introducing the concept of quota, which refers to a reduction in the admissible production and import of HFCs in Europe over time. This has already led to an increase in prices and a decrease in the availability of high GWP refrigerants such as R-410A, driving the use of alternatives with a much lower GWP.

Lower GWP alternatives to R-410A for heat pumps include R-290 (propane), a high efficiency natural refrigerant with very a low GWP and zero ODP. The only drawback is its flammability, being in group A3 in accordance with ASHRAE Standard 34 [3]. IEC 60335-2-40 [4] specifies particular requirements for electrical heat pumps when using flammable refrigerants, updated on April 2018, with different requirements for systems depending on the propane charge. For instance, additional mechanical ventilation is compulsory for systems with between 1 kg and 5 kg of propane.

Efficiency is currently another important subject in standards, which impact both the reduction of indirect CO_2 emissions and the electricity bill. Ecodesign and Energy Labelling Directives in Europe are very active in the definition of new regulations for energy-using and energy-related products. There are two Ecodesign regulations that include the requirements for different types of heat pumps: ENER Lot 1 [5] and ENER Lot 21[6]. Both of these, in line with regulations for other HVAC/R applications, establish seasonal energy

E-mail address: sergio.capanelli@carel.com.

efficiency limits, thus taking into account the variations in outside air temperature over the year. This brings more precision to the procedure and more advantages from the use of variable speed technology, which is able to adapt energy consumption to the needs of the application. The Energy Labelling regulation for heat pumps [7] includes space heaters, combination heaters, packages of space heater, temperature control and solar device, as well as packages of combination heater, temperature control and solar device. The second stage of this Energy Labelling regulation came into force on 26 September 2019, when new energy labels for classes A+++ to D were required.

In this context, accurate unit design and choice of components plays an essential role when developing a heat pump, in order to optimise energy consumption and reduce total CO_2 emissions, while ensuring safety. The aim of this project was to develop an R-290 air-to-water residential heat pump with high performance, meeting all the required safety and usability goals for the use of flammable refrigerants on the European residential heating/cooling market.

2. Description of the project

This project was completed by our company in collaboration with a European customer, and lasted almost three years, including component selection, unit design, performance testing, certification, field testing and start of production. The field tests and most of the data taken outside of the laboratory referred to an area in central Germany area, with an annual average temperature of 9°C.

The unit described is an air-to-water heat pump, comprising a packaged outdoor unit, connected via fluid piping to an indoor unit equipped with a distribution system for space heating and cooling, and a water tank for domestic hot water storage.

The outdoor unit includes a refrigerant circuit equipped with variable-speed DC scroll compressor and electronic expansion valve.

Table 1 shows the other main characteristics of the unit:

Table 1. Summary of heat pump characteristics

Heat pump characteristic	Value
Refrigerant	R-290
Power supply	400V 3-phase
Heating capacity (A2/W35)	1.9 - 7 kW
Cooling capacity (A35/W18)	2.3 - 7 kW

The unit is also equipped with an electric heater for auxiliary use, for example to reach a water temperature of 70°C in the event of system request, or for use as backup, to guarantee continuous heating service for the end user even in the event of a unit fault. This heater was not activated during the comparison tests.

3. Test results

3.1. Comparison with R-410A unit

To perform this comparison test, an existing unit equipped with R-410A refrigerant and with the same nominal heating capacity as the heat pump studied (7 kW) was used as reference. The sample is a standard unit already available on the market, coupled with an indoor unit for fluid management and distribution. The scheme can be seen in Fig.1. In this section, for brevity, the R-290 unit is called “Unit A” and the one with R-410A “Unit B”. To perform the tests, we used the same indoor unit for both Unit A and Unit B. The data used for this comparison between the two units was acquired by certification testing laboratories. The characteristics are summarised in Table 2.

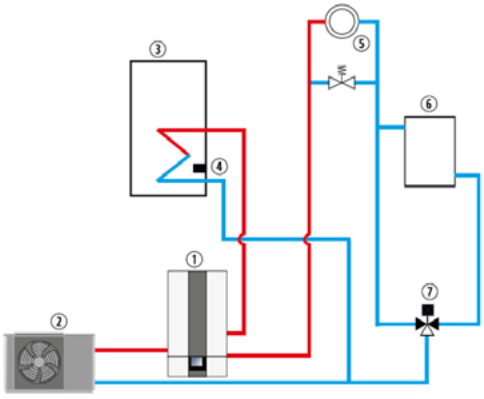

Fig. 1. Diagram of the fluid and distribution system used for the comparison test
1.Indoor unit | 2.Outdoor unit | 3.Hot water tank | 4.Storage tank sensor | 5.Heating circuit | 6.Intermediate water tank | 7.Three-way heating / cooling switching valve

Table 2. Summary of heat pump Unit A and Unit B characteristics

Heat pump characteristic	Unit A	Unit B
Refrigerant type / GWP	R-290 / 3	R-410A / 2088
Refrigerant charge	3.1 kg	2.15 kg
CO_2 equivalent	0.009 t	4.49 t
Heating operating limits (water)	+20°C to +70°C	+20°C to +55°C
Heating operating limits (air)	-22°C to +40°C	-20°C to +35°C
Cooling operating limits (water)	+7°C to +30°C	+7°C to +20°C
Cooling operating limits (air)	+10°C to +45°C	+10°C to +45°C

The most striking difference is the GWP value, i.e. the quantity of CO_2 that can be emitted into the environment. Considering that the two units have comparable power consumption (at -7°C air temperature, with a heating capacity of 6 kW, consumption of Unit A is 2.15 kW, and consumption of Unit B is 2.28 kW), the much lower GWP value makes Unit A the best solution to meet the emissions reduction requirements of the international agreements and regulations mentioned above.

Fig.2, Fig.3 and Fig. 4 show a comparison between the different efficiency levels in different test conditions.

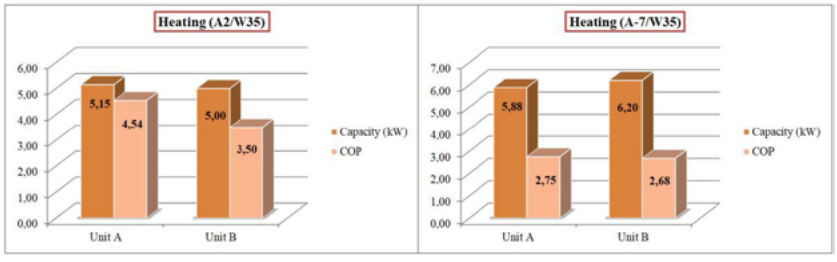

Fig. 2. Comparison test in heating mode. Nominal performance according to EN14511.

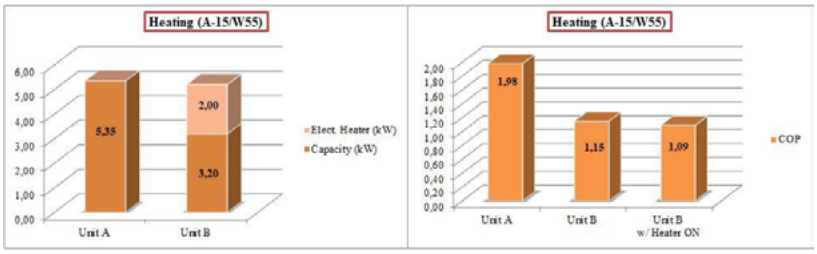

Fig. 3. Comparison test in heating mode with low air temperature.

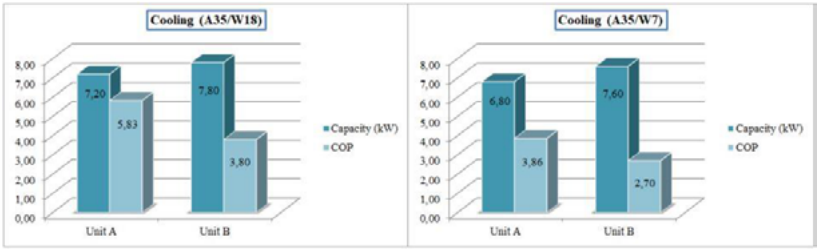

Fig. 4. Comparison test in cooling mode. Nominal performance according to EN14511.

The results shown in Fig. 2 indicate that, in both test conditions, the two units have a virtually identical heating capacity. The efficiency value is higher in Unit A, both with air at -7°C (+ 3%) and above all at + 2°C (+ 30%).

A significant difference is seen in working conditions with a low outside temperature, specifically -15°C: the characteristics of the refrigerant and compressor on Unit A allow a higher heating capacity and better efficiency than Unit B, as shown in Fig.3.

The results shown in Fig. 2 indicate that in both test conditions the two units have a comparable heating capacity: a difference of 1.5% with A2/W35, and 2.5% with A-7/W35. The COP value is higher for Unit A in both cases: +3% with A-7, +30% with A2.

An additional test was performed with lower outside temperature conditions, in order to highlight how the use of R-290, compared with R-410A, can avoid an excessive reduction in unit heating capacity.

The results are shown in Fig. 3. In test conditions A-15/W55 (high supply water temperature in cold climate conditions), Unit A has a capacity of 5.35 kW, with a COP value of 1.98, while Unit B has a capacity of 3.2 kW (40% lower than Unit A) with a COP value of 1.15. The electric heater on Unit B needs to be switched on (2 kW) in order to reach a comparable heating capacity between the two units, reducing the difference in capacity to 3%. However, this leads to a further reduction in the COP of unit B, which drops from 1.15 to 1.09.

The results shown in Fig.4 are related to cooling mode.

The comparison tests show that cooling capacity is a little bit higher in Unit B, +3.8% with W18 and +5.2% with W7. On the other hand, the COP coefficient measured is significantly higher in Unit A, +35% with W18 and +29% with W7 There are two important factors to consider when evaluating the results:

- The air heat exchangers on Unit A and Unit B are different in terms of size, design and plastic or polypropylene components used to guide the air flow inside the unit. We can assume by looking at the nominal performance data for the two heat exchangers that the one used on Unit A is +14% more efficient than the one used on Unit B;
- Unit B is equipped with a single EEV, used in two-way flow configuration so as to support both heating and cooling mode. In fact, the EEV is sized to assist operation in heating mode, in order to have the necessary flow control precision in the most extreme environmental conditions, such as high water temperature production with a low outside air temperature.
  Unit A is equipped with 2 EEVs: one is used in heating mode, the other in cooling mode. The EEV

for cooling mode can ensure an increase of 30% in the maximum allowable refrigerant flow rate, but at the same time a loss in control precision at low opening: each step of movement can increasingly affect the amount of refrigerant in the evaporator.
In this way, the modulation range for each EEV can be sized for the specific operating mode: this is especially useful in cooling mode, when performance is often not fully optimised in order to favour heating mode, considered the main operating mode.

3.2. Considerations about the use of R-290

Thanks to the operating envelope of the R-290 compressor, the two most significant values of extended operating range concern heating mode. A higher outside air temperature limit allows the production of domestic hot water even in the most severe summer conditions.

The most significant value concerns the higher hot water supply temperature, which has three main benefits:

- Production of hot water can also be used for systems with high temperature distribution systems, such as radiators. This allows the use of the unit in installations where the use of R-410A is difficult due to problems with high condensing pressure.

- It is possible to produce hot water with a temperature higher than 50°C even with an outside temperature below -15°C, with better efficiency than with the currently used refrigerants.

- The possibility to reach an outlet water temperature of 65-70°C, when conditions are favourable, to perform anti-legionella treatment on the domestic hot water without activating the electric heater: this means high energy savings for the system and therefore a considerable increase in COP.

4. Safety measures

One of most challenging issues of this project was the safe use of the electronic controls, devices and components normally used in HVAC applications, but not certified for compliance with EN 60079:15 [8] and EN 60335-2:40.

Appliances shall be constructed so that any leaked refrigerant will not flow or stagnate so as cause a fire or explosion hazard in areas within the appliance and connected ducts where electrical components, which could be a source of ignition and which could function normal conditions or in the event of a leak, are fitted.

These components shall comply with one of the following conditions:

- Components should be placed inside an enclosure which complies with Clause 20 of IEC 60079:15-2010;
- A test of Annex FF of EN 60335-2:40 must be performed with a leak simulation test: with this method must be demonstrated that a potentially flammable gas mixture will not accumulate;
- Components are compliant with Clause 16 to 22 of IEC 60079-15:2010.

The most critical components were the electronic control board and the compressor speed drive: both components are certified and fully eligible to be used for general HVAC residential applications. However, the presence of components that could be identified as possible spark sources, for example the relay, does not permit the use of these devices in the open air in this kind of application.

The solution selected follows the first of the conditions listed above: create a dedicated metal enclosure of dimensions and features compatible with its positioning within the outdoor unit. The most critical points of the panel design, construction and component selection are described as follows.

4.1. Panel tightness

First, it was necessary to guarantee tight closing of the panel, in order to avoid hazardous amounts of gas accumulated in critical concentrations inside. This is an issue that may occur in the event of malfunctions and leakages.

Fig. 5. Details of fixing system for the panel enclosure.

Fig.5 shows the details of the panel enclosure. The cover is equipped with an inner gasket, positioned around the entire inside perimeter. When the cover is positioned, the inner gasket is aligned exactly with the edge of the panel (see image on the left in Fig. 5), and after placement and fixing by the screws inserted in the side brackets (image on the right in Fig. 5), the gasket is pressed down by 3 mm, around 50% of its thickness. The position of soldered bracket guarantees the correct pressure of the bottom part of the enclosure against the cover gasket without any specific screw torque value: this makes it possible to guarantee panel tightness with a faster industrialised process, and only a visual check is performed on the presence of all 8 screws.

Furthermore, the size of the different cables needed for control of the unit may be the source of holes or openings that compromise insulation of the enclosure, creating a possible pathway that flammable gas can pass through and accumulate inside the enclosure: communication cables, sensors, driver cooling fan, compressor connection and panel power supply in general.

Fig. 6. Details of the connection kits for cable glands.

All cables connecting components inside the panel with the outside devices pass through specific cable glands, as shown in Fig. 6. The image on the left shows the outer part of the kit, while on the right is the inside view. The large rectangular gland with 8 subsections is a specific custom part, created to satisfy the specific combination of cables needed for these units. However, the gland comprises a main black part and inner grey parts: these are all standard components. This solution guarantees compliance of the enclosure with Clause 20 of IEC 60079:15-2010: the required degree of insulation is a subset of requirements for IP54 protection.

Except for the screw holes used for this gland and other holes made for compressor drive pass-through mounting or another specific cable glands, no other drilling operations are performed when manufacturing the enclosure: all of the screws present are welded directly onto the inside surface of the enclosure, in order to avoid further possible causes of loss of tightness.

At the end of enclosure manufacturing process, a negative pressure test is performed. During this test, automatic equipment is connected via a silicone pipe to the inside of the enclosure: the enclosure is de-pressurised until reaching a “pressure test setting”. The equipment then stops taking in air and starts checking the inside pressure value, so as to measure the volume of air that flows into the enclosure to rebalance the pressure. To guarantee compliance, the volume should be lower than 1.8 l/min, a value defined in relation to the size of the enclosure.

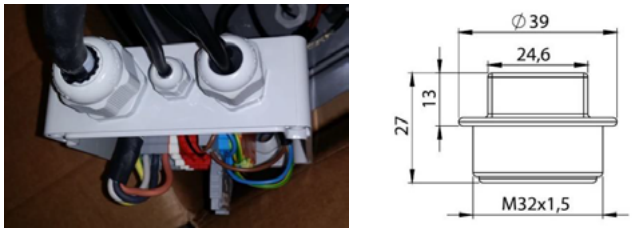

Fig. 7. Example of cable gland usage and selected model to satisfy requirements for correct enclosure usage in a residential heat pump.

Fig. 7 shows the junction box for power supply and serial communication connections. This box has been made separately from the main electrical panel as it must be guaranteed that installers or untrained personnel cannot open the enclosure in the field, especially during installation. This junction box is the connection point when placing the unit, in order to allow power connection to the supply line and serial connection for communication between the outdoor unit, where the enclosure is placed, and the indoor unit for fluid management, equipped with the control display.

For the junction box, the designers also selected a specific electrical box and cable glands compatible with this application, but at the same time easily purchasable on the market.

Table 3 shows some details of the connectors.

Table 3. Connector specifications.

Material	Polycarbonate (PC)
Flame class	UL94-V0, self-extinguishing
IP rating	IP54, with gasket and correct selection of the cable grommets
Temperature range	-30°C to +100°C
Properties	Halogen-free, silicone-free

4.2. Panel cooling

As the panel is sealed, it is necessary to guarantee correct heat dissipation from the panel in order to keep the contained devices in safe conditions. The compressor driver, due to its power consumption when operating, is the “hottest” critical point. The solution adopted was to use a driver equipped with pass-through ventilated heat sink system. In order to guarantee the air flow across the finned heat sink, two small fans are mounted on the front. The fan motors are insulated and compliant with the required clauses of the standards, so as to be used outside of the panel.

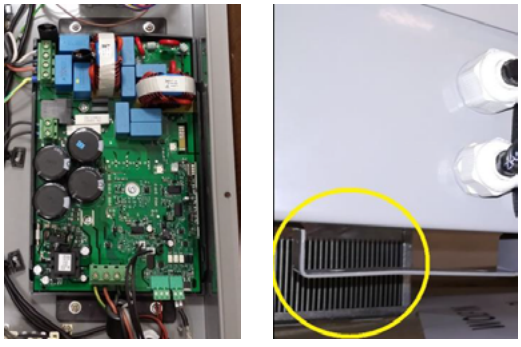

Fig. 8. Inverter drive placement in the panel and detail of pass-through heat sink.

To obtain this configuration, we used a standard device already equipped with a gasket underneath the moulded plastic base, which ensures tightness after fixing the drive to the panel using the special brackets. The only significant change was to use a plastic moulding for the base without holes for the cooling fan cables: the cables were passed through dedicated cable glands, of the type described above.

Using this specific base without holes and mounting the driver with correct positioning of the gasket around the hole, the tightness of the enclosure and IP54 protection were guaranteed when testing the complete panel solution.

With this equipment, the unit was tested up to the maximum outside air temperature allowed for operation (cooling mode): at 40°C the air surrounding electronic components does not exceed the limit threshold of 65°C. These values are compatible with the temperature operating range of the electronic components placed inside the enclosure.

5. Conclusions

The results of these tests, carried out in the field and in the laboratory, have shown how the use of R-290 refrigerant in heat pumps with packaged outdoor units is a fully usable, industrialised, efficient and safe solution. The high efficiency, low GWP and high energy yield values compared to traditional refrigerants, make these units optimal devices to reduce power consumption, increase system efficiency and contribute to a reduction in CO_2 emissions.

The goal for the near future is to expand the range of units in order to cover a greater variety of needs, maintaining the same structure presented above. At the same time, we are working, by mutual agreement with our customers and certification bodies, on further certification of standard components that can be used in specific HVAC applications in the presence of flammable refrigerants.

Clarification of the disproportionation reaction of HFO-1123 and evaluation of the reaction inhibitor

Zhihua Zhang, Makoto Ito, Chaobin Dang, Eiji Hihara *

Dept. of Human & Engineered Environmental Studies, University of Tokyo
Kashiwa, 277-0882, Japan

Abstract

The hydrofluoroolefin (HFO) refrigerant 1,1,2-trifluoroethene (HFO-1123) has a very low global warming potential (GWP) and ozone depletion potential (ODP); thus, it is proposed as a next-generation refrigerant. However, a short circuit of the motor under high-temperature and high-pressure conditions may cause a disproportionation reaction of HFO-1123. Therefore, to enable commercialization of HFO-1123 in split air conditioners, it is necessary to develop a technology to suppress the disproportionation reaction. In this study, disproportionation experiments were performed under various temperature and pressure conditions and changes due to these different pressure, temperature, and input energy were recorded. Conventionally, fusing and discharge methods are employed for ignition in experiments. Using the two ignition methods, we experimentally determined the threshold pressure of the disproportionation reaction and compared the differences in the reaction limits of the ignition methods. The disproportionation reaction was photographed with a high-speed camera, and the flame temperature was measured using the two-color temperature radiometry method (H & B method). The experiment was performed using difluoromethane (R32) and trifluoroiodomethane (R13I1) as disproportionation reaction inhibitors, and the suppression effect of the disproportionation reaction was evaluated.

Keywords: Refrigeration; HFO-1123; Reaction inhibitor; Disproportionation reaction.;

1. Introduction

In the fields of refrigeration and air conditioning, the development of alternative refrigerants such as hydrofluorocarbons (HFCs) has been promoted to prevent the depletion of the stratospheric ozone layer by chlorofluorocarbon (CFC) and hydrochlorofluorocarbon (HCFC) refrigerants. However, although the HFC refrigerant has a low ozone depletion potential (ODP), it has been regulated by the Global Change Framework Convention as a causative material for global warming due to its high global warming potential (GWP). Later, the Kigali amendment to the Montreal Protocol calling for the phase-down of HFC refrigerants was adopted in 2016; subsequently, UN member states were required to switch to low-GWP refrigerants, such as hydrofluoroolefins (HFOs) and natural refrigerants.

Trifluoroethene (HFO-1123, CF_2CHF) has a very low GWP, as shown in Table 1, because it has a short lifespan in the atmosphere. Therefore, it is expected to be a next-generation refrigerant in the fields of refrigeration and air conditioning. However, HFO-1123 is known to cause a disproportionation reaction under high-temperature and high-pressure conditions, as shown in Eq. (1). When energy is applied due to equipment failure, the generated flame propagates, and the pressure and temperature may increase significantly due to the generated heat. This is not a combustion reaction that requires oxygen, but a self-decomposition reaction.

Table 1. GWP and ODP of typical refrigerants (HFC-410A, HFC-32, and HFO-1123)

	HFC-410A	HFC-32	HFO-1123
ODP	0	0	0
GWP	2090	675	0.3

$$2CF_2=CHF \rightarrow CF_4+3C+2HF+500kJ \quad (1)$$

To put HFO-1123 to practical use, it is necessary to clarify the conditions under which the disproportionation reaction occurs and to suppress the reaction because the occurrence of a disproportionation reaction is dangerous. It is also effective to add a reaction inhibitor. There are two possible mechanisms for inhibiting the disproportionation reaction of HFO-1123 by the addition of substances.

(1) The thermal dilution effect of mixing inactive gases.

(2) The suppression of disproportionation reaction propagation by trapping radicals of the reaction intermediate products.

In this study, the conditions for the disproportionation reaction were investigated experimentally for the composition of HFO-1123 mixed with two types of inhibitors, as shown in the triangular diagram in Fig. 1. Table 2 summarizes the test gas composition, where R32 stands for difluoromethane and R13I1 denotes trifluoroiodomethane. The mixed composition of R32 was selected such that the GWP of the gas mixtures was 150 or 200. The initial temperature of the test gas was fixed at 150 °C, and the initial pressure was changed to determine whether the disproportionation reaction propagated. When the initial pressure is low, the flame does not propagate, but when it exceeds a certain pressure, it propagates. As the pressure increases and the density of the HFO-1123 molecules increases, the reaction continues, and the flame propagates. The pressure at the boundary where the flame propagates was examined. To investigate the mechanism of the reaction inhibitor, the flame temperature was measured, and a qualitative analysis of the reaction gas was performed using gas chromatography–mass spectrometry (GC–MS).

i

2. Experimental method

Figure 2 shows the experimental apparatus used for observing the disproportionation reaction of HFO-1123 and for investigating the pressure boundary where the disproportionation reaction was propagated. The experimental equipment consists of a stainless-steel pressure vessel, an ignition source, a vacuum pump, a refrigerant vessel, and a safety valve. After the pressure and temperature of the gas supplied to the pressure vessel were set at certain values and stabilized, energy was applied, and the disproportionation reaction was initiated. Subsequently, it was determined from the pressure change whether the reaction propagated or not. At the same time, the movement of the flame was observed from the two upper and lower observation windows installed in the pressure vessel.

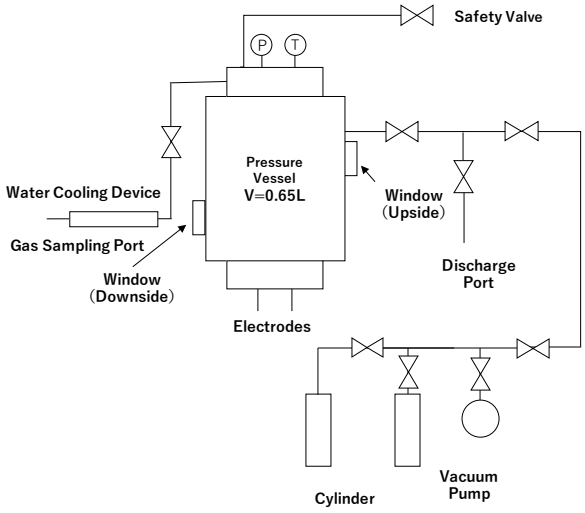

Fig. 2. Outline of the experimental apparatus

In previous studies, energy was introduced into the pressure vessel by fusing thin molybdenum wires; however, in this study, we switched to the arc discharge method. This is because the arc discharge is similar to a short circuit that may occur in the compressor motor of air conditioners. The arc discharge is a continuous large current generated between the electrodes at a low voltage, unlike a spark discharge, which is a discontinuous discharge generated between the electrodes at a high voltage.

In this experiment, a part of two copper spiral electrodes partially overlapped, and a 220 V DC was applied between the electrodes for 1.5 ms to generate an arc discharge between the spiral electrodes, and energy was supplied into the pressure vessel. The input energy was calculated from the results of the time-integrated changes in the voltage and current.

Figure 3 shows the current–voltage (I–V) curve of an ideal discharge that occurs in air. Because the high insulation resistance of the refrigerant gas hindered the discharge, the I–V curve is as shown in Fig. 4. The input energy during the discharge in air was in the range of 16–18 J, and it was in the range of 20–24 J during the discharge in the refrigerant after heating.

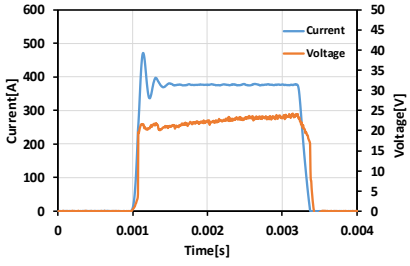

Fig. 3. I–V curve of the ideal discharge in air

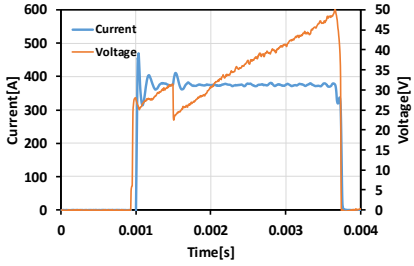

Fig. 4. I–V curve of the discharge in refrigerant

3. Experimental results

3.1 Ignition by fusing method

When the fusing method was employed for ignition, it was determined that the disproportionation reaction had propagated when a large pressure increase was measured; when the pressure increase was not measured, it was determined that the disproportionation reaction did not propagate. Figure 5 shows the results of the pressure boundary where the reaction propagates when the gas temperatures before the reaction were 100, 130, 150, and 170 °C. Although the disproportionation reaction was considered to propagate at a pressure above the solid line in Fig. 5, the boundary was stochastic and not deterministic.

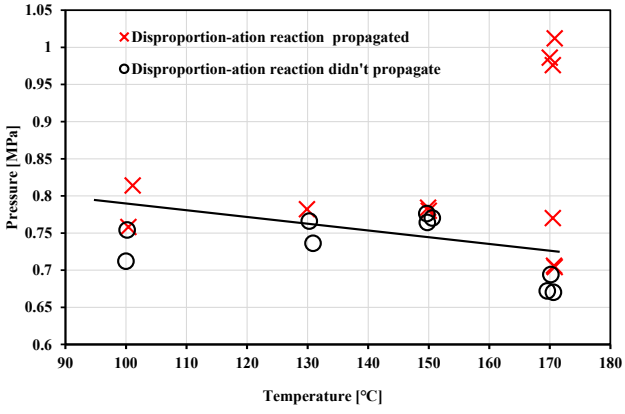

Fig. 5. Result of disproportionation reaction of HFO-1123 by fusing method

3.2 Ignition by discharge method

Compared with the fusing method, the discharge method could not easily determine whether the disproportionation reaction propagated as a result of the increase in pressure. In some cases, the pressure did

not increase even when a flame was observed, and the relationship between the flame propagation and pressure increase was unclear. In this study, we considered two criteria for determining the propagation of the disproportionation reaction of HFO-1123.

Judgment condition (1): When there is a sharp peak in the pressure change, as shown in Fig. 6, it is determined that the disproportionation reaction has propagated. If this condition is not satisfied, it is determined that the disproportionation reaction has not propagated even if a flame is observed from the observation window.

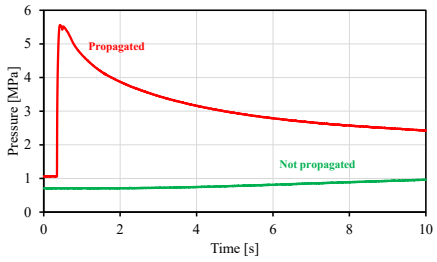

Fig. 6. Examples of the propagated and not propagated cases using judgment condition (1)

Judgment condition (2): Determine whether the reaction has propagated based on the pressure convergence value 10 s after ignition. When the pressure after 10 s exceeds the initial pressure by 1.5 times, it is determined that the disproportionation reaction has propagated.

Based on the judgment conditions described above, the pressure boundary at which the disproportionation reaction of HFO-1123 and gas mixtures propagate at a temperature of 150 °C was investigated.

3.3 Pure refrigerant HFO-1123

For the HFO-1123 refrigerant, the pressure boundary at which the disproportionation reaction propagated was investigated experimentally while maintaining a temperature of 150 °C. The pressure boundary was investigated based on the two judgment conditions described in Section 3.2. Figure 7 shows the pressure change after the voltage application. By observing the pressure change, it was found that the pressure waveform was divided into two cases: a sudden increase and a gradual increase. Even when the disproportionation reaction was considered not to have propagated when the fusing method was used (e.g., 150 °C and 0.70–0.76 MPa), an increase in the pressure was observed in the discharge method.

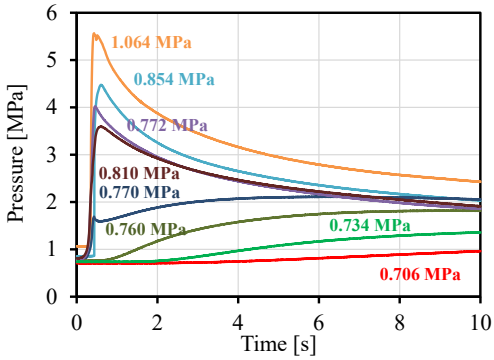

Fig. 7. Pressure curve of HFO-1123 after ignition

Figures 8 and 9 show the results of comparing the pressure boundary using the two judgment conditions and the pressure boundary using the fusing method. Based on the results of judgment condition 1, when the initial pressure is 0.772 MPa, the pressure increases stochastically with a peak, and when the initial pressure is 0.770 MPa, it increases stochastically gradually. The pressure condition at which the reaction propagated

was approximately 0.770 MPa. This is close to 0.780 MPa, which is the pressure boundary of the fusing method. Conversely, using judgment condition 2, the pressure boundary was approximately 0.75 MPa, which was slightly different from that of the fusing method. From the perspective of risk assessment, it is possible to prevent accidents due to compressor explosions by utilizing a pressure-relief valve if the pressure increases slowly. Hence, we considered that the speed of the pressure increase was more significant than the converging pressure and decided to use only judgment condition 1 to determine the pressure boundary.

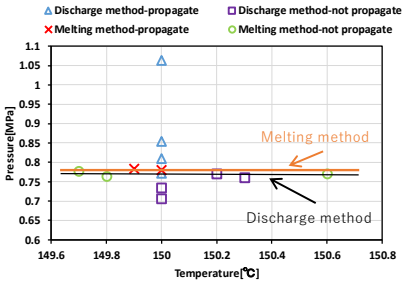

Fig. 8. Result using judgment condition (1)

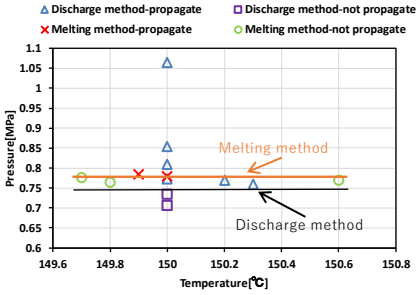

Fig. 9. Result using judgment condition (2)

3.4 Binary mixtures of HFO-1123 + R32 or R13I1

Experiments to determine the pressure boundary of the disproportionation reaction of gas mixtures containing HFO-1123, R32, and R13I1 were conducted using the discharge method at an initial temperature of 150 °C.

(1) Binary mixtures of HFO-1123 + R32

Mixing the R32 refrigerant with HFO-1123 is expected to lower the partial pressure of HFO-1123 and dilute the heat of the disproportionation reaction. The GWP of the mixed gases was set to 150 and 200 by mixing 22 mass% and 30 mass% of R32 (GWP 675), respectively. The test mixtures of HFO-1123 + R32 were named No. 2-1, No. 3-1, and No. 4-1 (Table 2).

Figure 10 shows the relationship between the initial pressure and the pressure increase of No. 2-1. The pressure boundary is between 0.82 and 1.05 MPa. When the concentration of R32 is 30 mass%, as shown in Figure 11, the pressure boundary of No. 3-1 is 1.54 MPa. When the concentration of R32 is increased to 40 mass% (No. 4-1), the pressure boundary is considered to be over 2.0 MPa.

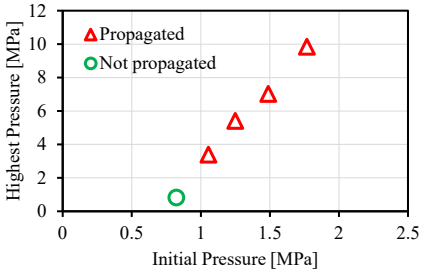

Fig. 10. Judgment map of reaction propagation for the gas mixture of HFO-1123 + 22 mass% R32 (No. 2-1)

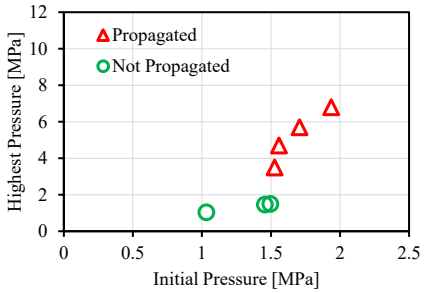

Fig. 11. Judgment map of reaction propagation for the gas mixture of HFO-1123 + 30 mass% R32 (No. 3-1)

(2) Binary mixtures of HFO-1123 + R13I1

R13I1 is a typical flame retardant and is often used as a fire extinguisher. It is also used in the non-flammable refrigerant R466A, developed by Honeywell. It is expected that iodine in the R13I1 molecule will trap the radicals generated during the disproportionation reaction. Because a small amount of addition is expected to have an inhibitory effect, mixed compositions of 5 and 20 mass% were used. The pressure boundary of the No. 1-2 results is shown in Fig. 12. The results show that when R13I1 is mixed at 5 mass%, the pressure boundary is approximately 0.92 MPa, and there is no dramatic reaction suppression effect. When the concentration of R13I1 was increased to 20%, as shown in Fig. 13, the pressure boundary of No. 1-3 decreased instead.

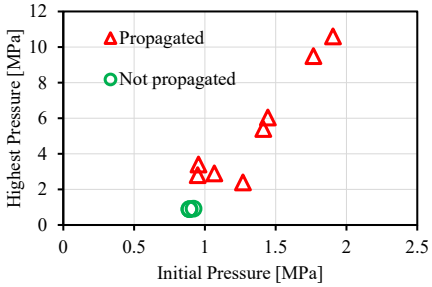

Fig. 12. Judgment map of reaction propagation for the gas mixture of HFO-1123 + 5 mass% R13I1 (No. 1-2)

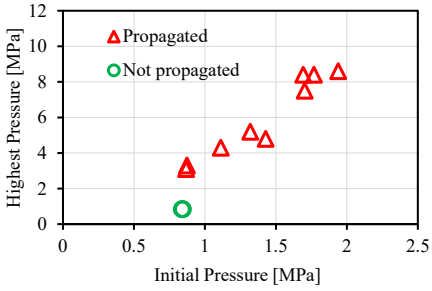

Fig. 13. Judgment map of reaction propagation for the gas mixture of HFO-1123 + 20 mass% R13I1 (No. 1-3)

3.5 Ternary mixtures of HFO-1123 + R32 + R13I1

As a result of the experiments with binary gas mixtures, in which R32 or R13I1 was mixed with HFO-1123, the suppression effect was not as great as expected. Therefore, experiments were conducted with ternary gas mixtures in which two types of inhibitors were mixed simultaneously. Figure 14 shows the results of the determination of gas mixture No. 3-3. The pressure boundary was between 1.54 MPa and 1.61 MPa. These results indicate that a synergistic effect can be obtained when the inhibitors with two types of inhibition mechanisms are mixed at the same time. In Fig. 15, when the concentration of R32 was 30 mass%, the pressure boundary increased to 2.36 MPa.

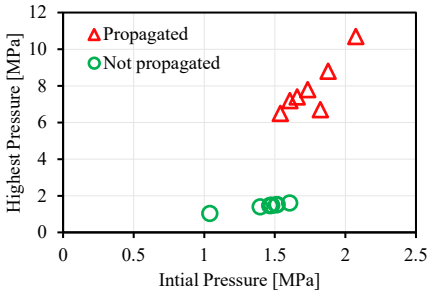

Fig. 14. Judgment map of reaction propagation for the gas mixture of HFO-1123 + 5.6 mass% R13I1 + 22 mass% R32 (No. 2-2)

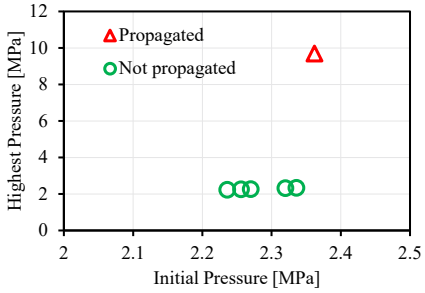

Fig. 15. Judgment map of reaction propagation for the gas mixture of HFO-1123 + 5 mass% R13I1 + 30 mass% R32 (No. 3-3)

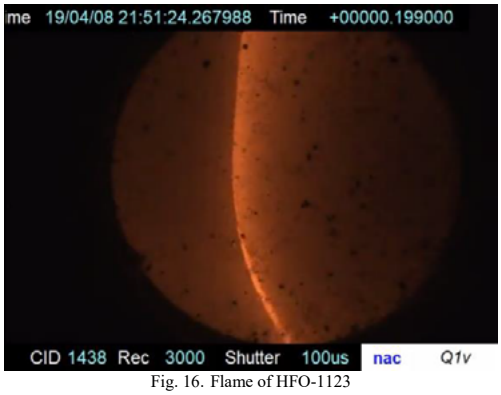
3.6 Flame temperature measurement by the two-color method

Flame temperature is an important parameter when analyzing combustion phenomena using a thermal model. The disproportionation reaction is similar to the combustion reaction from the viewpoint of flame propagation. Thus, it would be beneficial to measure the flame temperature. Therefore, in this study, the flames caused by the disproportionation reaction were photographed with a high-speed camera from two observation windows installed at the top and bottom of the pressure vessel, and the flame temperature was analyzed using the two-color method. The flame of HFO-1123 taken from the upper window is shown in Fig. 16. The generated soot appears black, and the flame shines brightly. The shooting speed is 3000 f/s, and the exposure time is 100 μs.



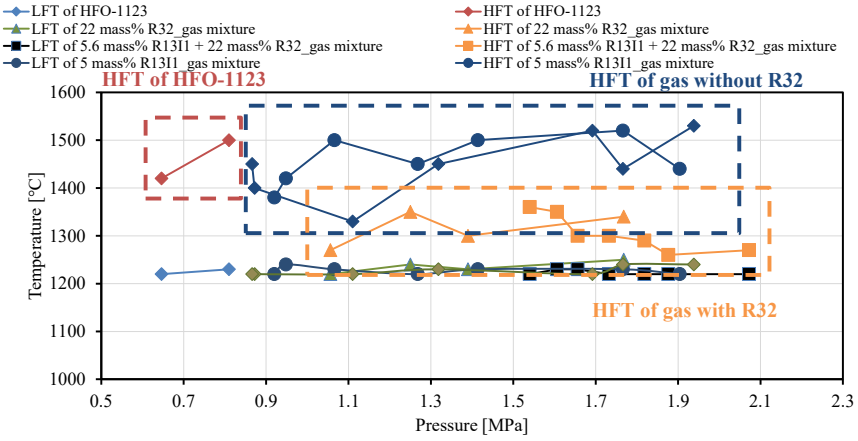


Fig. 16. Flame of HFO-1123

The flame temperature varies with a large distribution in place and time. In this study, the mode temperature of the flame was defined as the flame temperature, and the maximum and minimum values were analyzed. The results for pure HFO-1123 and the three types of gas mixtures are shown in Fig. 17.

The results of the flame temperature measurement show that the minimum flame temperature remains almost unchanged between 1200 and 1250 °C; however, the maximum flame temperature is divided into two groups, depending on whether or not R32 is included in the mixture. The maximum flame temperatures of HFO-1123 and the HFO-1123 + R13I1 mixture were 1400–1500 °C, whereas the maximum flame temperatures of the gas mixed with R32 were 1250–1350 °C. It is assumed that the decrease in the maximum flame temperature results from the thermal dilution effect of R32.

LFT: Lowest Flame Temperature HFT: Highest Flame Temperature

Fig. 17. Results of flame temperature analysis of the test gas mixtures

3.7 Qualitative analysis of the disproportionated reaction gas by GC–MS

In this study, when the disproportionation reaction propagated, the reaction gas was collected after water cooling, and a qualitative analysis of the gas composition was performed using GC–MS. Fig. 18 shows the composition analysis results of the reaction gas of HFO-1123. The reaction gas composition of the 22 mass% R32 gas mixture was almost the same as that of HFO-1123.

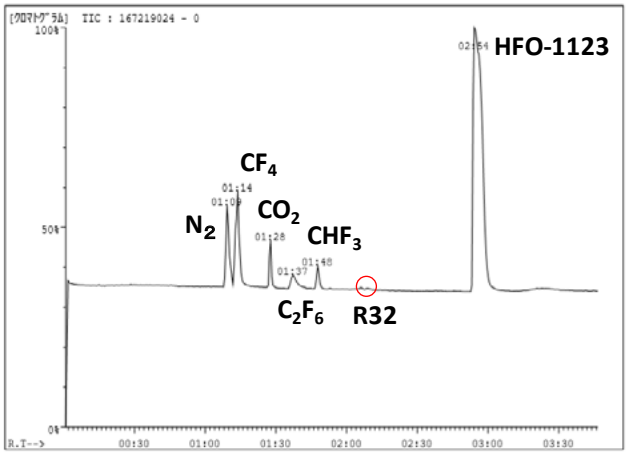

Fig. 18. Results of qualitative analysis of reaction gas of HFO-1123

The results of the qualitative analysis of the 5.6 mass% R13I1 + 22 mass% R32 + 72.4 mass% HFO-1123 gas mixture are shown in Fig. 19. A plurality of intermediate products could be detected in the reaction gas. This is presumed to be the result of the change in the disproportionation pathway caused by R13I1.

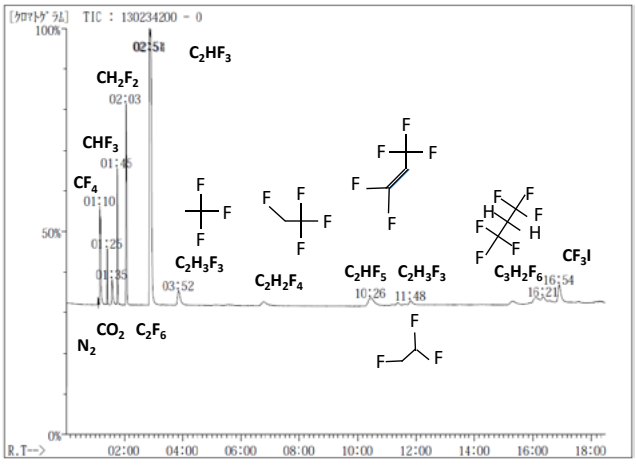

Fig. 19. Results of qualitative analysis of reaction gas of 5.6 mass% R13I1 + 22 mass% R32 + 72.4 mass% HFO-1123 mixture

4. Conclusion

In this study, the initial temperature was fixed at 150 °C, and the boundary was investigated of the initial pressure at which the disproportionation reaction of HFO-1123 and the gas mixtures was propagated. The pressure boundary of each gas mixture is illustrated in Fig. 20. The pressure boundary increased from 0.77 MPa to over 2.0 MPa by mixing with 40 mass% R32, which is expected to be suppressed by thermal dilution, and the pressure boundary increased to 0.92 MPa by mixing with 5 mass% R13I1, which is expected to be suppressed by radical trapping. The suppression effect of mixing only one type of inhibitor was not significant. However, in the case of the ternary gas mixed with inhibitors having two types of inhibition mechanisms simultaneously, an enhanced suppression effect could be obtained, and the pressure boundary increased to over 2.4 MPa (No. 3-5). In addition, to evaluate the suppression effect, the maximum and minimum values of the mode temperature of the flame were obtained using the two-color method, and the composition analysis of the reaction gas was also investigated using GC–MS. Consequently, it was found that R32 exerts a thermal dilution effect and R13I1 changes the reaction pathway.

Abstract

With the enactment of the Kigali amendment, the HFCs are falling into disuse and HFOs are proposed to be studied for replacement. R1233zd(E) as a new HTHP working fluid with low GWP has yet to be further developed. The HTHP is an ideal replacement of boiler to supply heat in industry. However, the construction of megawatt unit usually has a huge investment and may not achieve the desired results. Therefore, a mathematical model is imperative to conduct the performance prediction. This paper proposed a model and it can effectively verify the feasibility of the megawatt R1233zd(E) HTHP system, which recovers 60-80℃ waste heat and outputs 100-160℃ pressured water. The conditions of condensation temperature from 90-160℃ with temperature lift of 50K, were calculated and the COP changed in 3.0-3.8. When evaporating at 60℃ and condensing at 110℃, the heat capacity was up to 1.95MW with COP over 3.8. From the results, R1233zd(E) is a reliable refrigerant for both high temperature output and high system efficiency, which will be a direction for future experiments.

1. Introduction

Heat pump is an effective technology for improving grade of thermal energy, especially applied in absorbing heat from air or industrial waste source. In terms of high temperature heat pump (HTHP), it is mainly utilized in industry field to replace boiler [1] (e.g. coal combustion boiler, natural gas boiler, electrical boiler), which can enhance utilization of energy significantly and decrease the consumption of fossil fuels. R245fa has been recognized as the relative appropriate refrigerant for HTHP, which can achieve both high heat sink temperature and COP [2]. In France, there is an R245fa HTHP unit achieves COP of 2.3 at 60℃ heat source and 100℃ output temperature [3], and another large capacity unit (900-1200kW) can reaches 120℃ sink temperature [4]. But with the promulgation of Kigali amendment in the 28th conference of Montreal Protocol, HFCs with high GWP (Global Warming Potential) need to be cut down gradually [5]. To control the emissions of green-house gases, it is necessary and urgent to find better substitutes. HFOs with GWP only 1 has been recommended as potential candidate for both HTHP [6] and Organic Rankine Cycle (ORC) [7]. R1233zd(E), one kind of HFOs, has been studied widely in ORC to replace R245fa with satisfactory result [7, 8]. For HTHP, Kondou and Koyama [9] has achieved huge temperature lift of 80K (70/150℃) with remarkable COP of 5.3, similarly to that of R245fa. There is insufficient study of R1233zd(E) used in HTHP, especially theoretical study. Therefore, it is essential to have careful theoretical research of R1233zd(E) HTHP system for the optimization.

For theoretical research of heat pump, mathematical model is generally the basic key theory. There are some mature methods shown in Fig.1 [10], ranging from simplified lumped parameter model to detailed discretized model. This study mainly bases on the physics modeling methods and not takes black- and grey-box models into account. Lumped parameter model is a common and class physics-based models for heat pump system simulation. Typically, the temperature distribution in the heat exchanger is independent of the coordinates and can be considered as averaged during the heat transformation. This approach effectively simplifies the computation and leads to dimensionality reduction. Yao et al [11] proposed a lumped parameter model for vapor compression system and the prediction models met with experiments within 10% by converting the governing equations of conservation equations to state-space notation. Moving boundary method [12] is generally cooperated with lumped parameter model. Heat exchanger is divided into separate control volumes according single- and two-phase and properties are averaged in each phase. Moving boundary method can reduce computational cost while providing details of phase boundaries, with relative lower accuracy.

The detailed discretized models use finite volume and finite difference to divide the system component into multiple control volumes. From the discretion of governing equations and solving equations simultaneously, the time response of properties can be simulated. Therefore, the discretized models can predict property change over smaller spatial scale. Compared with moving boundary method, finite volume method was fond to be more robust [12]. But as a result of high accuracy, the calculation is more complex and huger [10]. To simplify the formulation, most models neglect the momentum conservation equation. The earliest dynamic research of vapor compression heat pump system can date back to 1985, Gruhle et al [13] proposed an evaporator model (including momentum conservation) and a method for the control of expansion valve. Mac Arthur et al [14] also proposed a discretized model of evaporator but neglecting momentum conservation and verified by experiments. Hermes et al [15] reviewed the modeling methods and simulated the response of a household refrigerator. Bendapudi et al reviewed the dynamic models of vapor compression equipment [16] and proposed a discretized finite volume model (not including momentum conservation) of a vapor compression system and validated with experiments [17]. They also discussed the detailed model formulation and approaches for numerical solution.

For refrigerant, the space for flow is huge inside the shell and the distance between inlet and outlet is relatively short. The pressure drop of refrigerant can be ignored. Therefore, discretized finite volume model (without momentum conservation) is the approach of this study to better simulate the operation of a

megawatt R1233zd(E) HTHP unit.

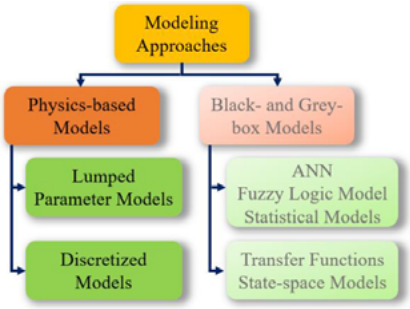

Fig. 1. Classification of modeling approaches for heat pump.

2. Model description

The studied unit is mainly composed of falling film evaporator, double-stage centrifugal compressor, shell-and-tube condenser, electronic expansion valve and flash tank, shown as Fig.2. The double-stage centrifugal compressor is divided into two independent compressors to show the intermediate vapor injection process more clearly.

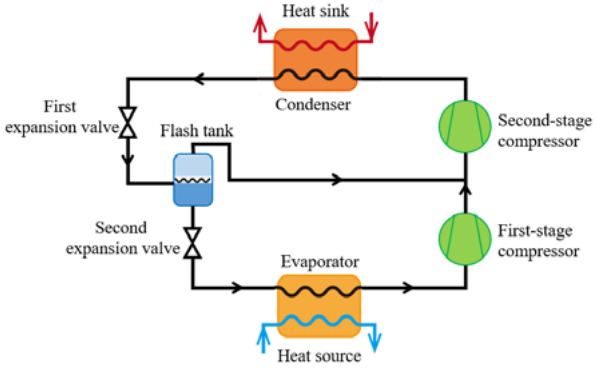

Fig. 2. Schematic of heat pump system cycle

2.1 Compressor model

The type of the compressor is double-stage centrifugal, of which the frequency N_{COM} is 50r/s, the adiabatic efficiency (η_s) is 75%, mechanical efficiency (η_{me}) is 98% and the motor efficiency (η_{mo}) is 97%. Actually, the capacity of centrifugal compressor is controlled by variable inlet guide vanes. In this study, to simplify model the compressor is simulated to operate under wide-open vanes with maximum flow rate. The basic governing equations are shown as equation 1, the mass flow rate $m_{r,COM}$ can be obtained, and given the $i_{r,COMint}$ (enthalpy of refrigerant from evaporator inlet) can get the $i_{r,COMout}$ (enthalpy of condenser outlet). Finally, the power consumption of compressor can be calculated.

$$\begin{cases} m_{r,COM} = N_{COM} V_{COM} \rho_{r,COMin} \\ i_{r,COMout} = \frac{(i_{r,iso-entropy} - i_{r,COMin})}{\eta_s} + i_{r,COMin}, \quad \eta_s = 0.75 \\ P_{COM} = \frac{m_{r,CM}(i_{r,COMout} - i_{r,COMin})}{\eta_{me}\eta_{mo}}, \qquad \eta_{me} = 0.98, \eta_{mo} = 0.97 \end{cases} \tag{1}$$

2.2 Expansion valve

The function of expansion valve is to expand the refrigerant from high pressure and temperature to low pressure and temperature meeting the evaporation condition. At the same time, the expansion can adjust the flow rate of refrigerant by controlling the opening degree of valve to response to the load change. According to equation 2, the mass flow rate $m_{r,TV}$ of the expansion valve is determined by the pressure difference ($p_{r,TVin}$-$p_{r,TVout}$), and the inlet enthalpy $i_{r,TVin}$ is considered to be the same with outlet enthalpy $i_{r,TVout}$ because of the ideal iso-enthalpy throttling process.

$$\begin{cases} m_{r,TV} = K\sqrt{(p_{r,TVin} - p_{r,TVout})\rho_{r,TVin}} \\ i_{r,TVin} = i_{r,TVout} \end{cases} \tag{2}$$

2.3 Evaporator

In this model, the four tube-passes falling film evaporator is applied, with the arrangement of tubes inside the evaporator approximately displayed in Fig. 3 and detailed number of tubes listed in Table 1. The outer and inner diameter of tube (light tube) inside evaporator and condenser are all 19.05mm and 16.2mm respectively. The general flow patterns of a falling film evaporator can be divided into film shape, column shape and dry shape from top to bottom. There will be pluges of heat trasfer coefficent when drop spot occurs, so the heat transfer process needs to be discussed seperatelly. The heat transfer coefficient inside tube of evaporator and condenser is the same, calculated as equation 7. The coefficient of refrigerant outside the evaporator in the falling film area is estimated as equation 8 [18]. When the liquide film evaporates to dry out, the coefficent of heat transfer follows equation 10. In full liquid area, pool boiling heat tansfer coefficient is calculated as the Cooper formula (equation 10) [19].

$$h_W = \frac{\lambda Nu}{Di} = \frac{\lambda_w * 0.023 * Re_w^{0.8} Pr_w^{0.4}}{Di} \tag{7}$$

$$\begin{cases} h_{r,f} = Kh_p \\ K_f = (1 - 0.335\frac{d_t}{d_{t,sta}})[2.059 + 2.37\frac{q_{i,j}}{q_{crit}} + 7.793(\frac{q_{i,j}}{q_{crit}})^2] \end{cases} \tag{8}$$

$$\begin{cases} h_{r,f} = Kh_p \\ K_d = \frac{K_{f,crit}}{Re_{crit}} Re_r, \qquad Re_r = \frac{4m_r}{\mu_r} \\ \frac{Re_r}{Re_{crit}} = (\frac{q_{i,j}}{q_{crit}})^2, \qquad Re_{crit} = 2(0.00339 * q_{crit} + 82.3) \end{cases} \tag{9}$$

$$\begin{cases} h_{r,l} = 55 * q_{i,j}^{0.67} M_r^{-0.5} p_r^m (-lgp_r)^{-0.55} \\ m = 0.12 - 0.21gR_p, \qquad R_p = 0.3 - 0.4\mu m \end{cases} \tag{10}$$

2.4 Condenser

A horizontal shell-and-tube condenser with one shell process and two tube processes, shown as Fig. 4. The tubes of condenser adopted an equilateral triangle arrangement with total 356 tubes and the number of every row is listed at Table 1. Because of the staggered arrangement, condensate may not fall directly on the tube beneath as Fig. 5 shown, but falls on the slanted and middle tubes, which is defined as lateral drainage. since the condensate drains over intermediate tube, the rows number of tubes should be adopted as Fig.5 reflected. From some ideal simplification, almost half of one tube volume is flooded. Above the analysis, Eissenberg et al [20] proposed the heat transfer coefficient of condensation according different rows (equation 11). From the equation, hn is set to the valve of h1 which is the first row of condensation.

$$\begin{cases} \frac{h_n}{h_1} = 0.7974 + 0.2327n^{-1/5} \\ \frac{h_1}{\lambda_1}[\frac{\mu_l^2}{g\,\rho_l^2}]^{1/3} = 1.523(\frac{4m_1}{\mu_l})^{-1/3} \end{cases} \tag{11}$$

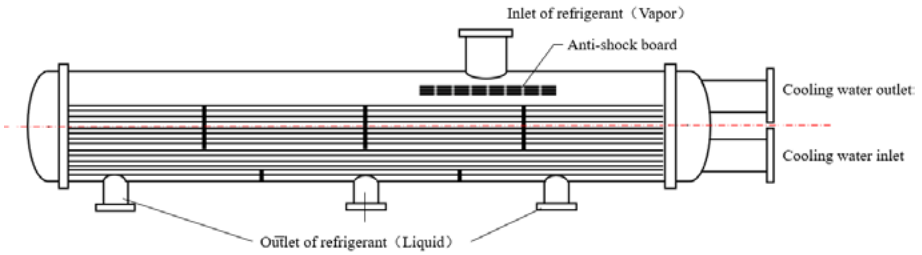

Fig. 4. Structure diagram of horizontal shell-and-tube condenser<1-2>

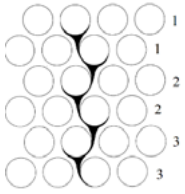

Fig. 5. Pure lateral drains and tube rows.

Here, the methods for control volume division and finite difference of condenser are described carefully, and they are similar to evaporator. With the method of finite volume, heat exchanger is divided into limited control volume according to the inner node method, shown in Fig.6. In condenser, superheated vapor enters

from top and passes through the anti-shock plate, then it flows downward more uniformly. The vapor condenses on the surface of the heat exchange tube, and the condensation liquid gradually flows downward due to gravity. Cooling water flows into heat exchanger from low tubes and out of heat exchanger from up tubes. When cooling water is out of low tubes ($i_{9\text{-}N}j_{M+1}$ side), there is a mixed process of tubes of i_9-i_N which is assumed as well mixed to T_{wmid} and the inlet temperature of i_1-i_8 is also T_{wmid}. The results of discretized equations (3-7) are in appendix, and it should be noted that the boundary of the model like nodes i_0j_1, i_1j_{M+1}, $i_{N+1}j_1$ and $i_{N+1}j_M$, using Taylor expansion method to discretize. Because of the flow direction of refrigerant and water, second-order upwind difference scheme is used as discretization method of governing equations. Second-order center difference is called for discretization of tube wall governing equations due to no fluid flowing and only energy conservation.

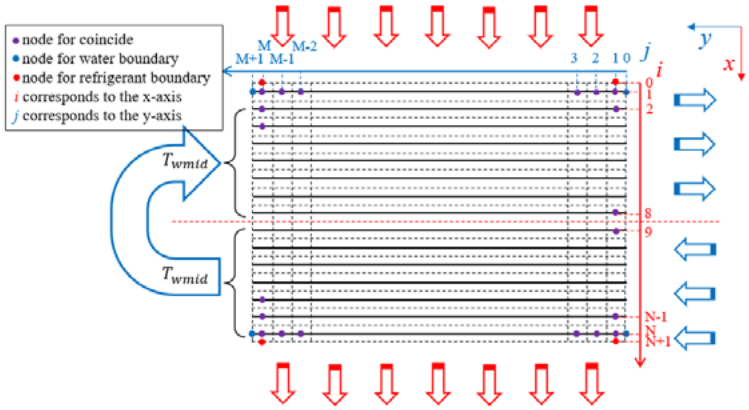

Fig. 6. Schematic of discretized finite volume of condenser.

2.5 *Flash tank model*

The flash tank mainly works to adjust the mass flow rate of vapor injection. The pressure inside flash tank is same with outlet of first expansion valve and first-stage compressor. The saturated vapor is injected to the middle of compressor and mix with the superheated vapor of outlet first-stage compressor to a moderate superheat temperature. At the same time, the mass flow rate of main stream (evaporator) contains constant.

3. Calculation algorithm

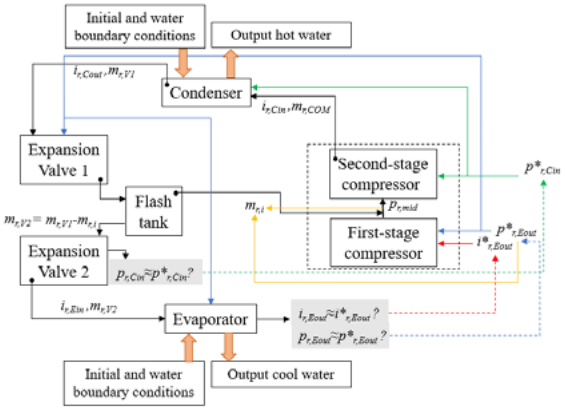

Fig. 7. Framework of the system simulation of the HTHP

The calculation algorithm of double-stage compression with intermediate vapor injection heat pump system is shown in Fig.7. First, the evaporation pressure ($p^*_{r,Eout}$), enthalpy of evaporator outlet ($i^*_{r,Eout}$) and condensation pressure ($p^*_{r,Cin}$) are assumed and the pressure between two-stage compressor is set, then the mass flow rate of intermediate vapor injection can be determined. Refrigerant flows through compressor, condenser and expansion valves, with current pressure of condensation ($p_{r,Cin}$) calculated. With current $p_{r,Cin}$ as initial input $p^*_{r,Cin}$, iterate $p_{r,Cin}$ until $p_{r,Cin}$ is equal to $p^*_{r,Cin}$. Similarly, $i_{r,Eout}$ and $p_{r,Eout}$ can be updated after calculating the properties of evaporator and set $i_{r,Eout}$ and $p_{r,Eout}$ as assumed value of initial input until they are equal. Transient properties of refrigerant, tube and water during the operation can be estimated by the repeated calculation of iteration. The calculation is finished by C++ program.

4. Results and discussion

The simulated system is equipped with intermediate vapor injection system, in which saturated vapor from flash tank was injected to the suction port of Second-stage compressor. Therefore, there will be an optimum mid-pressure injection. Fig. 8-11 shows the system performances varying with the increasing of mid-pressure, and the calculated working condition is evaporating at 55℃, condensing at 80℃, 2℃ subcooling at the outlet of condenser and mass flow rate of First-stage compressor constant at 15kg/s. In Fig.8, the vapor injected mass flow rate shows a downward trend. When the open degree of first-stage throttle remains unchanged, the pressure difference between inlet and outlet of throttle shrinks, and mass flow rate decreases (according equation 2). Further, the superheat of Second-stage compressor discharge decreases slightly, which is mainly due to the physical properties of R1233zd(E) that the slope of isentropic line is larger than saturated gas line and the distance between them is closer in higher temperature area. Therefore, the refrigerant compressed from mid-pressure to Second-stage will get the state closer to saturated gas line when mid-pressure higher. The heating capacity is larger than 2 MW, and decreases with the mid-pressure increasing, which is mainly due to the decreasing of mass flow rate in condenser (shown as Fig. 9). In Fig. 10, the power consumption of First-stage and Second-stage compressor are compared and the consumption of Second-stage compressor decreases with the increasing of mi-pressure. The decline is mainly because of the decrease of injected vapor mass flow rate and enthalpy difference. The increasing enthalpy difference with mi-pressure increasing is the reason of power consumption of First-stage compressor increase. Last, the system COP is calculated, shown in Fig. 11. There is a peak value with the increasing of mid-pressure, therefore, an optimum mid-pressure exists. The COP is calculated according to the definition that ratio of heating capacity to power consumption. Actually, the heating capacity and total power consumption are both decreasing, so, the changing trend of COP is owing to the relative changing trend of them.

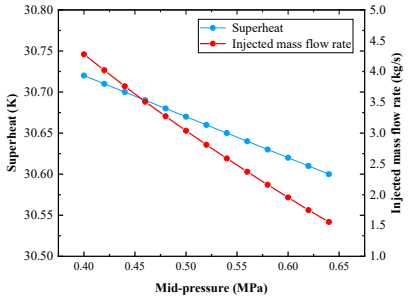

Fig. 8. Variation of superheat of compressor and injected vapour mass flow rate with mid-pressure increasing

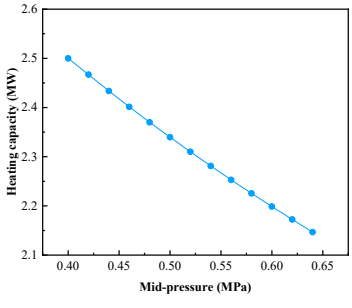

Fig. 9. Variation of heating capacity with mid-pressure increasing

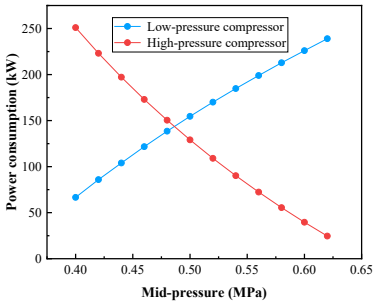

Fig. 10. Variation of power consumptions of First-stage and Second-stage compressor with mid-pressure increasing

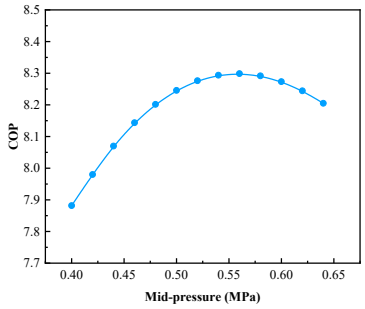

Fig. 11. Variation of COP with mid-pressure increasing

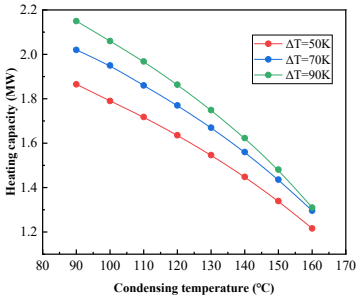

Fig. 12. Variation of heating capacity with condensing temperature increasing (in different ΔT)

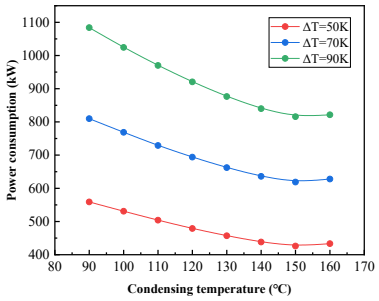

Fig. 13. Variation of power consumption with condensing temperature increasing (in different ΔT)

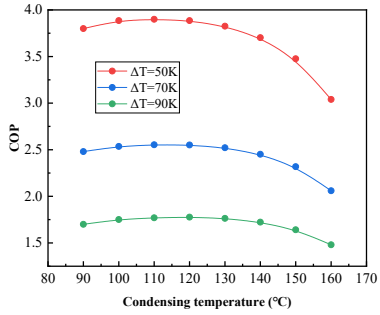

Fig. 14. Variation of COP with condensing temperature increasing (in different ΔT)

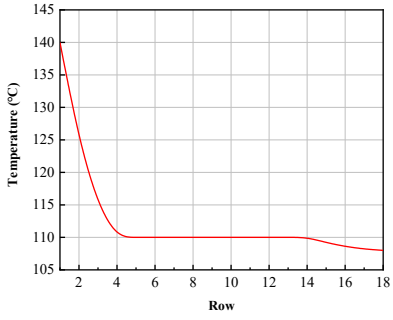

Fig. 15. The temperature distribution of refrigerant inside shell-tube condenser according to the tube row

Further, the system performance in different working conditions are simulated at fixed temperature lift and optimum mid-pressure injection (evaluated as equation12 [21]), shown as Fig12-14. Heating capacity reduces with the condensing temperature increasing (Fig.12), which is mainly attributed to the enthalpy difference decreasing in higher temperature area. At the same time, the heating capacity decreases with the temperature lift dropping, which is owing to that higher evaporation temperature leads to higher optimum mid-pressure and less injected mass flow rate. In Fig. 13, the total power consumption decreases with the absolute slope smaller. The power consumption increases with the temperature lift larger. Even the heating capacity of condition ΔT=90K higher than other, the higher power consumption decides the COP of ΔT=90K is the smallest. And from the comprehensive consideration of heating capacity and power consumption, the COP also has a fluctuating change with the increasing of condensing temperature (shown as Fig. 14). The change is also because of the different reduced rate of heating capacity and power consumption.

$$p_{opt} = \sqrt{p_e p_c} \tag{12}$$

To reveal the inner detailed heat transfer process, temperature distribution of refrigerant inside shell according to the tube row is reflected as Fig. 15. Initially, cooling water (100℃, 115kPa) is pumped to heat

exchange tube of condenser with 32L/s, and the vapor refrigerant (110℃ and 1.28MPa), with about 30℃ superheated. In the first three rows, the superheated refrigerant vapor exchange sensible heat with tube. In the 4-14th row, refrigerant condenses to liquid gradually and exchange latent heat with tube. During the condensation process, the condensate flows from top to full liquid area, therefore, some single-phase heat transfer also appears in two-phase heat transfer area. In the bottom of condenser, there is full liquid area, with saturated liquid cooling to subcooled liquid. The outlet temperature of refrigerant in condenser is about 108℃, with about 2℃ subcooled.

5. Conclusion

In this paper, a mathematical model of megawatt HTHP system adopting R1233zd(E) refrigerant is built. From the discretization of governing equations and the division of limited finite volume, parameters at each control volume can be obtained. The optimum injection mid-pressure is estimated, and due to the physical properties of R1233zd(E), the injected mass flow rate dropping with the increasing of mid-pressure. To predict the operation performance of megawatt R1233zd(E) HTHP, the conditions of condensation temperature from 90-160℃ with temperature lift of 50K, 70K and 90K were calculated. In the condition of 50K temperature lift, he COP changed in 3.0-3.8, and there is a peak value in the range. When evaporated at 60℃ and condensed at 110℃, the heat capacity of this heat pump system was up to 1.9MW with COP above 3.8 during stable operating. From the results of model, R1233zd(E) is kind of a reliable refrigerant for both high temperature output and high system efficiency, which will be a direction for future experiments.

Abstract

In cold winter season, most air heat pumps suffer from the frost formed on the surface of the outdoor heat exchanger. This frost must be removed, otherwise the heat pump performance will keep degrading and deviate from the design conditions, causing severe damage to the components. For this reason, it is necessary to determine the appropriate defrost start time. Several methods have been suggested, however, most of them are either based on empirical studies that require large number of experiments or less practical because they use expensive sensors. In this study, a new method is proposed to determine the defrost start time and verified with experiment. Three steps are required. First, calculate the frost mass that is generated per unit time using the heat and mass transfer analogy. Second, obtain the volume by dividing the frost mass with the density of frost. Third, the frost volume generated per unit time is accumulated and compared with the heat exchanger volume to determine the defrost start timing. With this method, the defrosting operation can be appropriately initiated.

Keywords: heat pump, heat exchanger, frost, defrost start time, frost volume, blocking ratio;

1. Introduction

In cold winter season, most air heat pumps in humid region suffer from the frost. It forms naturally due to the sublimation from air to the surface of the outdoor heat exchanger when the surface temperature becomes lower than the freezing temperature of water and the dew point temperature of the ambient air. This frost disturbs the air flow in the outdoor heat exchanger and lowers the heat exchange rate, thus reduce the overall performance of the heat pump system. In the experiment from Yan et al. [1], heat transfer rate and overall heat transfer coefficient drop while pressure drop of the heat exchanger rises under frosting conditions. In addition, Shao et al. [2] showed the decline of both heating capacity and COP in fin-tube microchannel heat exchangers during frost formation process. The frost on the surface must be removed, otherwise the heat pump performance will keep degrading and cause significant energy loss. Moreover, heat pump operation might deviate from the design conditions. Thereby determining the proper defrosting start time to prevent severe damage to the components is one of the important issue in heat pumps

Up to now, several methods have been suggested to judge defrosting start time. For direct frost detection methods, photoelectric sensors with emitter and receiver that measure the intensity of infrared ray between the inlet and outlet of air flow at the outdoor heat exchanger is proposed by Byun et al. [3]. Similarly, from the study of Chung et al. [4], the differential pressure can be measured to monitor the frost formation. The direct detection method measures a certain spot of the heat exchanger and let us know whether there is frost in that spot or not. This approach generally raises the issue of representativeness as to whether the point can represent the whole. For indirect frost detection methods, Kim and Lee [5] proposed the effective mass flow fraction (EMF) that follows the trend heating capacity. Zhu et al. [6] suggested temperature–humidity–time (T-H-T) method that utilizes a frosting map which is evolved from simple temperature-time (T-T) method. In this

E-mail address: jwyoo@kimm.re.kr

method, a concept of accumulated time is introduced to determine the defrost start time. However, it only considered outdoor air condition and not the conditions of heat pump itself. The indirect detection methods generally describe overall system performance change but proposed methods are either hard to implement or limited on certain cases.

In this study, a new indirect frost detection method is proposed to determine the defrost start time and verified with experiment. The accumulated frost volume is calculated and compared with the volume of heat exchanger. The concept of accumulation is important because the state of the heat pump continues to change during its operation. This method also considers both factors of outdoor air (temperature and humidity) and heat pump itself (speed of compressor, the temperature of heat exchanger).

2. The calculation of frost volume and blocking ratio

Yoo et el. [7] explains the frost formation depends on the air temperature, humidity, and surface temperature of heat exchanger and heat exchange rate at evaporator. To form frosts two conditions must be met. The evaporator temperature should be lower than 0°C and the humidity ratio of outdoor air needs to be higher than that of air at the saturated condition at surface temperature of heat exchanger. The point 1 in Fig. 1 explains this condition. Otherwise, frost will not form. (point 2)

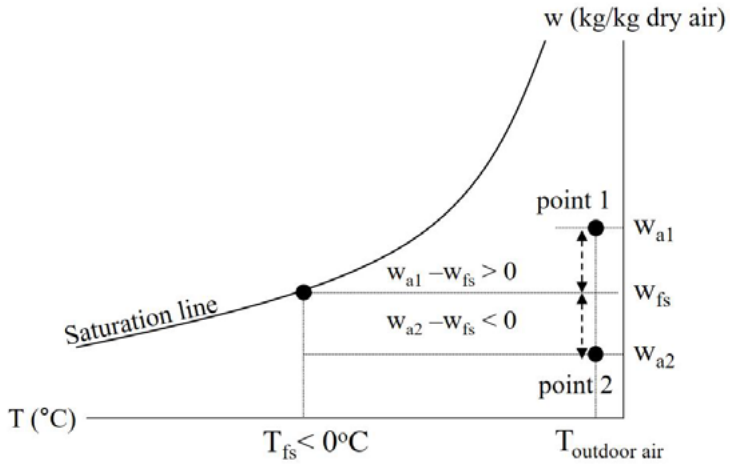

Fig. 1. Humidity ratio in psychrometric chart [7]

For the calculation of accumulated frost volume, three steps are required. First, we calculated the frost mass that is generated per unit time (Eq. (2)) by using the heat and mass transfer analogy in Eq. (1). Detailed derivation is represented in the study of Yoo et al. [7]

$$h_m = \frac{h_a}{C_{p,a}\rho_a Le^{2/3}} \tag{1}$$

$$\Delta m_f(t) = \frac{\dot{m}_{ref}\left(h_{comp,in} - h_{cond,out}\right) \times (w_a - w_{fs})\Delta t}{C_{p,a}Le^{2/3}(T_a - T_{fs}) + (w_a - w_{fs})L_{ig}} \tag{2}$$

Second, we obtained the frost volume per unit time by dividing the frost mass with the density which is Eq. (3).

$$\Delta V_f(t) = \frac{\Delta m_f(t)}{\rho_a(t)} \tag{3}$$

The equations of frost density were developed over time. We used the equation (Eq. (4)) that has the same form from Hayashi *et al*. [8]

$$\rho_f = f(T_{fs}) = C_1 \exp(C_2 T_{fs}) \tag{4}$$

Third, the frost volume generated per unit time is accumulated (Eq. (5)) and compared with the heat exchanger volume to determine the defrost start timing. In Eq. (6), blocking ratio (BR) is defined to evaluate the ratio between two volumes.

$$V_{f,accum}(t) = \sum_{\tau=0}^{t} \Delta V_f(\tau) \tag{5}$$

$$BR = V_{f,accum}/V_{heat\ exchanger} \tag{6}$$

With the BR, which is an index of the ratio of frost volume and heat exchanger size, the time of defrost can be determined. In this work, the defrost process starts at the timing when BR becomes 1.

3. Experiment setup and test condition

In order to calculate the frost volume and blocking ratio that were presented in section 2, several sensor data are needed which are dry bulb temperature and relative humidity of outdoor air inlet, the evaporator inlet temperature, the pressure and temperature at the inlet of compressor and the outlet of condenser. Heat pump data are also required which are outdoor heat exchanger size, compressor displacement, current compressor rotational speed. Fig. 2 provides the measurement information of heat pump experiment. The properties of air such as density, enthalpy, specific heat and humidity ratio, were calculated by the equations from ASHRAE Handbook [9]. The air flow rate of the indoor units was obtained according to the ANSI/AMCA 210 [10].

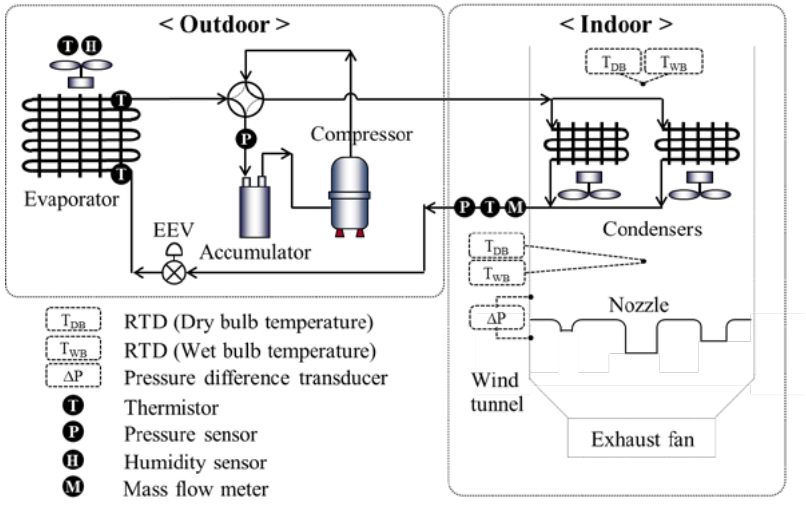

Fig. 2. The schematic of the heat pump system for experiment [7]

Table 1 gives the specification of the heat pump. It has variable speed compressor and fin-tube type heat exchangers, electronic expansion valve and uses refrigerant R410A.

Table 1. Specifications of heat pump system

Component	Specifications
Compressor	Inverter-driven scroll compressor / Stroke volume : 62.1 cm^3
Condenser side (2 Indoor units)	Fin-tube heat exchangers Tube inner / outer diameter (mm): 6.3 / 7.7 Row / Step: 2 / 10 Width / length / height (mm): 3000 / 40 / 200 Fin pitch (mm): 1.5
Evaporator side (1 Outdoor unit)	Fin-tube heat exchanger Tube inner / outer diameter (mm): 6.3 / 7.7 Row / Step: 3 / 45 Width / length / height (mm): 1650 / 60 / 1220 Fin pitch (mm): 1.7
Expansion device	Electronic expansion valve
Refrigerant	R410A

In Table 2, experiment conditions and results are presented. To verify the proposed frost volume calculation method, total 7 experiments were conducted. In case 1, 2 and 3, outdoor dry bulb temperature is set at 2, -4, -10˚C and all the other variables were fixed. Likewise, in case 1, 4 and 5, outdoor relative humidity changed from 68 to 83.8 %, in case 1, 6 and 7, compressor rotational speed was varied from 60 to 100 Hz.

Table 2. Experiment conditions and results

Experimental case	1	2	3	4	5	6	7
Indoor inlet T_{DB} (˚C)				20			
Indoor inlet T_{WB} (˚C)				15			
Outdoor inlet T_{DB} (˚C)	2	-4	-10	2	2	2	2
Outdoor inlet RH (%)	83.8	83.8	83.8	75	68	83.8	83.8
Compressor speed (Hz)	100	100	100	100	100	80	60
Q drop at the defrosting start time at BR=1 (%)	12.8	17.1	16.6	17.3	13.3	12.8	15.4
COP drop at the defrosting start time at BR=1 (%)	8.3	12.3	12.2	10.7	10.0	9.6	14.2
Time from start of operation to BR=1 (minutes)	72.0	70.0	65.2	96.5	135.1	82	108.6

The uncertainty analysis was done with respect to each cases, according to ASHRAE Guideline 2 [11]. At 95% confidential level, the maximum uncertainty of heating capacity and COP were 5.43% and 5.49% respectively.

4. Results

4.1. Determination of the defrost start time with the calculated blocking ratio

With the calculated BR derived from section 2, the defrost starts at the timing of BR equals 1 in all 7 experiment cases. The change of heating capacity, COP and BR for every cases is shown in Fig. 3. In Case 1 (Fig.3 (a)), when heat pump starts to operate the heating capacity and COP increases until 15 minutes. After that, heating capacity and COP does not show as drastic change between 15 and 60 minutes. However, after 60 minutes, the performance drop becomes noticeable. 72 minutes later, BR reaches 1 and at that time, the heating capacity and COP are dropped 12.8 % and 8.3% respectively. On the other hand, BR continues to grow from the beginning of operation because the value of humidity ratio difference in Eq. (2) is positive during operation and increases the value of frost volume in Eq. (5). All the other cases show similar trend which is divided into three stages. After heat pump is on, the performance value increases at first, shows only minor change at certain amount of time and begins to drop prominently. At the condition of BR =1, the defrost start timing for all cases lies at the 3rd stage where performance drop occurs and the specific percentage at that time is shown in Table. 2. Heating capacity drop is between 12.8 and 17.3 % while COP drop is between 8.3 and 14.2 %. With the proposed volume calculation method, it properly judges the defrost start time.

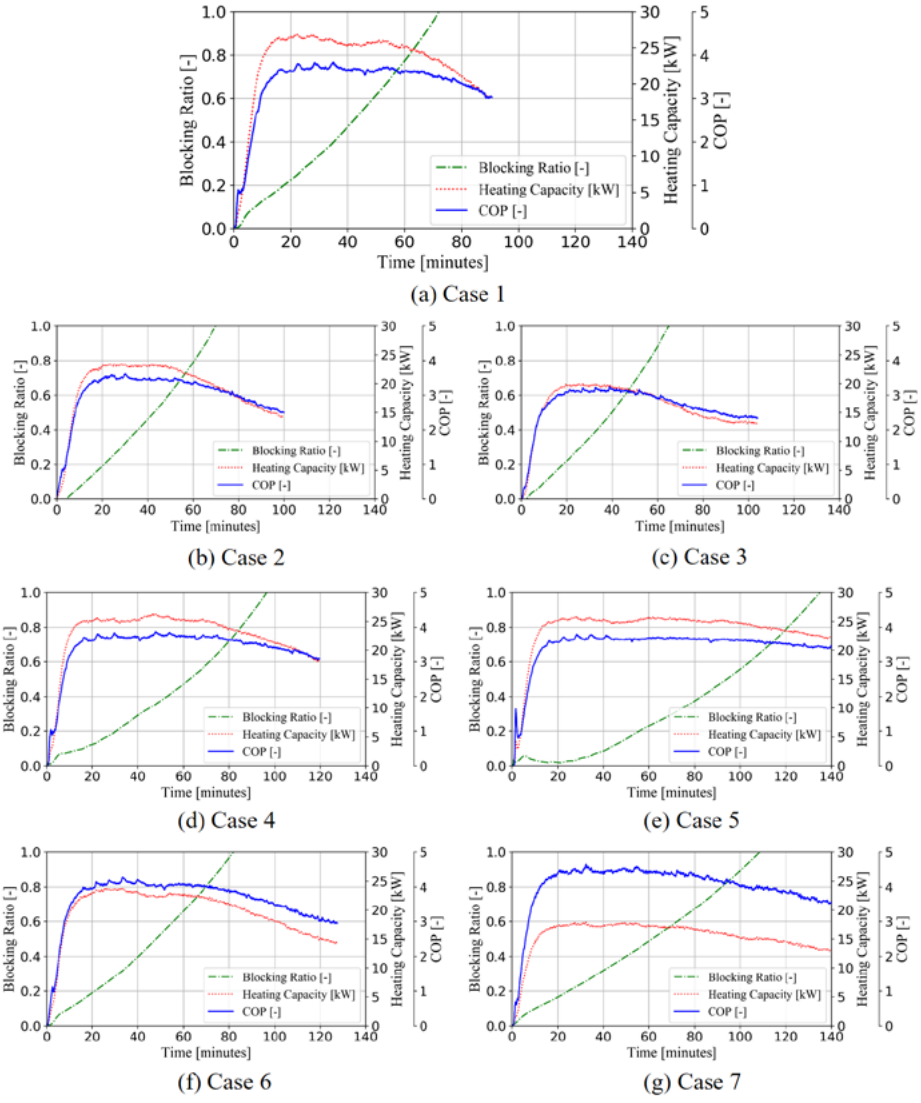

Fig. 3. Time vs. locking ratio, Heating capacity and COP at each cases

To support usefulness of the volume calculation method, the pictures of both front and right side of the outdoor heat exchanger were taken for every cases in Fig.4. At the defrosting start time, the majority of the area is covered with frost. No experimental cases show any mal-defrost.

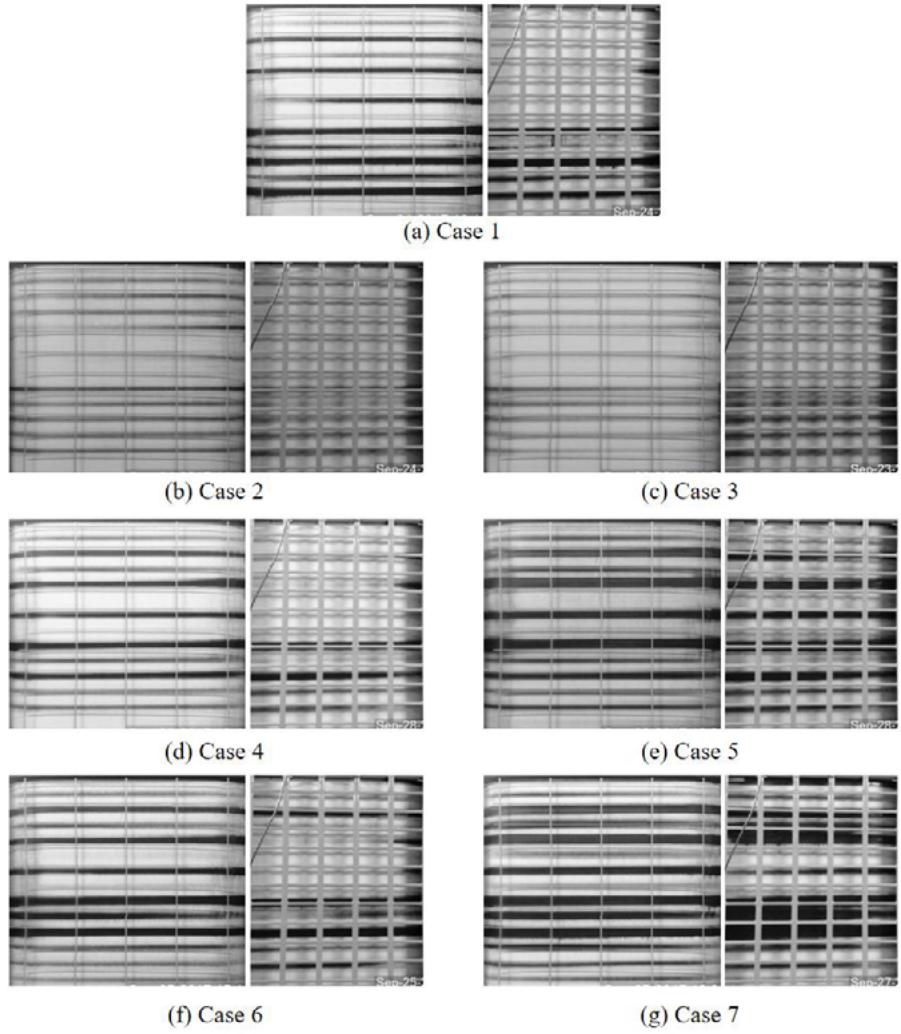

Fig. 4. The picture of outdoor heat exchanger at the defrost start time (front and right side)

4.2. The effect of outdoor dry bulb temperature, relative humidity and compressor rotational speed

With the 7 experiments in Table 2, the effect of outdoor dry bulb temperature, relative humidity and compressor rotational speed can be found. In case 1-3, all the other conditions are the same except outdoor dry bulb temperature. As the dry bulb temperature decreases, the start timing becomes shorter because the frost covers heat exchanger faster due to the lower frost density. (larger specific volume) When comparing case 1, 4 and 5, only the outdoor relative humidity is different. The relative humidity drop causes longer time from start of operation to BR=1. This is because the difference in humidity ratio ((w_a-w_{fs}) in Fig.1) decreases and forms less frost mass from Eq.(2).The effect of compressor rotational speed can be compared from case 1, 6 and 7. As the speed gets slower the mass flow rate of the refrigerant gets lower thereby creates less frost from Eq.(2).

5. Conclusion

In this study, a frost volume and blocking ratio calculation method is suggested in order to determine the defrosting start time. Detail calculation of BR and experiment setup is presented in section 2. To verify the method at various operating conditions, total 7 experiment were done at different outdoor dry bulb temperature, relative humidity and compressor rotational speed. In all cases, the defrosting start time (when BR becomes 1) were properly predicted at the performance decrease stage. The performance drop of heating capacity and COP is between 12.8 and 17.3 %, 8.3 and 14.2 % respectively at the defrost start time.

Is HFO the last generation of synthetical refrigerants?

Kenneth Hoffmann[a], Jan Gerritsen[a], Armin Hafner[b]

[a]GEA Refrigeration, De Beverspijken 7c, 5221 EE `s-Hertogenbosch, Netherlands
[b]NTNU, Trondheim, Norway

Abstract

Since 1920 many different synthetical refrigerant have been introduced onto the market. The latest so-called 4th generation synthetical refrigerant is the unsaturated HFC or HFO (Hydrofluoroolefins). They introduced to combat an environmental issue, i.a. the global warming potential of HFC refrigerant, however, they are creating a new challenge. Recent research has shown that there is a build-up of fluoride substances as Trifluoroacetic acid (TFA) in drinking water globally. Some of the HFO molecule are breaking down 100% into trifluoroacetic acid, which can lead to large health cost in the future, due to this environmental pollution. Whereas the heat pump industry working with natural refrigerant are focusing on low charge and no leakages solutions, due to the flammability and toxicity of some of the natural refrigerant, there is very little effort by the industry working with synthetical refrigerant to create similar safe and low charge solutions. Research have shown that all current HFO based system solutions could be replaced by units applying natural refrigerants without significant cost implication.

Keywords: HFO; R1234yf; TFA; global warming; heat pumps; toxicity; natural refrigerant.

1. Introduction

The market of refrigeration and heat pump is growing each year, however, also the concern for the global environment and humans' impact on Earth's climate. We all want to keep the Earth healthy for the next generations to come. This paper has collected some of the recent research into the effect of introducing HFO as a refrigerant in large scale. Most of the research have been made on R-1234yf which is the main refrigerant discussed in this paper, although many other HFO refrigerants with similar properties have been introduced into the marked lately.

2. The history of refrigerants

Humans learned already from the primitive times that keeping food cold helped to extend their shelf life. In Egypt and Greek time there where, widespread use of storage pits to keep products cool. In the 1740's the first scientific results of creating cold by creating pressure change was proven by William Cullen. It took however another 60 years before Thomas Moore invented commercial refrigeration by taking energy from an ice storage into a dairy plant. This was the start of refrigeration as we know it today. Up through the 19th hundred mechanical compression refrigeration was introduced using CO_2, Ammonia or SO_4 as refrigerants. Due to lack of knowledge, training and material quality there where several accidents with these first refrigeration system, with several of them being fatal. By 1930 the first synthetical refrigerants, chlorofluorocarbons also known as CFC's, where commercialised by Thomas Midgley[1]. The CFC's where introduced as safe refrigerants as they are not flammable. This led to a large increase in use of refrigeration, in new areas where the end user's knowledge of refrigeration was limited like home appliances, supermarket- and HVAC units.

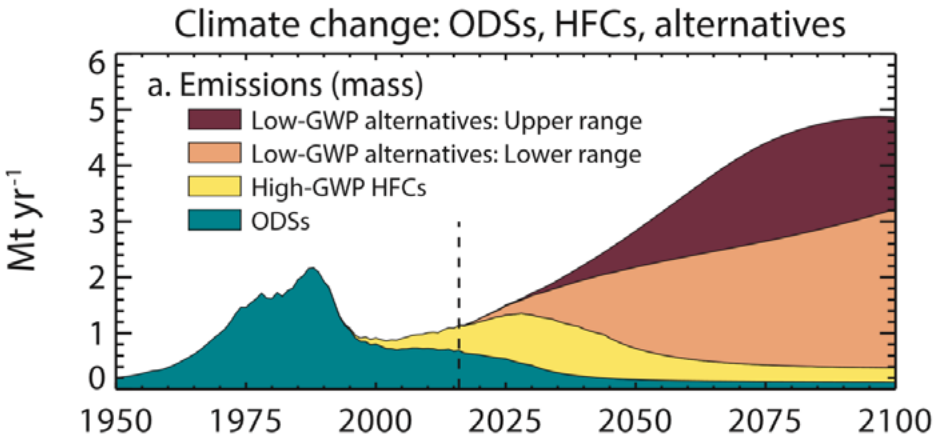

Figure 1: The figure shows the emission of refrigerant gas in Mt per year[4]. After 2016 it is a forecast based on current global development and legislation. By 2040 the release of low GWP refrigerants (HFOs) will exceed the peak release of ODS refrigerants (CFCs).

In the 1980's it was realised that the CFC refrigerants was causing a hole in the ozone layer in the stratosphere, which protects the Earth from UV radiation[2] . Although the CFC's were deemed safe, this was partly on a local level, on a global level, they had the potential to eradicate the human population if no action was taken and the ozone layer would have disappeared completely. To avoid this, it was decided in 1987 (Montreal protocol [3]) to curb the use of CFC with the goal to stop using all CFC's within 26 years (Last legal production of CFC in Article 5 countries where in 2003[3]). As alternative to the CFC's the refrigerant industry developed the HCFC, which had 10 times less ozone depleting effect compared to the CFC's, these where accepted as an intermediate refrigerant until a better solution was found. The HCFC will be fully phased out by 2040 in Article 5 countries. Since followed the developments of the hydrofluorocarbons - HFC's which have no ozone depleting effect. This was great news for the ozone layer and in recent years there has been some restoring of the ozone layer in the stratosphere [4].

Table 1: Article 5 country phase-out schedule for HCFC production and consumption [3]

Schedule	Year
Baseline	Average of 2009 and 2010
Freeze	2013
90% (reduction of 10%)	2015
65% (reduction of 35%)	2020
32.5% (reduction of 67.5%)	2025
Annual average of 2.5%	2030 to 2040
0% (reduction of 100%)	2040

The HFC's unfortunately raise another potential issue as they have a significant high global warming potential. With increasing temperatures on earth, due to the excessive usage of fossil fuels over the last 100 years it seems not logical to apply such harmful refrigerants. With increased water level and more severe weather phenomena's, there are potentially many deaths in the future related to global warming. This is especially the case if the human population does not manage to keep the goals from the Paris agreement of "keeping global average temperature to well below 2 °C above pre-industrial levels and pursuing efforts to limit the temperature increase to 1.5 °C" [5]. The Paris agreement have been ratified by 185 of the 197 participating countries. It has been followed up by the Kigali amendment [6] in 2016, declaring that all high GWP refrigerants will be phased out by 2047 globally, this will avoid 0.4˚C global warming. The lessons learned is that if it was only the refrigeration industry polluting the world the effect on the global climate would be limited. However, as there are many other sources which effect the global climate, we must be very vigilant regarding the exposure to the global climate as there is only one Planet Earth.

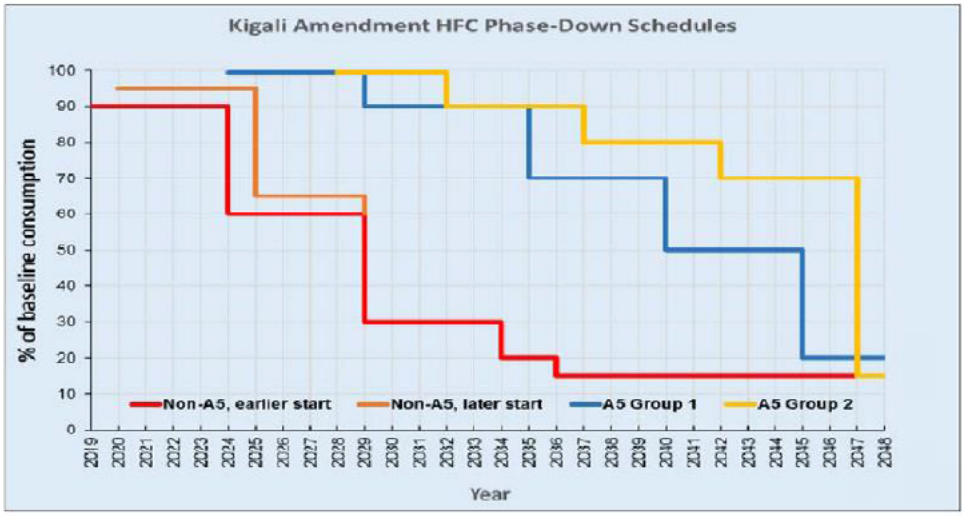

Figure 2: Global phasedown schedule for HFC production and consumption [3].

With growing global demand and sales of refrigerants of more than 15 bn US dollar, the refrigerant manufactures have a huge interest in replacing HFC's and they launched the first alternatives in 2008 [8]. Shortly after, the first articles appeared about the properties of unsaturated HFC's (HFO) refrigerants, which have a very short life in the atmosphere (a few days only). The issue is that HFOs are not safe refrigerant as previous synthetical refrigerants, however, they are flammable and toxic when combusting.

3. How do HFO differ from HFC?

HFC are created of stable molecules bonds, which are difficult to break down. This makes them good refrigerants, but it also gives them high global warming effect, as these stable fluids stay in the atmosphere for a very long time while absorbing radiation. HFO-1234yf is an unstable molecule with a double bond that breaks up quickly in the atmosphere, the degradation produces a 100% molar yield of trifluoroacetic acid (TFA) within days of release. Although TFA is naturally occurring on the oceans there is significant evidence that all TFA found in freshwaters, is human made. R134a does also break down to TFA, but only 20% of the molecules break down to TFA and it's over a much longer period.

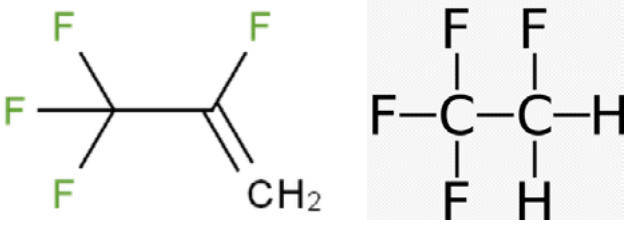

Figure 3: The molecule the left is the unsaturated HFO-1234yf 2,3,3,3-tetrafluoroprop-1-ene, C3H2F4; CF3CF=CH2 with an unstable double bound that breaks down within 10 days[4] in atmosphere. To the right is an HFC-134a 1,1,1,2-Tétrafluoroéthane, $C_2H_2F_4$ molecule, which has a stable structure that stays in the atmosphere for 10 years[4].

Table 2: Table showing the mass amount of TFA created from the refrigerant when decomposed in atmosphere

Molar yields of TFA from degradation of HFO's and HFC's	
HFOs	
R1234ze	<10% (as cited by WMO, 2010)
R1234yf	100% (as cited by WMO, 2010)
HFCs	
R134a	21% (as cited by WMO, 2010)
R227ea	100% (as cited by WMO, 2010)
R245fa	<10% (as cited by WMO, 2010)
R365mfc	<10% (as cited by WMO, 2010)
R236fa	<10% (as cited by WMO, 2010)

4. Toxicity of combustion products from HFO

HFO refrigerants are most commonly categorised as A2L refrigerants as they are so-called mildly flammable. This is a major change from the commonly applied R134a, which is and A1 refrigerant and classified as non-flammable. Although most refrigeration engineers in Europe have been trained since 2007 according to the F-gas regulations a new set of training of the personnel is required to keep themselves and the environment safe when handling HFO refrigerant.

Table 3: Flammability comparison of HFO with other commonly used refrigerants. LFL (lower flammability limit), UFL (upper flammability limit) [8].

Property	R290	R152a	R32	R717	R1234yf
Flame limits (ASTM E681-04) @ 21˚C					
Lower Flammability Level (vol% in air)	2.2	3.9	14.4	15.0	6.2
Upper Flammability Level (vol% in air)	10.0	16.9	29.3	28.0	12.3
Delta UFL – LFL	7.8	13.0	14.9	13.0	5.8
Minimum Ignition energy (mJ)	0.25	0.38	30 – 100	100 – 300	5.000 – 10.000
Burning velocity (cm/s)	46	23	6.7	7.2	1.5

The new refrigerants also require new standard from the equipment suppliers. They need to thoroughly assess the component used to ensure enough effort is made to make the system leak tight. Unfortunately, a lot of global economy is driven by lowest capital cost and not life cycle cost. With most heat pump installation being used where there is a continued heat demand for more than 20 years, there should be a greater focus on durability than only fit for purpose throughout the warranty period. With the heat pump industry mainly using flammable refrigerant it could backfire on the industry not focusing on quality if there is an increase in fatal failures.

Based on test made by Umaa University in 2016 the following findings are reported when investigating the products from combustion of HFO-1234yf "Amongst the detected chemicals with relatively high emission factors, COF_2, HF and CO are of greatest health concern. COF_2 (which is about three times as potent as chemical warfare agent phosgene used in World War I) reacts immediately with water to form HF. This will take place in the airways upon contact with the lung lining fluid; mucus and surfactants. HF is highly toxic and corrosive. HF may induce pulmonary edema upon inhalation and may cause severe burns following skin exposure. It can be adsorbed and penetrate tissues, and by binding to calcium HF may cause hypocalcemia. CO binds to haemoglobin and forms carboxyhaemoglobin which inhibits the transport of oxygen in the body resulting in hypoxia in many tissues of organs." [10]

$$CF_3CFCH_2 + 2.5(O_2 + 3.76N_2) \Rightarrow 2CO_2 + 2HF + COF_2 + 9.4N_2 \qquad (1)$$

Formula 1: This is the chemical process that takes place when combusting HFO-1234yf

Due to the slow burning of HFO-1234yf it is difficult to create conditions where you get 100% combustion of the refrigerants. Most of the by-product are unburned HFO-1234yf (220-480 mg/g), but there is also a significant amount of carbonyl difluoride (170-360 mg/g), carbon dioxide (120-320 mg/g) and hydrogen fluoride (70-240 mg/g) which all can cause a health risk in very small quantities.

Table 4 [11]: There are three categories of Protective Action Criteria (PACs) representing concentrations at or above which the general population may experience health effect based on 60 minute exposure. PAC-1: Mild, transient health effect, PAC-2: Irreversible or other serious health effect that could impair the ability to take protective action, PAC-3: Life-threatening health effects [12].

	PAC-1 (mg/m^3)	PAC-2 (mg/m^3)	PAC-3 (mg/m^3)
HFO-1234yf; 2,3,3,3-Tetrafluoropropene	10,000	11,000	66,000
Carbonyl difluoride (COF_2)	0.069	0.76	2.2
Hydrogen fluoride (HF)	0.82	20	36

In case of a fire in a car with (typically around 700g refrigerant) HFO-1234yf within a tunnel (cross section area 10 x 5 m), there is a potential health risk to anyone within 154 m (based on HF, PAC-2 level).

$$\frac{220\frac{mg}{g}HF\times 700\ g\ of\ R1234yf}{(10\times 5\ m^2)\times 20\frac{mg}{m^3}} = 154\ m \qquad (2)$$

Formula 2: Calculation of the distance the air will contain more than 20 mg/m^3 HF, based on Umaa University's combustion test.

If this is transferred to industrial refrigeration where centrifugal chillers can contain up to 10,000 kg of refrigerant the health risk of the HFO-1234yf becomes very apparent. HFO refrigerants should not be treated as safe refrigerant as they are flammable and the combustion products are highly toxic.

5. Environmental impact of fluorinated gasses

Nordic Council of Ministers [13] highlighted in their report that almost all people have fluorinated substances in their bodies today. It is estimated that this leads to an annual health-related costs to 52 – 84 billion EUR for all EEA countries. Exposure occurs primarily through contamination of drinking water. Most of this pollution is not from refrigerant releases, however, as for the global warming gasses and ozone depletion gasses it is part of the puzzle and we need to take responsibility.

HFO refrigerants breaks down to trifluoroacetic acid (TFA) within days in the atmosphere, which is toxic in larger amount to humans and can affect the reproduction [14]. Although TFA is naturally occurring in the oceans it has only become detectable in fresh water in Europe within the last 10 years.

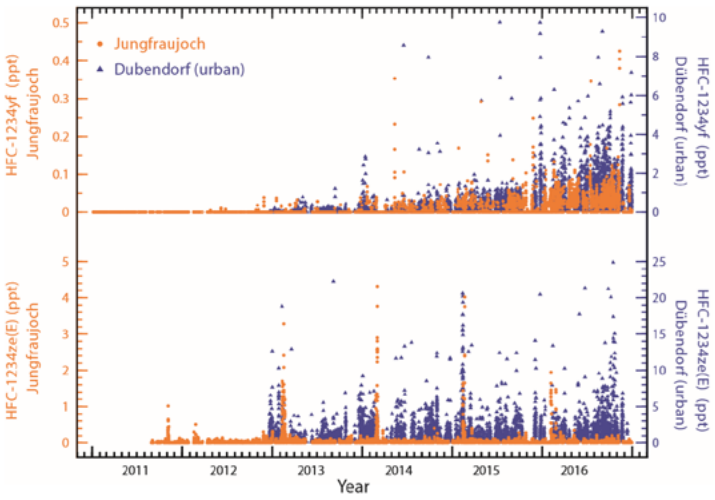

Figure 3: The table shows the increase amount of HFO found in the atmosphere at 2 European sites, The Mountaintop site Jungfraujoch (3,580 meteres above sea level) and urban Dubendorf site. The different colours indicate results from different sites. By mid-2016, 1 – 4 ppt of R1234yf and ~1 ppt of R1234ze(E) were regularly observed at Dubendorf, with pollution events containing up to 20 ppt of R1234ze(E), suggesting that it is more prevalent used in this region.

Several studies of the increased level of TFA in our drinking water due to refrigerant gas releases have shown that at the current amount of release there is very limited concerns. However, with the projected rise in

release over coming years (See figure 1), in 20 years' time when the release to atmosphere is at the same level as at the peak of Ozone depletion substances a review will be needed. This is under the assumption that only refrigeration will add to the TFA pollution, however, we need to realise that many other processes are adding to the fluoride acid pollution and we need to act. The Norwegian Environment Agency recommend in their report from 2017[14] "phasing out HFOs (and consequently TFA), or emission reduction strategies along with best practise measures that help ensure efficient capturing of HFO/TFA during recycling operations"

After 90 years of different type of synthetical refrigerants it is time to realise that there is not such a thing as "safe refrigerant". Some refrigerant poses a local risk if not handled with due care and others pose a global risk. HFO poses both a local and global risk if not handled safely and kept inside the refrigeration system until disposed. All refrigerants should be handled with due care. Refrigerant charge should be minimised in all systems. Systems should be made "leak tight" and everyone handling refrigerants should have proper training. In IEA Annex 54[18] "Heat pump systems with low GWP refrigerants" more investigation has been made into handling refrigerant with due diligence.

6. The economic dilemma

The global market for synthetical refrigerant gasses exceeds $15 bn US dollars per year[7] and it is forecasted to continue to grow in the coming years. Every time a new generation of synthetical refrigerants have entered the marked the specific price per kg have increased. The 4th generation of refrigerant is priced at around £70 per kg which is almost 50 times more than = the most commonly used natural refrigerants.

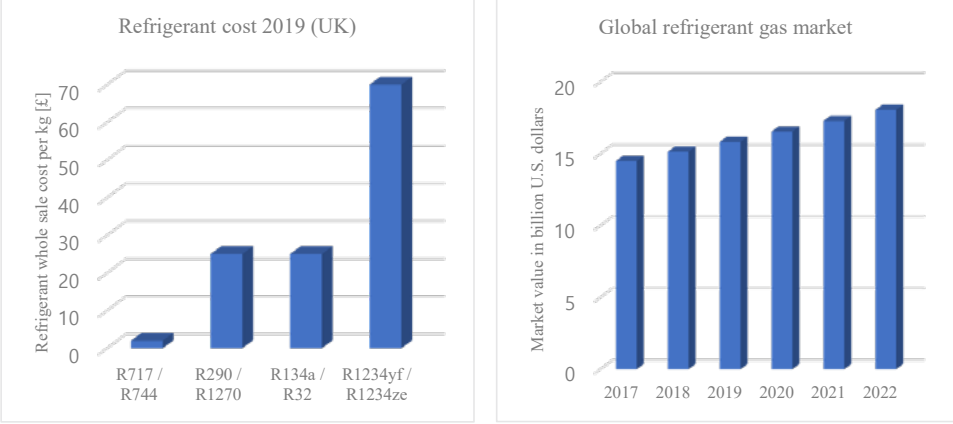

Figure 4: On the graph to the left is the retail cost of refrigerant in the UK 2019 (Source: BOC/Wolseley), to the right is a forecast of the global value of refrigerant sales in billion US dollars [7]

If the refrigeration and heat pump industry hypothetically would stop all production of synthetical refrigerants it would have a huge impact on the turnover for the companies producing and selling refrigerant gasses globally. The main question is whether the global and local consequences of increased releases of HFO are acceptable for the society, since only a few companies are benefitting economically. The next generation will have to tackle the consequences, in the same way as we have had to pay the price for replacing the ozone depletion substances (CFC's) in the first place and global warming fluids (HFC's) lately. Is it worth the risk and is it fair?

Many end-users have been forced to change their refrigeration / heat pump installation before the end of service life due to phase-out of previous generation of synthetical refrigerants. We saw a large replacement of industrial refrigeration system before 2015 in Europe due to the phase-out of HCFC-22. The same is now happening in commercial refrigeration with the phase-out of R404A in 2020 in EU. This will also happen in the rest of the World as they get closer to their deadline for phase out of these refrigerants. This is an added cost to the end-user, which was not communicated at the time of sales. There is no guarantee from the current sales people of refrigerant that this will not happen again in the near future with the HFO's. Does the refrigeration industry need this detour?

7. What are the alternatives?

The fake argument is often used that there is no alternative to HFO and that the alternatives are too costly. But is this true? As HFO are classified as A2L refrigerants they are not "safe" refrigerants so the quality of the components and assembly of heat pumps using HFO should be the same as used for natural refrigerants like CO_2, Ammonia or propane. If HFO heat pumps units are only build as "fit for purpose" throughout the warranty period then there is high risk to the end-user of the system, as small leaks can go undetected for a while until the ignition limit is reached with risk of fire and the toxic by-products from this.

For hydrocarbon refrigerants like R1270, R290 and R600a which all are classed A3 refrigerants, there are additional ATEX requirement to the electrical installation. However, this has been proven by many suppliers to have a very small impact on the cost and is outweighed by the significant lower cost of the refrigerant compared to HFO refrigerants.

For industrial heat pumps where customers do not only evaluate the equipment based on purchase price but also consider the service and operation costs as part of a total life cycle cost analysis, ammonia heat pumps do have significant advantages.

Table 5: Comparison for natural refrigerant (ammonia) industrial heat pump with an industrial heat pump using R1234ze refrigerant. Whereas the ammonia heat pump has a refrigerant charge of 41 kg, there is 140kg of R1234ze refrigerant on the synthetical refrigerant option. This is based on the industry standard for these type of heat pumps. Carrier have informed that they would have 210kg of R1234ze on a 1200 kW heat pump.

Example	RedGenium 1100 heat pump (source: GEA)	HFO Heat pump (Source: Oilon)
Chilled water inlet:	15˚C	15˚C
Chilled water outlet:	10˚C	10˚C
Cooling duty:	557 kW	494 kW
Heating water in:	45˚C	45˚C
Heating water out:	65˚C	65˚C
Heating duty:	716 kW	701 kW
Heating COP:	4.06	3.31
Refrigerant charge	41 kg	140 kg
Capital cost:	£177,000	£120,000
Refrigerant cost:	£80	£10,000
Service cost (20 year):	£125,000	£145,000
Running cost (20 years, £0.1 per kWh, 5000 h per year):	£1,724,137	£2,114,803
Total life cycle cost:	**£2,026,217**	**£2,389,803**

When taking into consideration that for large industrial heat pumps where the refrigerant charge can be up to 10,000 kg, there is also a considered financial risk. In case of a catastrophic failure where the entire charge of the plant is lost the customer would need to spend £700,000 on new refrigerant.

Currently there is a lot of research ongoing in developing high temperature (>100˚C) heat pumps. Where some HFO refrigerant can be used due to their relatively low saturated pressure at high temperature. However similar results can be achieved which R600a and R600, which has been proven by experimental investigations at NTNU / Sintef in Norway[17].
For car AC units many of the manufactures have now introduced alternatives to HFO. Fiat have launched a model with propane and both Daimler and Volkswagen [15] have introduced car models with CO_2 as refrigerant, so there certainly are alternatives to HFO. CO_2 air conditioning and heat pumps have also been proven to be very efficient in electric busses where Valeo[16] has demonstrated that the CO_2 heat pump can add up to 30% extra kilometres in temperatures as low as -20˚C.

For domestic heat pumps many manufacturers also have models with hydrocarbon. For ground source heat pumps there are manufacturer like Heliotherm, and Kensa who has introduced hydrocarbon heat pumps and for airsource heat pumps Nibe and Innotec have introduced a range of airsource heat pumps with hydrocarbons.

For split units air-conditioning and heat pumps there is also many suppliers globally, although some of the main suppliers have been reluctant to include hydrocarbon refrigerant models in their portfolio as they claim

that there is added risk of using these refrigerants. Fact is that there is a larger risk by installing a leaking HFO system than a tight hydrocarbon split unit.

Abstract

In recent years, urban areas in Japan have been experiencing a phenomenon called the heat island effect, which causes the temperature in cities to increase to a few degrees warmer than the surrounding suburban areas. It has attracted attention as one of many environmental issues. By utilizing the green roof units as thermal storage tanks and combining it into the building air-conditioning system which has an auxiliary heat source apparatus, a new air-conditioning system with low energy consumption can be designed, and there is the possibility that this technology could provide a solution to both the heat island effect and global warming. This paper relates to an experimental apparatus as a reduction model which we produced to evaluate the effectiveness of this compound system. The reduction model apparatus has a heat storage planter, a tank of hot water, artificial solar heat and an air conditioner.

In this paper, we presented operation characteristics of summer mode on this reduction model apparatus, and results show that the green roof building air-conditioning system is one promising candidate as a new building air-conditioning system.

Keywords: Heat pump; Green roof; Heat storage; Artificial sun; Heat recovery

1. Introduction

In recent years, urban areas in Japan have been experiencing a phenomenon called the heat island effect, which causes the temperature in cities to increase to a few degrees warmer than the surrounding suburban areas. It has attracted attention as one of many environmental issues. The heat island effect is a phenomenon in which atmospheric temperature is elevated due to increases in artificial heat releases and artificial land surfaces. In urban areas, the heat release rate is high because of the higher energy consumption rate. Additionally, since the coverage of artificial land surfaces such as roads or concrete buildings is extensive in urban areas, these materials act as a thermal storage medium through energy consumption, causing temperature increases in these areas. Especially in summer time, there is concern about health issues related to heat exhaustion, etc. caused by the temperature rise, and it becomes a serious environmental issue when a vicious spiral occurs due to the temperature rise driving up energy consumption. As a preventive measure, attention is being given to green roof projects that allow for a reduction in asphalt or concrete surface coverage in urban cities and are expected to promote the transpiration effect of plants. Consequently, various types of green roof units have actually been made available for practical use.

In addition to the remedial measure against the heat island effect, green roofs are also expected to provide other positive impacts including prolonging a building's life span and saving energy consumption as a result of reductions in air conditioning usage, since it increases building insulation. One of the global environmental problems of importance is global warming. To suppress global warming requires a decrease in load in the power plants.

Thus, increasing the energy efficiency of electrical equipment is an important policy. Especially, the energy efficiency of air-conditioning systems for buildings should be improved immediately, because they are less efficient than household air conditioners. From these facts, the author and other staff have been conducting fundamental researches by focusing on a combined system of a green roof and air-conditioning for buildings [1]. And the heat transfer characteristic of lightweight soil was clarified [2]. Current building air-conditioning systems are operated under excessive heat loads, and when a green roof unit is used as a thermal storage tank, the excessive heat can be utilized by establishing an energy saving type air-conditioning system which produces efficient energy use. However, a combined system of a green roof and air-conditioning is currently not on the market. By utilizing the green roof units as thermal storage tanks, and combining it into the building air-conditioning system which has an auxiliary heat source apparatus, a new air-conditioning system with low energy consumption can be designed, and there is the possibility that this technology could provide a solution to both the heat island effect and global warming. Furthermore, we developed an experimental apparatus of a reduction model which is designed to evaluate the effectiveness of this compound system [3].

This paper relates to the green roof air-conditioning system under summer times conditions by using collector as a function of a water retention rate by lightweight soil from results of experiments using this reduction model apparatus.

2. Reduction Model Apparatus

2.1. Outline of a system to target

Figure 1 shows expected summer and winter mode of a system with a green roof unit for a building. If a green roof unit is utilized as a thermal storage unit for air conditioning, an air-conditioning system for a building can be made energy efficient. In winter time, excess waste heat is transferred from the interior to a green roof unit in the building, which allows the plants to grow without dying all year. A green roof improves the thermal insulating properties of the building, which increase the energy efficiency of the air conditioning. A green roof can also receive solar energy to heat water. The efficiency of these co-generation systems for buildings is around 0.5 as COP of a trial calculation which was predicted with an assumption.

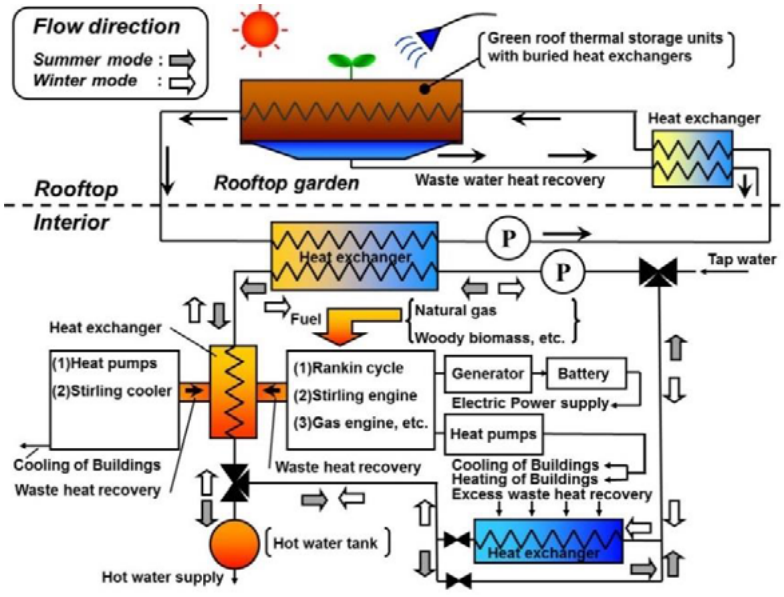

Fig. 1. Structure of a system

2.2. Reduction Model Apparatus

The author has designed an apparatus as a reduction model which we produced to evaluate the effectiveness of this compound system based on basic experimental results. We assumed a building which has 8 rooms of 23 m^2 and total floor area of 200 m^2. The reduction model reduced this to 1/15. Table 1 shows specifications of the reduction model apparatus.

Figure 2 shows the reduction model apparatus. Then also Figure 3 shows a circuit diagram of this model. This apparatus has a heat storage planter, a tank of hot water, and an air conditioner. The heat storage planter is heated by artificial solar heat, and collected heat is done heat storage of by hot water tank. The hot water tank is united with an air-conditioning system through a heat exchanger.

Table 1. Specifications of the reduction model

	A building to assume	A reduction model
Floor area	200 m^2	13.3 m^2
Planter area	3.75 m^2	0.25 m^2
Hot water supply	28 L/min.	1.8 L/min.
Capacity of air conditioner	40 – 46.8 kW (2 HP ×8)	2.5 – 2.8 kW (1 HP)
Waste heat from a building	6.51 kW	0.43 kW
Solar irradiance from an artificial solar		800 W/m^2 (max.)

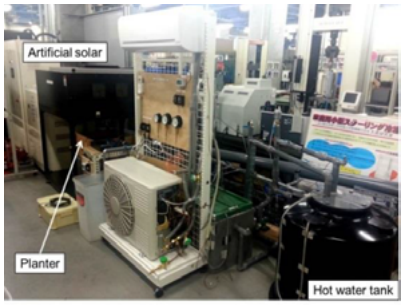

Fig. 2. The reduction model

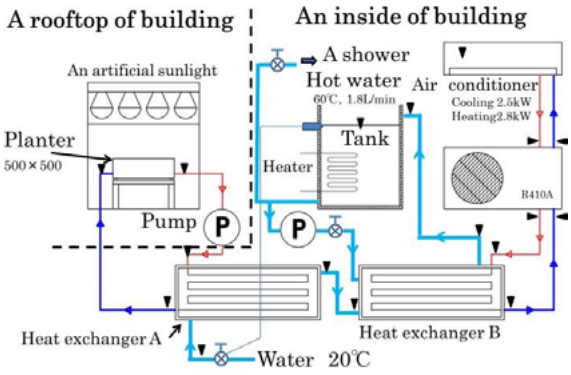

Fig. 3. Circuit diagram of the reduction model

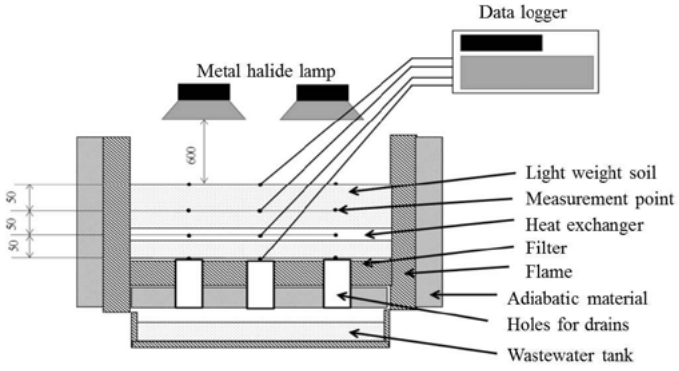

Fig. 4. Schematic view of the planter

A design of the planter used for the reduction model apparatus is shown in Figure 4 for greening units, the bottom part has holes for drains so that the excess water could always be discharged from the unit. Furthermore, on the ground, thermocouples are placed at five places numbered as No.1 to No.5, each place has depths of 0 mm, 50 mm, 100 mm, and 150 mm from the surface. Instead of the sun, we use artificial sunlight to adjust solar irradiance. The adjustment of solar irradiance was set between 700 and 800 W/m^2. The metal halide lamp has a distance of 600 mm from the soil surface. To avoid temperature effects from the outer environment, insulation materials are set at the side and bottom surface of the greening unit. The copper pipes are buried to 100 mm depth as a heat exchanger, and water passes through in it consecutively.

3. Experimental

3.1. Experimental conditions

Table 2 shows the experimental conditions. The selection of water retention rate is on the mass of water to be 0 kg, 3kg, 6kg, 9kg and through Formula (1) to calculate the water retention rate.

Table 2. Experimental conditions

	Conditions
Water retention rate (%)	0%, 33%, 50%, 60%
Solar irradiance (W/m^2)	700~800 (W/m^2)
Temperature of water (˚C)	15(˚C)
Flow rate of water (L/min.)	4.0~4.5 (L/min.)
Time of measurement (hours)	6 (hours)
Mass of dry soil (kg)	6 (kg)

Here, the definition of water retention rate is shown as

$$u = W_w/(W_w + W_s) \times 100\% \quad (1)$$

where
u = Water retention rate (%), W_w = Mass of water (kg), W_s = Mass of dry soil (kg)

3.2. Experimental results

The experimental results are shown in Figure 5 to Figure 7.

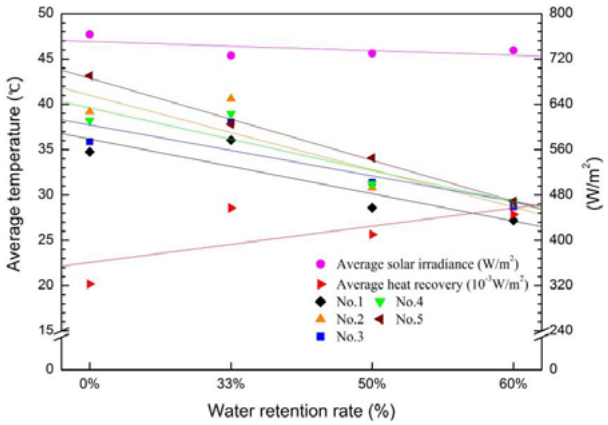

Fig. 5. Water retention rate affects average temperature and average heat recovery

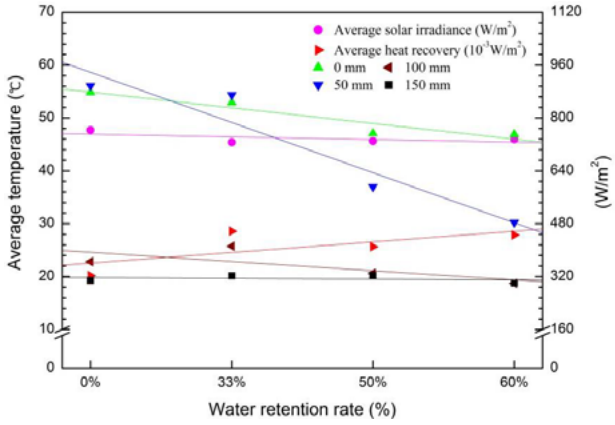

Fig. 6. Water retention rate affects different depth measurement point average temperature and average heat recovery

In Figure 5 to Figure 7, each point represents the average measurements in 6 hours and each linear regression is drawn by its points. The measurement point in average heat recovery represents the copper pipe with tap water which buried in the planet is heat-exchanged with the waste heat generated by the artificial sun.

As shown in Figure 5, a soil average temperature decrease as the water retention rate increase. In contrast, there is an increasing trend for average heat recovery. Also, at a water retention rate of 60%, the average temperature of No.1 to No.5 (about 28.7 ˚C) is more uniform than others.

In Figure 6, 0 mm and 50mm has a relatively large average temperature difference. The copper pipe with tap water is buried in depth 100 mm which has the average heat recovery about 0.45 (W/m^2) at a water retention rate of 60%.

Figure 7 shows the higher a water retention rate, the higher an average heat recovery efficiency tends to be. Finally, the average heat recovery efficiency has about 0.06% at a water retention rate of 60%.

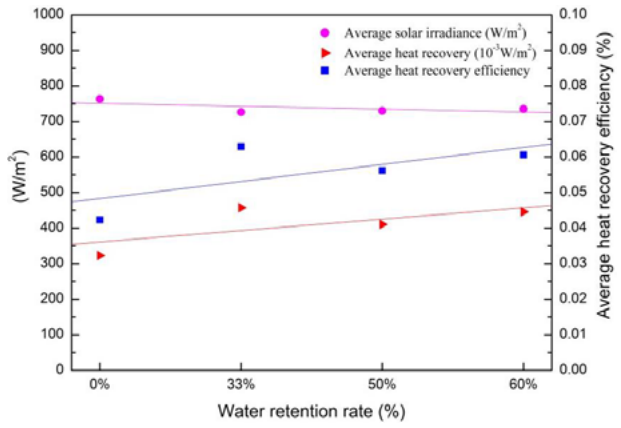

Fig. 7. Average heat recovery and average heat recovery efficiency

4. Conclusion

The thermal energy stored in the planter unit as a function of moisture content was recovered and a basic experiment was conducted to clarify the heat storage characteristics of this model device. In addition, since practicality is confirmed in this system, the function utilization test of this reduction model device is carried out and the result is reported. From this experiment result, it was seen that the heat recovery efficiency increased in proportion to the water retention rate. These results show that the green roof building air conditioning system is one promising candidate as a new building air conditioning system.

Abstract

In commercial buildings, the energy consumption by air conditioning amounts to 30% -40% of the entire building. Therefore, the energy saving of air-conditioning in those buildings is important to reduce their total energy consumption. In this background, the evaporating temperature rising operation of multi-split type air conditioner during cooling have been applied as one of the energy saving operations.

In general, the increase of the evaporating temperature can improve the efficiency of the air conditioner, and the reduction of the energy consumption can be expected. On the other hand, since the cooling latent heat capacity decreases in this operation, the humidity of the air-conditioned room may increase and the thermal comfort may decrease.

In this study, the energy saving effect and the thermal comfort of evaporating temperature rising operation in the air conditioning system for offices and a store were investigated by simulation. It was found that 7% - 17% cooling energy saving effect can be obtained by the rising the evaporating temperature in consideration of thermal comfort in the room, and larger energy saving effect can be obtained in the building having a high cooling sensible heat ratio.

Keywords: Air conditioner, Evaporating temperature, Energy saving, Thermal Comfort ;

1. Introduction

In order to prevent global warming, it is important to reduce air conditioning energy, which accounts for a large proportion of building energy. In this background, the performance improvement of air conditioners and appropriate air conditioning operation have been conducted. As examples of energy saving operation of multi-split type air conditioner, rising operation of the evaporating temperature during cooling or reducing operation of the condensation temperature during heating have been reported[1][2]. Among them, the rising of the evaporating temperature is attracting operation because a greater effect can be expected.

In general, the evaporating temperature for cooling is controlled to be about 6 °C due to dehumidify indoor air and create a comfortable environment. As shown in Fig.1, by rising the evaporating temperature of the refrigerant, the efficiency of the air conditioner can be improved and the equipment energy consumption can be reduced. On the other hand, since the cooling latent heat capacity is reduced, the humidity of the air conditioned area increases depending on the state of the air conditioning load, and the thermal comfort of the resident is impaired.

Conventionally, commercial multi-air conditioners have been adjusted for capacity by the “refrigerant circulation rate control” method in order to perform individual operation for each indoor unit and to maintain the comfort of each indoor unit. In this method, the refrigerant temperature (evaporating temperature) cannot basically be changed, but it is possible to reduce the equipment energy consumption by forcibly increasing the

E-mail address: Nakayama.Hiroshi2@chuden.co.jp.

evaporating temperature with a control software. Recently, it has been developed some air conditioning systems that can increase the evaporating temperature when the refrigerant evaporating temperature is controlled by the dedicated controller of the air conditioner manufacturer according to the air conditioning load and it is determined that the air conditioning load becomes low.

This study focuses on the effect of the rising in the evaporating temperature of the commercial air conditioner on the energy saving effect and the thermal comfort of the air-conditioned room. In particular, the energy efficiency and thermal comfort were evaluated for the building type and air conditioner capacity as parameters.

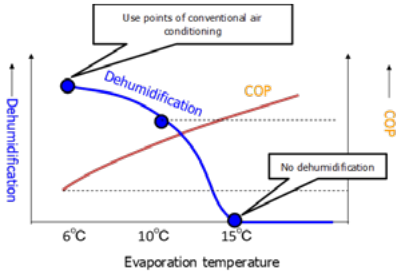

Fig. 1. Relation between evaporating temperature, dehumidification and COP

2. Calculation conditions

2.1. Building conditions

It is considered that the energy saving effect due to the increase in evaporating temperature is greater for buildings with higher sensible heat loads. Therefore, energy simulations are conducted for the office and the business store models which have different cooling sensible ratios (annual cooling sensible heat load/ total cooling load) with total floor area of about 1,000m^2.

Table 1 shows the calculation conditions for these buildings. Two cases for offices are considered. One is Office A which has a conventional specification and the other is Office B which has a nearly ZEB (net Zero Energy Building) specification as next-generation building. Office B not only has better skin performance than Office A, but also has low emissivity (low-e) glass and light shelf near the ceiling (Fig. 2.), which actively uses daylight and has reduced internal air-conditioning load.

These offices are operated to light up from 8:00 to 19:00 except from 12:00 to 13:00, and the occupancy rate and equipment usage rate gradually decrease from 17:00. The specifications of the store model were determined with reference to the previously reported home appliance mass sales store [3]. In this study, we used meteorological data in Nagoya area of Japan. AMeDAS(Automated Meteorological Data Acquisition System) were used for the data [4].

	Inside air condition (Tem./Relative Humidity)	Summer 26°C/50% Winter 22°C/40% Mid-season 24°C/45%	Summer 26°C/50% Winter 22°C/40% Mid-season 24°C/45%	Summer 26°C/60% Winter 20°C/40% Mid-season 24°C/60%

2.2 Air conditioning load

At first, the air-conditioning loads for each hour were calculated using the BEST (Building Energy Simulation Tool) program for the conditions of Table1[5]. The BEST program was developed in Japan as a simulation tool for building air conditioning load and annual energy consumption. The program has the same accuracy in terms of room temperature and air conditioning load of the building as the simulation tools (BLAST, DOE2, ESP, SERIRES, etc.) which commonly used in Europe and the United States [6],[7].

Figure 3 shows the calculation results of the annual air conditioning load in each case. Generally, latent heat is affected by amount of outside air and human density, and sensible heat is affected by internal heat generation and the insulation performance of buildings. Since the store has a longer operating time and larger internal heat generation than the offices, the air-conditioning load and cooling sensible heat have the largest among them. In Office B oriented to nearly ZEB, the internal heat generation is smaller than that of Office A, so that the cooling sensible heat load is small and the heating sensible heat load is large. As a result, the sensible heat ratio during the cooling period (= cooling sensible heat load/cooling total load) tends to be Store> Office A> Office B.

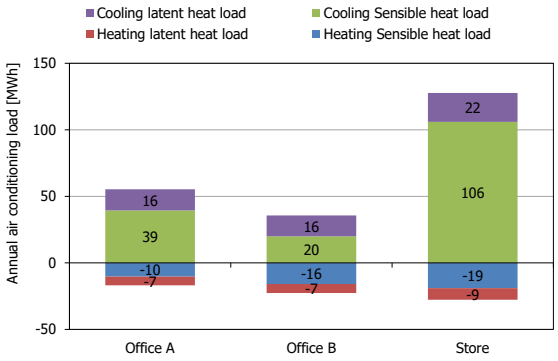

Fig.3. Comparison of annual air-conditioning load

2.3 Air conditioner assumption

In general, the capacity of air conditioners is set with a margin for the maximum air conditioning load. In this calculation, the capacities of 100%, 120%, 140%, and 160% were set for the maximum air conditioning load calculated in each case in order to confirm the effect of the installed capacity.

Figure 4 shows the relationship between the evaporating temperature and the cooling capacity normalized by the total cooling capacity at 6 °C. This relationship between the cooling capacity of the air conditioner and the evaporating temperature of refrigeration which published by the manufacturer were used [8]. As the evaporating temperature rises, the total cooling capacity gradually decreases, reaching a capacity of about 60% at an evaporating temperature of about 15 °C. Although the sensible heat capacity does not change much, latent heat capacity decreases as the amount of dehumidification decreases, and the latent heat capacity becomes 0 at 15 °C.

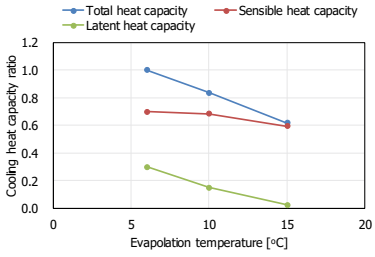

Fig.4. Relationship between the evaporating temperature and the cooling capacity

2.4 Energy consumption / comfort calculation method

Figure 5 shows the calculation procedure. At first, we determined the air-conditioner rated capacity based on the air-conditioning maximum (peak) load calculated by the BEST program. And then, the capacity was corrected by the evaporating temperature and the outside air temperature at each time, and the sensible heat capacity/latent heat capacity and power consumption of the equipment were calculated. Here, when the sensible heat/latent heat capacity is insufficient with respect to the air-conditioning load, the indoor temperature and humidity air-conditioning are changed. When the air conditioning load cannot be processed at the calculation time, the unprocessed load was added to the next time. PMV (Predicted Mean Vote) which considered to be most recognized in thermal comfort standard was used as the thermal comfort index in the air-conditioned room [9]. PMV was calculated with indoor temperature, humidity, radiation temperature, wind velocity and so on, and the values based on experimental results in Table 2 were used for this calculation.

We calculated four conditions for the evaporating temperature. Three of these conditions fixed the evaporating temperature at 6 °C, 9 °C, and 12 °C, and one of them changed the evaporating temperature. That is, the evaporating temperature was changed within ± 0.5 which is the comfortable range of PMV. In this paper, this condition is called “PMV control”.

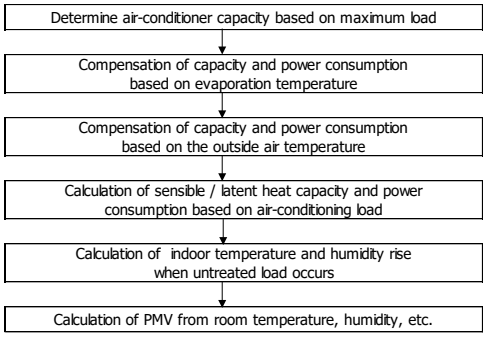

Fig.5. Calculation procedure

Table.2. Calculation condition of PMV

	Indoor temperature and humidity	Radiation temperature (°C)	Wind Velocity (m/s)	clo	Mets
Office	Calculated value	Indoor temperature+0.5	0.05	0.43	1.1
Store	Calculated value	Indoor temperature	0.05	0.3	1.4

3. Calculation results

3.1 Calculation results for Office A

Figures 6(a) to (d) show temporal changes of latent-heat load, untreated latent heat load, indoor temperature, and indoor humidity on the summer representative day (August 1) when the evaporating temperature is fixed at 6 °C (standard), 9 °C, and 12 °C and PMV controlled. Figure 7 shows temporal changes of PMV in each case. In all cases, the capacity of the air conditioner is 120%, which is close to the actual condition. As shown in Fig. 6(a), at the standard evaporating temperature of 6 °C, all the sensible heat and latent heat load can be processed, so the temperature and humidity do not change during the day. When the evaporating temperature is set as high as 9 °C and 12 °C, though the sensible heat load is processed, the untreated latent heat load increases with time, and the indoor humidity and PMV shift to the warmer side. In particular, when the evaporating temperature is fixed at 12 °C, the untreated load increases, and the indoor humidity becomes extremely high at 10:00 (Fig.6(c)).

Actually, humidity is not expected to rise to nearly 100% due to mixing of outside air and room air due to ventilation not considered in this calculation, but it is expected that the environment will become extremely uncomfortable. On the other hand, in the case of PMV control as shown in Fig. 5(d) and Fig.6, the PMV is maintained within 0.5, and although untreated load occurs, thermal comfort is maintained. It is noted that similar treads were seen in Office B.

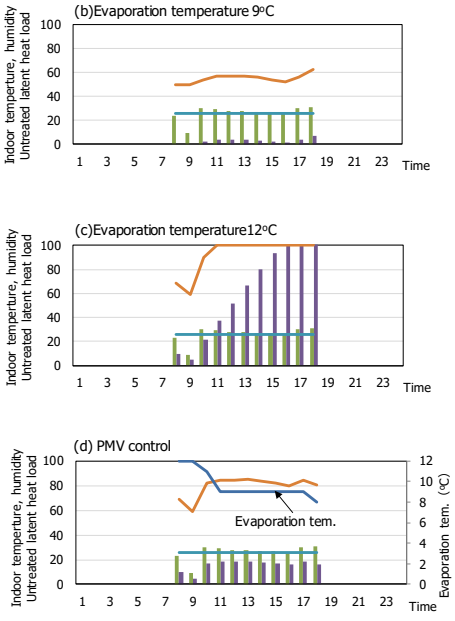

Fig.6. Temporal change of temperature/humidity and latent heat load (Office A)

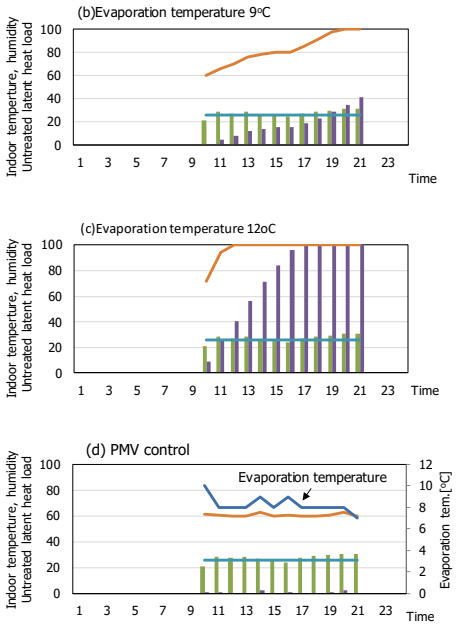

Fig.8. Temporal change of temperature/humidity and latent heat load (Store)

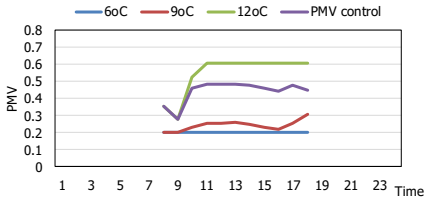

Fig.7. Temporal change of PMV (Office A)

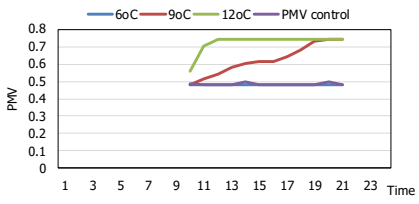

Fig.9. Temporal change of PMV (Store)

3.2 Calculation results for Store

Figures 8(a) to (d) show temporal changes of latent-heat load, untreated latent heat load, indoor temperature, and indoor humidity on the summer representative day (August 1) when the evaporating temperature is fixed at 6 °C (standard), 9 °C, and 12 °C and PMV controlled, and Figure 9 shows temporal changes of PMV. Similar to Office A, in the case of the evaporating temperature 6 °C, the sensible heat and latent heat load can be processed, so both the temperature and humidity are stable. However, when the evaporating temperature is set to 9 °C and 12 °C, the untreated latent heat load increases with time, the indoor humidity and PMV shift to the warmer side, and PMV finally becomes about 0.75 as shown in Fig.9. On the other hand, in the case of PMV control, since PMV is high at the time of air conditioning start-up, the air conditioner quickly decreases the evaporating temperature and almost no untreated load occurs.

3.3 Influence on power consumption and thermal comfort (Office A)

Figure 10 shows a comparison of the cooling power consumptions in Office A. In these case, cooling period is from May to October. Comparison parameters are evaporating temperature and air-conditioner capacity.

When the evaporating temperature is increased from 6 °C to 9 °C and 12 °C, the power consumption during cooling decreases. For example, in the case of 100% for air-conditioner capacity, cooling power consumption is reduced by 26% at evaporating temperature of 12 °C compared to evaporating temperature of 6 °C. In the

case of PMV control, a reduction effect of 17% can be obtained.

Figure 11 and Fig.12 show time that PMV exceeds 0.5 (uncomfortable time) and cooling COP, respectively. In the case of evaporating temperature 12 ° C, the time that PMV exceeds 0.5 increases in the midsummer season, and the uncomfortable time increases significantly. Basically, the air-conditioner load which can be processed increases as the installed air-conditioner capacity increases. Therefore, as shown in Fig. 10 and Fig.11, an increase in the air-conditioner capacity leads to a decrease uncomfortable time and an increase in the cooling power consumption.

When the evaporating temperature is fixed, the COP is almost the same regardless of the capacity of the air conditioner. This is because air-conditioning capacity is small relative to the air-conditioning load, and high-load operation continues. On the other hand, in the case of PMV control, as the air conditioner capacity increases, the cooling power consumption decreases and COP increases as shown in Fig.10 and Fig.12. This is because the air conditioner is operated at an efficient medium load.

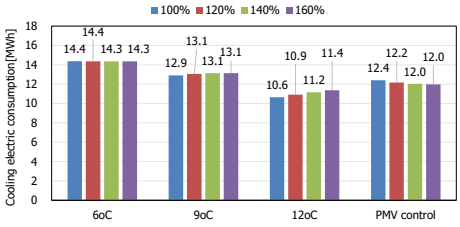

Fig.10. Cooling power consumption

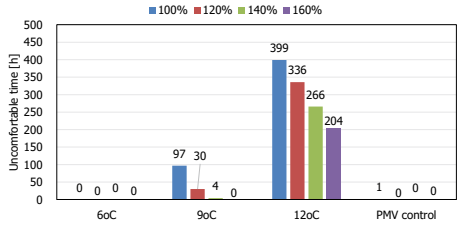

Fig.11. Uncomfortable time

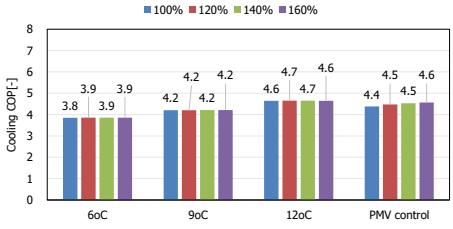

Fig.12. Cooling COP

3.4 Considerations for further energy saving

In order to investigate further energy saving effect by PIV control, the cases where PMV is allowed to 0.6(slightly uncomfortable region) were calculated. Table 3 shows comparison of the power consumption reduction rates at Office A, Office B, and Stores in the case of PMV<0.5 and PMV<0.6. These power consumptions at each case were normalized by that of the evaporating temperature 6 °C. Compared to the standard evaporating temperature of 6 °C, the power consumption can be reduced by 7-17% in the case of PMV<0.5 considering energy saving and thermal comfort. In either case, even if PMV<0.6 is allowed, the energy saving effects only increase by 1 to 4 points compared to those in the case of PMV<0.5.

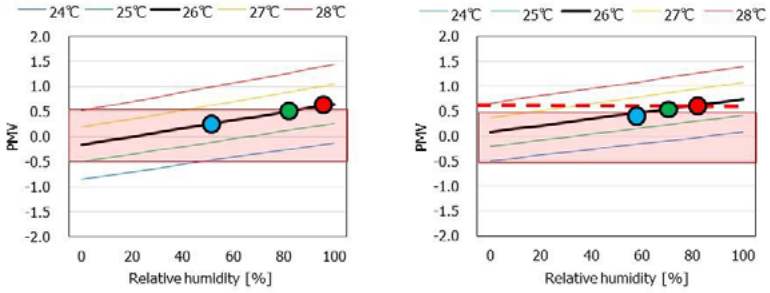

Figure 13(a) and (b) show the relationship among indoor temperature, relative humidity, and PMV in the Office and Store, respectively. In this calculation, the sensible heat load could be processed in all cases, so the room temperature did not change from 26 °C and only the relative humidity increased. In addition, even if PMV=0.5 (green circle in the figure) or PMV=0.6 (red circle in the figure) is allowed for the standard temperature and humidity conditions (blue circle in the figure) in this calculation, there is no significant difference. Therefore, it seems that the increase in energy saving effect has become small. However, if the temperature/humidity setting is set to a low value, the temperature/humidity control range is increased, and it is considered that a large energy saving effect can be obtained by introducing PMV control.

Figure 14 shows the relationship between the cooling sensible heat ratio and the cooling power consumption reduction rate in the PMV control. Although there is a difference in the power consumption reduction rate due to the difference in temperature and humidity settings between the office and the store, the higher the sensible heat ratio in summer, the higher the energy saving effect. Therefore, a large power consumption reduction effect can be expected in commercial buildings such as warehouses and data centers with large sensible heat ratio.

Table.3. Power consumption reduction rate (Cooling season)

	Office A		Office B		Store	
Air-conditioning	PMV<0.5	PMV<0.6	PMV<0.5	PMV<0.6	PMV<0.5	PMV<0.6

Capacity						
100%	-14%	-15%	-7%	-10%	-11%	-13%
120%	-15%	-16%	-8%	-10%	-14%	-15%
140%	-16%	-17%	-9%	-12%	-15%	-16%
160%	-17%	-17%	-9%	-13%	-16%	-17%

(a) Office (b) Store

Fig.13. Relationship among temperature, relative humidity, and PMV

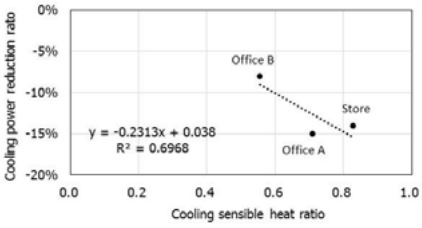

Fig.14. Relationship between cooling sensible heat ratio and cooling power reduction ratio

4. Summary

In this study, we calculated on the effect of the rising in the evaporating temperature of the multi-type air conditioner on the energy saving effect and the thermal comfort of the air-conditioned room. The main results are as follows,

Compared to the standard evaporating temperature of 6 °C, the power consumption can be reduced by about 21-26% in the case of the evaporating temperature 12 °C, and 7-17% in the case of PMV control considering energy saving and thermal comfort. When the evaporating temperature is fixed at 12°C, a large energy saving effect is obtained, but the thermal comfort is significantly deteriorated.

When the evaporating temperature is fixed, the COP is almost the same regardless of the capacity of the air conditioner. An increase in the air-conditioner capacity leads to a decrease uncomfortable time and an increase in the cooling power consumption.

When PMV control is used, a large energy consumption reduction effect can be expected in commercial buildings with a large cooling sensible heat ratio.

Abstract

In air conditioners installed in commercial buildings, their efficiencies are often deteriorated by short circuits of airflows in which hotter (cooling operation) or cooler (heating operation) air blown out from the outdoor units is sucked again in the outdoor units. From viewpoints of energy savings of air conditioners, it is necessary to understand the influence of short circuits of airflows on operations of air conditioners quantitatively and to take measures against them. The purpose of this study is to make clear the influence of installation conditions of the outdoor unit of an air conditioner on the short circuit of airflow issued from it.

We made laboratory measurements and field measurements of airflow temperatures around the outdoor unit of a packaged air conditioner. The short circuit of the airflow from the front face to the side face of the outdoor unit was enhanced when there was a wall near the side face. In such cases, linear relationships were found between suction air temperatures of the outdoor unit and outdoor air temperatures.

Keywords: Air conditioner, Outdoor unit, Airflow, Short circuit, Suction air temperature ;

1. Introduction

Individual distributed air conditioner may cause a short circuit of air flow in which high-temperature air blown from its outdoor unit (cooling operation) is directly sucked by its suction face, depending on the outdoor unit installation situation (close to walls, under the roof, concentrated equipment installation, etc.). It is known that the performance of the air conditioner is deteriorated by this short circuit. In addition, there are cases in which the air conditioner shuts down due to capacity control when the impact of the short circuit becomes large. In order to save energy and keep proper operation, it is required to quantitatively understand the influences of short circuits and take measures against them.

Several papers on short circuits have been reported so far [1][2], but there are few reports on the influences of outdoor unit installation conditions, changes in outdoor air temperature and load factors on short circuits and capacity degradation of an air conditioner.

The purpose of this study is to quantitatively understand the influences of short circuits of air flow in the outdoor unit on the performance of air conditioners, taking the outdoor unit installation conditions, outdoor air temperature and load factor as parameters.

In the first half of this paper, we show the results obtained in the environmental test laboratory in which influences of a building wall or an obstacle on the performance of a packaged air conditioner were examined to clarify the relationship between the outdoor unit's suction temperature and the outdoor air temperature. In the second half, we will clarify the effect of short circuits when two or more air conditioners installed in an actual building are operated with walls around the outdoor unit.

2. Laboratory Test

2.1. Test Method

This test was conducted in the environmental test laboratory of the Chubu Electric Power Co., Inc. by installing one side blown 5-horsepower packaged air conditioner with a specification shown in Table 1. Figure 1 shows the outdoor unit installation conditions. Pattern 1 is a standard installation in which there are no obstacles around the suction face (back and side faces) and the blowing face (front face) of the outdoor unit.

On the other hand, since many outdoor units are often installed near the building walls, a test was performed on Pattern 2 in which walls simulating building walls were installed near the back and side faces (suction faces) of the outdoor unit. Here, the distances between the wall and those faces were set to effective spaces of 0.3 m as described in the manufacturer's installation manual. In addition, a test was also conducted on Pattern 3 that simulated an installation in a small space with walls near the back, side (suction) and the front (blowing) faces of the outdoor unit. The distance between the front face of the outdoor unit and the wall was set at 1.0 m as described in the manufacturer's installation manual.

Figure 2 shows the positions of thermo-sensors set on the suction and the blowing faces with the wall setting situation of Pattern 2 in the environmental test laboratory.

Table 1. Specifications of test air conditioner

5 HP packaged air conditioner (manufactured in 2017)		
	Cooling operation	Heating operation
Rated capacity	12.5 kW	14.0 kW
Rated power consumption	3.31 kW	3.30 kW
APF*(2015)	6.3	

*APF: Annual Performance Factor

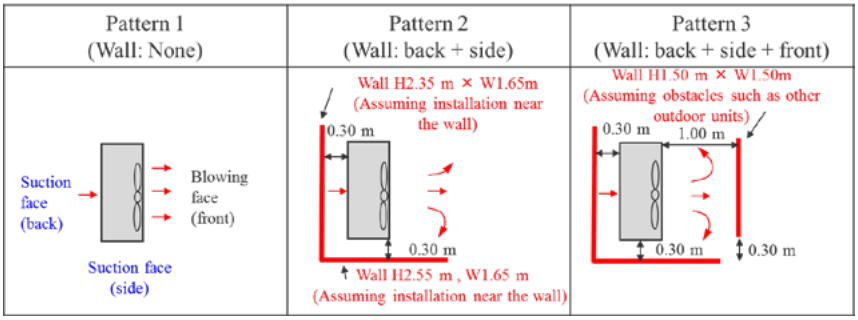

Fig. 1. Wall installation patterns around the outdoor unit of the air conditioner

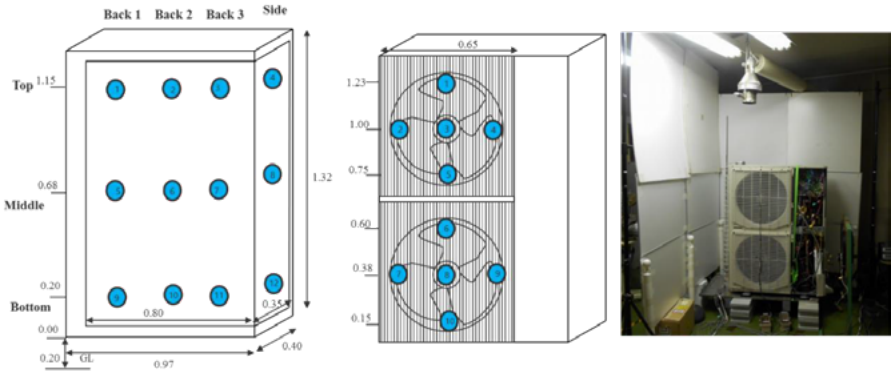

Fig. 2. Positions of sensors on the outdoor unit and wall installation condition of Pattern 2

2.2. Test Conditions

The air conditioning capacity was measured by the indoor enthalpy method. Test conditions are shown in Table 2, the air dry bulb temperature in the outdoor test room was set at 35 ºC, 30 ºC or 25 ºC in the cooling performance test, and at 12 ºC, 7 ºC or 2 ºC in the heating performance test.

A part of tests was conducted considering the situation that the air conditioning load is large and the air conditioner is always operating at full power (100%). In these tests, the indoor test room was controlled at 27 ºC and the remote control temperature was set to 18 ºC in the cooling operation, and the indoor test room was controlled at 20 ºC and the remote control temperature was set to 30 ºC in the heating operation.

Tests were also conducted assuming the situation that the air conditioning load is reduced in the intermediate period. In the case of cooling, the air conditioning load was set at 25% and 50% of the actual rated cooling capacity of the tested air conditioner, and the air temperature of the indoor test room was controlled at 27 ºC by the air conditioner itself. In the heating performance test, the indoor air temperature was controlled at 20 ºC with the heating load corresponding to 25% and 50% of the actual rated heating capacity.

Measurement data were sampled at 10-second intervals, and they were averaged in 60 minutes for the steady operation and in one cycle for the intermittent (on-off) operation.

Table 2. Test conditions (dry bulb temperature / wet bulb temperature)

Operations	Outdoor temperature conditions	Indoor temperature conditions	Load factor
Cooling	35 ºC / -	27 ºC /19 ºC	100%
Cooling	30 ºC / -	27 ºC /19 ºC	50%
Cooling	25 ºC / -	27 ºC / 19 ºC	25%
Heating	12 ºC / 11 ºC	20 ºC / -	25%
Heating	7 ºC / 6 ºC	20 ºC / -	50%
Heating	2 ºC /1 ºC	20 ºC / -	100%

2.3. Results

2.3.1. Influence of Wall Installation

Table 3 shows the results of average suction air temperatures (back, side, and overall average) and Table 4 shows the average blowing air temperature in each pattern in the cooling performance test at the outdoor air temperature of 35 ºC with full power operation.

In Pattern 1, the suction air temperatures on the back and side faces are about 37 ºC, and the difference from the outdoor air temperature is not so large. It should be noted that the temperature sensor position for setting the test room was different from the positions of the thermo-sensors on the suction face, so there was a difference between the test room setting temperature and the suction air temperature in Pattern 1.

In Pattern 2 in which the walls are installed on the back and side of the outdoor unit, the suction temperature is about 2 ºC higher than Pattern 1 on average. In particular, the suction air temperature is as high as 41.2 ºC on the side face, and it can be seen that the influence of the short circuit is greatly reflected on the side of the outdoor unit. Pattern 3 shows a similar trend to Pattern2.

Regardless of the change in the suction air temperature, the blowing air temperature is almost constant at about 48 ºC in all patterns as shown in Table 4.

Table 3. Average of suction air temperature during cooling operation at the outdoor air temperature of 35 ºC with 100% operation

Suction air temperature	Pattern 1	Pattern 2	Pattern 3
Back	37.0ºC	38.6ºC	39.1ºC
Side	37.6ºC	41.2ºC	42.3ºC
Overall	37.1ºC	39.2ºC	39.9ºC

Table 4. Average of blowing air temperature during cooling operation at the outdoor air temperature of 35 ºC with 100% operation

	Pattern 1	Pattern 2	Pattern 3
Blowing air temperature	48.1ºC	47.9ºC	48.6ºC

For more detailed changes in the air temperature on the suction face, Table 5 shows differences between suction air temperatures in Pattern 2 and Pattern 1, and Table 6 shows a comparison with Pattern 3. Here, the positions described in these tables correspond to the sensor positions shown in Figure 2. As can be seen from Table 5, the place where the temperature change is particularly large is from the center to the bottom of the back and side faces of the outdoor unit, rising by 6-7 ºC. Table 6 of Pattern 3 shows a similar tendency. It is thought that hot air blown from the front face of the outdoor unit stayed around the bottom of the side face where there was little air flow.

In addition, from the overall average temperature change in Table 5 and Table 6, it rises to 2.1 ºC by wall setting on the back and side, whereas it rises to 2.8 ºC by wall setting on the back, side and front. It can be seen that the influence of the back and side walls on the short circuit is greater than that of the front wall.

Table 5. Difference of suction temperatures of pattern 2 from pattern 1 at the outdoor air temperature of 35 ºC with 100% operation

	Back 1	Back 2	Back 3	Side
Top	-0.1ºC	-0.3ºC	-0.6ºC	-0.5ºC
Middle	-0.9ºC	0.8ºC	3.6ºC	5.1ºC
Bottom	1.3ºC	3.5ºC	7.2ºC	6.2ºC
Average of Back		1.6ºC		-
Average of Side		-		3.6ºC
Average of Overall		2.1ºC		

Table 6 Difference of suction temperatures of pattern 3 from pattern 1 at the outdoor air temperature of 35 ºC with 100% operation

	Back 1	Back 2	Back 3	Side
Top	0.2ºC	0.5ºC	0.7ºC	0.7ºC
Middle	-0.8ºC	1.7ºC	5.2ºC	6.3ºC
Bottom	1.5ºC	3.5ºC	6.4ºC	7.2ºC
Average of Back		2.1ºC		-
Average of Side		-		4.7ºC
Average of Overall		2.8ºC		

Table 7 shows the power consumption, cooling capacity and COP of the air conditioner during 100% cooling operation at the outdoor air temperature of 35 ºC for each pattern. From these results, the power consumption increased by 2-4%, the cooling capacity decreased by 1-3% and consequently COP decreased by 3-6% in Patterns 2 and 3 compared to Pattern 1, due to the short circuit.

Table 7 Power consumption, Cooling capacity and COP at the outdoor air temperature of 35 ºC with 100% operation

	Pattern 1	Pattern 2	Pattern 3
Power consumption	4.43kW	4.54kW	4.62kW
(Rate of change)	(Basis)	(+2.36%)	(+4.12%)
Cooling capacity	14.19	14.04	13.81
(Rate of change)	(Basis)	(-1.06%)	(-2.68%)
COP	3.20	3.09	2.99
(Rate of change)	(Basis)	(-3.34%)	(-6.53%)

2.3.2. Influence of Partial Load Operation

In actual use an air conditioner is often operated under a partial load. Therefore, we conducted partial load performance tests. In order to understand the influence of the short circuit under partial load, the setting of outdoor temperature and lord factor of the environmental test laboratory was changed, and the relationship between the suction average temperature, the outdoor air temperature and load factor was investigated. As mentioned in Section 2.3.1, there was a difference between the test room setting temperature and the suction air temperature in Pattern 1, in which the influence of the short circuit was negligibly small. Hence, in order to clarify the difference between Patterns 2 and Pattern 3 that have a strong influence of short circuit, the suction air temperature of Pattern 1 was used as the outdoor air temperature.

2.3.2.1 Cooling Operation

Figure 3 shows the relationship between the outdoor air temperature and the mean suction air temperature at each load factor close to actual operations measured under the test conditions shown in Table 2.

In Pattern 2, it can be seen that the lower the outdoor air temperature and the load factor, the smaller the difference from Pattern 1 and the smaller the influence of the short circuit. As for Pattern 3, only the result of one high outdoor air temperature is shown, and the difference from Pattern 2 is negligibly small. This suggests that the wall installed in the side of the outdoor unit is more dominant in the occurrence of the short circuit than that installed in the front. From this result, it should be noted that the short circuit of airflow may occur even if the outdoor unit is installed at a distance from the building wall recommended by the manufacturer. It is recommended that the distance between the suction face of the outdoor unit and the building wall be set larger than the manufacturer's recommendation value.

Table 8 shows the difference between the blowing air temperature and the suction air temperature. Compare to low outdoor air temperature and the load factor, the difference is large at high outdoor air temperature and the load factor.

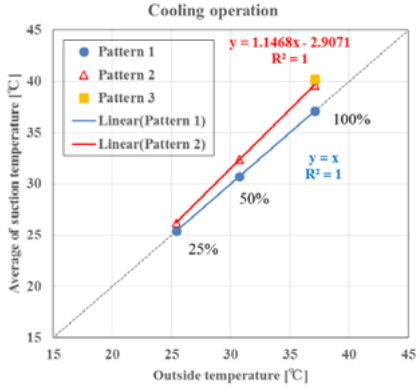

Fig. 3. The relationships between outdoor air temperature and suction air temperature in cooling operation

Table 8. Blowing air temperature during cooling operation

Outdoor temperature conditions	Pattern 1	Pattern 2	Pattern 3
25ºC	28.6ºC (+3.1)	29.0ºC (+2.8)	-
30ºC	36.1ºC (+5.3)	37.3ºC (+4.9)	-
35ºC	48.1ºC (+11.0)	47.9ºC (+8.3)	48.6ºC (+8.4)

( ) Indicates the difference between the blowing air temperature and the suction air temperature

In order to quantitatively express the influence of the short circuit, the short circuit ratio (SCR) [3] shown in Equation (1) was calculated.

$$SCR[\%] = \frac{Suction\ air\ temperature - Outdoor\ air\ temperature}{Blowig\ air\ temperature - Outdoor\ air\ temperature} * 100 \quad (1)$$

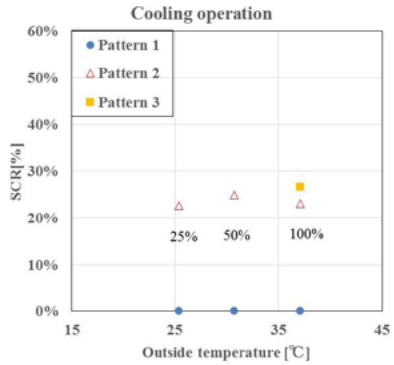

Fig. 4. SCR during cooling operation

Figure 4 shows the results of SCR under the low load conditions in each pattern. It can be seen that the SCR is about 20-25% in Patterns 2 and 3.

2.3.2.2 Heating Operation

Next, the influence of the short circuit during heating operation is examined. Figure 5 shows the suction air temperature during heating operations at 100% load at 2 ºC and partial loads shown in Table 2. It can be seen that there is no significant difference among the results for three patterns. The reason why the influence of the short circuit (decrease in the suction air temperature) was small in comparison with the cooling operation may be that the difference between the suction air temperature and the blowing air temperature was small in the heating operation. In 100% cooling operation, the difference between the blowing air temperature and the suction air temperature was as large as 8 ºC to 11 ºC (Table 8). On the other hand, the difference in the heating operation was smaller than 3 ºC (Table 9).

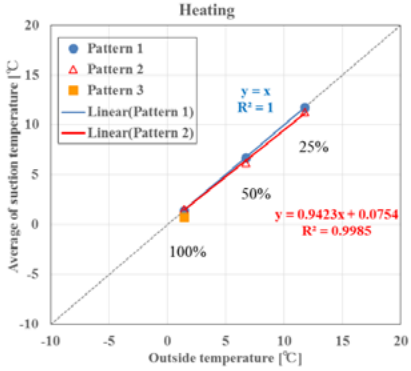

Fig. 5. The relationships between outdoor air temperature and suction air temperature in heating operation

Table 9 Blowing air temperature during heating operation

Outdoor temperature conditions	Pattern 1	Pattern 2	Pattern 3
2ºC	-1.7ºC (▲3.1)	-1.3ºC (▲2.8)	-2.2ºC (▲2.9)
7ºC	4.4ºC (▲2.3)	4.1ºC (▲2.1)	-
12ºC	10.4ºC (▲1.4)	10.2ºC (▲1.0)	-

( ) Indicates the difference between the blowing air temperature and the suction air temperature

3. Field Test

3.1. Test Method

In this test, we used two packaged air conditioners installed in a building of Mie University. By measuring the blowing air temperature, suction air temperature, outdoor air temperature, etc. of the outdoor unit, the occurrence of the short circuit was examined. We also examined the installation conditions of outdoor units where short circuits are likely to occur. The measurements were conducted mainly in September and October to avoid the cooling capacity shortage in midsummer that might be caused by the short circuit.

The air conditioner used for the measurement was a packaged air conditioner with a rated cooling capacity of 8 kW (manufactured in 2009). As shown in Figure 6, the left side (air conditioner No.1) of two adjacent outdoor units was the main measurement target. As for the air conditioner on the right side (air conditioner No.2), we measured only power consumption in order to understand its operating state.

As can be seen from this figure, there were building walls on the back side of these outdoor units, but there were no walls on the side and front. Therefore, as shown in Figure 7, a partition wall (height 2.0 m, width 1.0 m) simulating the building wall was put on the side and/or front of the outdoor unit of air conditioner 1 to generate the short circuit artificially. An experiment was conducted based on the air conditioner installation manual, and the distance between the outdoor unit and the partition wall was set at 0.15 m when the wall was installed on the side of the outdoor unit and 1.0 m when it was installed on the front.

Figure 8 shows the positions of the thermos-sensors installed in the outdoor unit of air conditioner 1. The temperatures of the blowing and suction air were measured at 1 minute intervals. In addition, the outdoor air temperature was measured at a position away from the outdoor unit, and the power consumptions of both air conditioners were also measured.

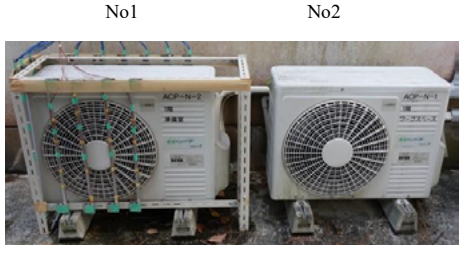

Fig. 6 Air conditioner installation condition (the air conditioner 1 to be measured is on the left)

Fig. 7 Wall installation conditions (left: Side, right: Side + Front)

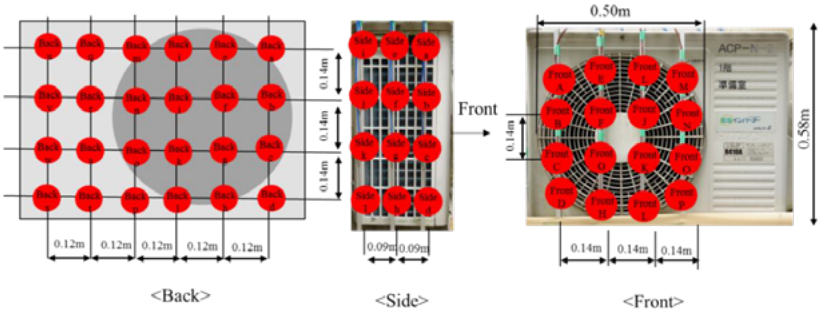

Fig. 8 Measurement position of suction (Back and Side) and blowing (Front) air temperature

3.2. Results

3.2.1. Influence of Wall

Table 10 shows the results of temperature measurements. When the adjacent air conditioner 2 was not operating and the wall was installed on the side, the suction air temperature on the side face increased by 4.6 ºC. On the other hand, the temperature rise on the back face was not so much. The same tendency is observed when the wall was installed in the front. These results are very similar to those of the laboratory tests.

When the air conditioner 2 was operating, the temperature rise in the side and back faces is remarkable. The situation when the air conditioner 2 was operating is described in detail in the next chapter.

Table 10 Rise of average suction air temperature under each condition

Wall	Air-conditioner 2	Side suction temperature – Outdoor air temperature	Back suction temperature – Outdoor air temperature
None	OFF	-0.2ºC	-1.1℃
	ON	0.7 ºC	0.8℃
Side	OFF	4.6 ºC	1.0 ºC
	ON	6.1 ºC	3.2 ºC
Side + Front	OFF	5.0 ºC	1.4 ºC
	ON	4.3 ºC	2.4 ºC

3.2.2. Influence of Adjacent Air-Conditioner

Figure 9 shows the temporal change of the suction air temperature at the representative point "Back 1" on the back of the air conditioner 1 when the air conditioner 2 was operated without any walls. Here Δt on the ordinate denotes the difference between the suction air temperature and the outdoor air temperature. For comparison, the suction air temperature of “Back 1” when the air conditioner 2 was stopped is also shown. The suction air temperature at “Back l” with the operation of air conditioner 2 is 2 ºC higher than that without the operation of air conditioner 2. From this result, it is presumed that when the adjacent air conditioner 2 is in operation, the air blown from the air conditioner 1 wraps around the back of the outdoor unit due to the influence of air blown from air conditioner 2.

Next, let us describe the case where the wall was installed on the side of the outdoor unit. Figure 10 shows the blowing air temperature and the suction air temperature on the back face ("Back a" to "Back d") when the air conditioner 2 was operating. Figure 11 shows changes in the power consumption of the air conditioner 2 and the suction air temperature at the back of the air conditioner 1. The rise of the suction air temperature at the back of the outdoor unit increases compared to the results without the wall (Figure 9). In addition, the influence of air conditioner 2 is more noticeable.

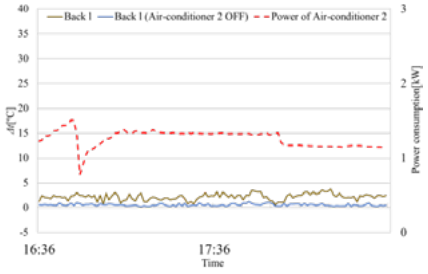

Fig. 9 Comparison of suction air temperature on the back-face and power consumption of air conditioner 2 (No walls)

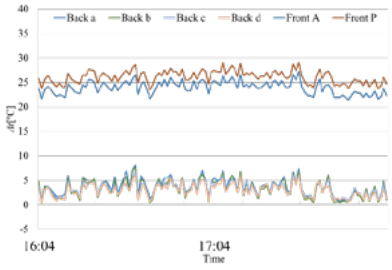

Fig. 10 Comparison of blowing air temperature and back-face suction air temperature (Wall: side installation)

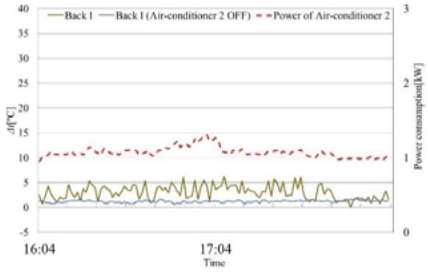

Fig. 11 Comparison of suction air temperature on the back-face and power consumption of conditioner 2 (Wall: side installation)

Table 11 Example of correlation coefficients between blowing air temperature and suction air temperature

Wall	Blowing position	Suction position	Correlation coefficient (Air-conditioner 2 OFF)	Correlation coefficient (Air-conditioner 2 ON)
None	Front D	Side a	0.147	0.258
		Side b	0.128	0.464
		Side c	0.509	0.437
		Side d	-0.008	0.760
Side	Front D	Side a	0.239	0.896
		Side b	0.454	0.832
		Side c	0.020	0.746
		Side d	0.091	0.780
Side + Front	Front D	Side a	0.540	0.775
		Side b	0.535	0.718
		Side c	0.413	0.523
		Side d	0.272	0.715

3.2.3. Correlation Coefficient between Blowing Air Temperature and Suction Air Temperature

In this study, we obtained the correlation coefficient of the time-series changes of the blowing air temperature and the suction air temperature. Based on this correlation coefficient, we can estimate the position at which the air blown from the front of the outdoor unit was easily sucked.

As an example of the correlation coefficient calculation results, Table 11 shows the correlation coefficient calculated between "Front D" (blowing air) on the front face of the outdoor unit and "Side a" to "Side d" (suction air) on the side face. The correlation coefficient between the blowing position "Front D" and the suction position "Side a" is expressed as follows.

$$\text{Correlation coefficient} = \frac{\overline{t_D' \cdot t_a'}}{\sqrt{\overline{t_D'^2}} \cdot \sqrt{\overline{t_a'^2}}} \quad , \quad t_D' = t_D - \overline{t_D} \quad \text{and} \; t_a' = t_a - \overline{t_a}$$

Here t_D and t_a are instantaneous air temperatures at "Front D" and "Side a" measured at every one minute, and overbar means time-averaged values. Therefore, t_D' and t_a' designate the temperature fluctuations of blowing and suction air with time. The value of the correlation coefficient was calculated based on air temperatures measured in two hours.

The correlation coefficient with the wall installation is generally higher than that without the wall. In addition, when the air conditioner 2 was in operation, the correlation coefficient further increases. This suggests that a short circuit tends to be strengthened due to the synergistic effect of the wall and air blown from air conditioner 2. When there were no walls, the correlation coefficient tends to be higher on the lower side face, whereas when the wall was installed, the correlation coefficient on the upper region of the side face tends to be higher. It is thought that the air tends to go to the upper side by the influence of the wall.

4. Conclusions

In this report, in the environmental test laboratory and in an actual building, a wall simulating a building wall or an obstacle was installed near the outdoor unit of the air conditioner, and the relationship between the outdoor air temperature, load factor and the performance degradation were investigated. Due to the influence of the wall installation, SCR and power consumption increased, and COP decreased. The main results are shown below.

1. In the cooling operation, when there are walls near the back and side faces of the outdoor unit, the suction air temperature becomes higher than the case of no wall installation. The increase in the suction air temperature is particularly remarkable on the side face of the outdoor unit.
2. Short circuit is more likely to occur when the wall is installed on the side than when the wall is installed on the front of the outdoor unit.
3. COP decreased by 6.5% in the case of patern3, high outdoor air temperature and the load factor in cooling operation.
4. In the cooling operation, a short circuit may occur in 100% load operation even at low outdoor air temperatures, but the influence of the short circuit is reduced under lower load operation.
5. Under the partial load operation, the influence of the short circuit is large in the cooling operation, whereas the influence of the short circuit is small in the heating operation.
6. In the cooling operation, the suction air temperature also increases on the back face of the outdoor unit, and the temperature rise becomes more remarkable when the adjacent air conditioner is operating.

Abstract

In air conditioners installed in commercial buildings, their efficiencies are often deteriorated by short circuits of airflows in which hotter (cooling operation) or cooler (heating operation) air blown out from the outdoor units is sucked again in the outdoor units. From viewpoints of energy savings of air conditioners, it is necessary to understand the influence of short circuits of airflows on operations of air conditioners quantitatively and to take measures against them. The purpose of this study is to make clear the influence of installation conditions of the outdoor unit of an air conditioner on the short circuit of airflow issued from it.

We made laboratory measurements and field measurements of airflow temperatures around the outdoor unit of a packaged air conditioner. The short circuit of the airflow from the front face to the side face of the outdoor unit was enhanced when there was a wall near the side face. In such cases, linear relationships were found between suction air temperatures of the outdoor unit and outdoor air temperatures.

Keywords: Air conditioner, Outdoor unit, Airflow, Short circuit, Suction air temperature ;

1. Introduction

Individual distributed air conditioner may cause a short circuit of air flow in which high-temperature air blown from its outdoor unit (cooling operation) is directly sucked by its suction face, depending on the outdoor unit installation situation (close to walls, under the roof, concentrated equipment installation, etc.). It is known that the performance of the air conditioner is deteriorated by this short circuit. In addition, there are cases in which the air conditioner shuts down due to capacity control when the impact of the short circuit becomes large. In order to save energy and keep proper operation, it is required to quantitatively understand the influences of short circuits and take measures against them.

Several papers on short circuits have been reported so far [1][2], but there are few reports on the influences of outdoor unit installation conditions, changes in outdoor air temperature and load factors on short circuits and capacity degradation of an air conditioner.

The purpose of this study is to quantitatively understand the influences of short circuits of air flow in the outdoor unit on the performance of air conditioners, taking the outdoor unit installation conditions, outdoor air temperature and load factor as parameters.

In the first half of this paper, we show the results obtained in the environmental test laboratory in which influences of a building wall or an obstacle on the performance of a packaged air conditioner were examined to clarify the relationship between the outdoor unit's suction temperature and the outdoor air temperature. In the second half, we will clarify the effect of short circuits when two or more air conditioners installed in an actual building are operated with walls around the outdoor unit.

2. Laboratory Test

2.1. Test Method

This test was conducted in the environmental test laboratory of the Chubu Electric Power Co., Inc. by installing one side blown 5-horsepower packaged air conditioner with a specification shown in Table 1. Figure 1 shows the outdoor unit installation conditions. Pattern 1 is a standard installation in which there are no obstacles around the suction face (back and side faces) and the blowing face (front face) of the outdoor unit.

On the other hand, since many outdoor units are often installed near the building walls, a test was performed on Pattern 2 in which walls simulating building walls were installed near the back and side faces (suction faces) of the outdoor unit. Here, the distances between the wall and those faces were set to effective spaces of 0.3 m as described in the manufacturer's installation manual. In addition, a test was also conducted on Pattern 3 that simulated an installation in a small space with walls near the back, side (suction) and the front (blowing) faces of the outdoor unit. The distance between the front face of the outdoor unit and the wall was set at 1.0 m as described in the manufacturer's installation manual.

Figure 2 shows the positions of thermo-sensors set on the suction and the blowing faces with the wall setting situation of Pattern 2 in the environmental test laboratory.

Table 1. Specifications of test air conditioner

5 HP packaged air conditioner (manufactured in 2017)		
	Cooling operation	Heating operation
Rated capacity	12.5 kW	14.0 kW
Rated power consumption	3.31 kW	3.30 kW
APF*(2015)	6.3	

*APF: Annual Performance Factor

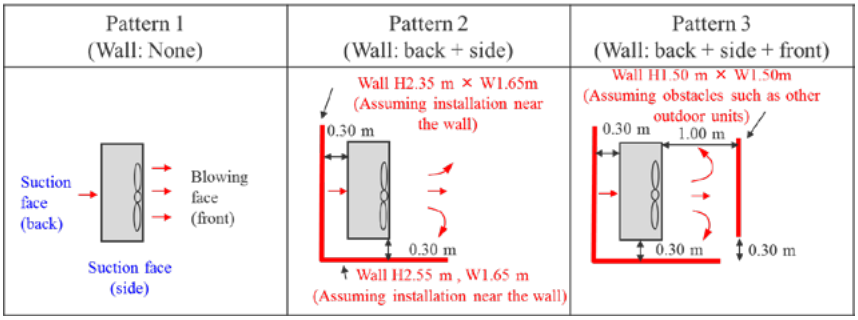

Fig. 1. Wall installation patterns around the outdoor unit of the air conditioner

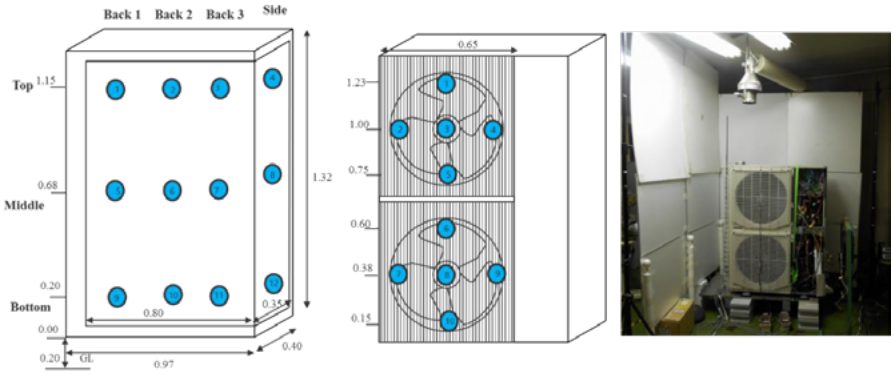

Fig. 2. Positions of sensors on the outdoor unit and wall installation condition of Pattern 2

2.2. Test Conditions

The air conditioning capacity was measured by the indoor enthalpy method. Test conditions are shown in Table 2, the air dry bulb temperature in the outdoor test room was set at 35 ºC, 30 ºC or 25 ºC in the cooling performance test, and at 12 ºC, 7 ºC or 2 ºC in the heating performance test.

A part of tests was conducted considering the situation that the air conditioning load is large and the air conditioner is always operating at full power (100%). In these tests, the indoor test room was controlled at 27 ºC and the remote control temperature was set to 18 ºC in the cooling operation, and the indoor test room was controlled at 20 ºC and the remote control temperature was set to 30 ºC in the heating operation.

Tests were also conducted assuming the situation that the air conditioning load is reduced in the intermediate period. In the case of cooling, the air conditioning load was set at 25% and 50% of the actual rated cooling capacity of the tested air conditioner, and the air temperature of the indoor test room was controlled at 27 ºC by the air conditioner itself. In the heating performance test, the indoor air temperature was controlled at 20 ºC with the heating load corresponding to 25% and 50% of the actual rated heating capacity.

Measurement data were sampled at 10-second intervals, and they were averaged in 60 minutes for the steady operation and in one cycle for the intermittent (on-off) operation.

Table 2. Test conditions (dry bulb temperature / wet bulb temperature)

Operations	Outdoor temperature conditions	Indoor temperature conditions	Load factor
Cooling	35 ºC / -	27 ºC /19 ºC	100%
Cooling	30 ºC / -	27 ºC /19 ºC	50%
Cooling	25 ºC / -	27 ºC / 19 ºC	25%
Heating	12 ºC / 11 ºC	20 ºC / -	25%
Heating	7 ºC / 6 ºC	20 ºC / -	50%
Heating	2 ºC /1 ºC	20 ºC / -	100%

2.3. Results

2.3.1. Influence of Wall Installation

Table 3 shows the results of average suction air temperatures (back, side, and overall average) and Table 4 shows the average blowing air temperature in each pattern in the cooling performance test at the outdoor air temperature of 35 ºC with full power operation.

In Pattern 1, the suction air temperatures on the back and side faces are about 37 ºC, and the difference from the outdoor air temperature is not so large. It should be noted that the temperature sensor position for setting the test room was different from the positions of the thermo-sensors on the suction face, so there was a difference between the test room setting temperature and the suction air temperature in Pattern 1.

In Pattern 2 in which the walls are installed on the back and side of the outdoor unit, the suction temperature is about 2 ºC higher than Pattern 1 on average. In particular, the suction air temperature is as high as 41.2 ºC on the side face, and it can be seen that the influence of the short circuit is greatly reflected on the side of the outdoor unit. Pattern 3 shows a similar trend to Pattern2.

Regardless of the change in the suction air temperature, the blowing air temperature is almost constant at about 48 ºC in all patterns as shown in Table 4.

Table 3. Average of suction air temperature during cooling operation at the outdoor air temperature of 35 ºC with 100% operation

Suction air temperature	Pattern 1	Pattern 2	Pattern 3
Back	37.0ºC	38.6ºC	39.1ºC
Side	37.6ºC	41.2ºC	42.3ºC
Overall	37.1ºC	39.2ºC	39.9ºC

Table 4. Average of blowing air temperature during cooling operation at the outdoor air temperature of 35 ºC with 100% operation

	Pattern 1	Pattern 2	Pattern 3
Blowing air temperature	48.1ºC	47.9ºC	48.6ºC

For more detailed changes in the air temperature on the suction face, Table 5 shows differences between suction air temperatures in Pattern 2 and Pattern 1, and Table 6 shows a comparison with Pattern 3. Here, the positions described in these tables correspond to the sensor positions shown in Figure 2. As can be seen from Table 5, the place where the temperature change is particularly large is from the center to the bottom of the back and side faces of the outdoor unit, rising by 6-7 ºC. Table 6 of Pattern 3 shows a similar tendency. It is thought that hot air blown from the front face of the outdoor unit stayed around the bottom of the side face where there was little air flow.

In addition, from the overall average temperature change in Table 5 and Table 6, it rises to 2.1 ºC by wall setting on the back and side, whereas it rises to 2.8 ºC by wall setting on the back, side and front. It can be seen that the influence of the back and side walls on the short circuit is greater than that of the front wall.

Table 5. Difference of suction temperatures of pattern 2 from pattern 1 at the outdoor air temperature of 35 ºC with 100% operation

	Back 1	Back 2	Back 3	Side
Top	-0.1ºC	-0.3ºC	-0.6ºC	-0.5ºC
Middle	-0.9ºC	0.8ºC	3.6ºC	5.1ºC
Bottom	1.3ºC	3.5ºC	7.2ºC	6.2ºC
Average of Back		1.6ºC		-
Average of Side		-		3.6ºC
Average of Overall		2.1ºC		

Table 6 Difference of suction temperatures of pattern 3 from pattern 1 at the outdoor air temperature of 35 ºC with 100% operation

	Back 1	Back 2	Back 3	Side
Top	0.2ºC	0.5ºC	0.7ºC	0.7ºC
Middle	-0.8ºC	1.7ºC	5.2ºC	6.3ºC
Bottom	1.5ºC	3.5ºC	6.4ºC	7.2ºC
Average of Back		2.1ºC		-
Average of Side		-		4.7ºC
Average of Overall		2.8ºC		

Table 7 shows the power consumption, cooling capacity and COP of the air conditioner during 100% cooling operation at the outdoor air temperature of 35 ºC for each pattern. From these results, the power consumption increased by 2-4%, the cooling capacity decreased by 1-3% and consequently COP decreased by 3-6% in Patterns 2 and 3 compared to Pattern 1, due to the short circuit.

Table 7 Power consumption, Cooling capacity and COP at the outdoor air temperature of 35 ºC with 100% operation

	Pattern 1	Pattern 2	Pattern 3
Power consumption	4.43kW	4.54kW	4.62kW
(Rate of change)	(Basis)	(+2.36%)	(+4.12%)
Cooling capacity	14.19	14.04	13.81
(Rate of change)	(Basis)	(-1.06%)	(-2.68%)
COP	3.20	3.09	2.99
(Rate of change)	(Basis)	(-3.34%)	(-6.53%)

2.3.2. Influence of Partial Load Operation

In actual use an air conditioner is often operated under a partial load. Therefore, we conducted partial load performance tests. In order to understand the influence of the short circuit under partial load, the setting of outdoor temperature and lord factor of the environmental test laboratory was changed, and the relationship between the suction average temperature, the outdoor air temperature and load factor was investigated. As mentioned in Section 2.3.1, there was a difference between the test room setting temperature and the suction air temperature in Pattern 1, in which the influence of the short circuit was negligibly small. Hence, in order to clarify the difference between Patterns 2 and Pattern 3 that have a strong influence of short circuit, the suction air temperature of Pattern 1 was used as the outdoor air temperature.

2.3.2.1 Cooling Operation

Figure 3 shows the relationship between the outdoor air temperature and the mean suction air temperature at each load factor close to actual operations measured under the test conditions shown in Table 2.

In Pattern 2, it can be seen that the lower the outdoor air temperature and the load factor, the smaller the difference from Pattern 1 and the smaller the influence of the short circuit. As for Pattern 3, only the result of one high outdoor air temperature is shown, and the difference from Pattern 2 is negligibly small. This suggests that the wall installed in the side of the outdoor unit is more dominant in the occurrence of the short circuit than that installed in the front. From this result, it should be noted that the short circuit of airflow may occur even if the outdoor unit is installed at a distance from the building wall recommended by the manufacturer. It is recommended that the distance between the suction face of the outdoor unit and the building wall be set larger than the manufacturer's recommendation value.

Table 8 shows the difference between the blowing air temperature and the suction air temperature. Compare to low outdoor air temperature and the load factor, the difference is large at high outdoor air temperature and the load factor.

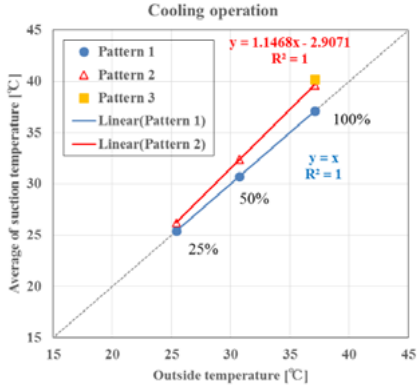

Fig. 3. The relationships between outdoor air temperature and suction air temperature in cooling operation

Table 8. Blowing air temperature during cooling operation

Outdoor temperature conditions	Pattern 1	Pattern 2	Pattern 3
25ºC	28.6ºC (+3.1)	29.0ºC (+2.8)	-
30ºC	36.1ºC (+5.3)	37.3ºC (+4.9)	-
35ºC	48.1ºC (+11.0)	47.9ºC (+8.3)	48.6ºC (+8.4)

( ) Indicates the difference between the blowing air temperature and the suction air temperature

In order to quantitatively express the influence of the short circuit, the short circuit ratio (SCR) [3] shown in Equation (1) was calculated.

$$SCR[\%] = \frac{Suction\ air\ temperature - Outdoor\ air\ temperature}{Blowig\ air\ temperature - Outdoor\ air\ temperature} * 100 \quad (1)$$

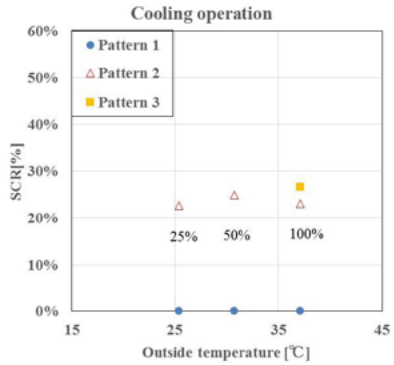

Fig. 4. SCR during cooling operation

Figure 4 shows the results of SCR under the low load conditions in each pattern. It can be seen that the SCR is about 20-25% in Patterns 2 and 3.

2.3.2.2 Heating Operation

Next, the influence of the short circuit during heating operation is examined. Figure 5 shows the suction air temperature during heating operations at 100% load at 2 ºC and partial loads shown in Table 2. It can be seen that there is no significant difference among the results for three patterns. The reason why the influence of the short circuit (decrease in the suction air temperature) was small in comparison with the cooling operation may be that the difference between the suction air temperature and the blowing air temperature was small in the heating operation. In 100% cooling operation, the difference between the blowing air temperature and the suction air temperature was as large as 8 ºC to 11 ºC (Table 8). On the other hand, the difference in the heating operation was smaller than 3 ºC (Table 9).

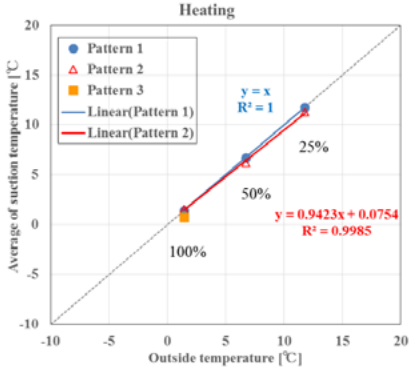

Fig. 5. The relationships between outdoor air temperature and suction air temperature in heating operation

Table 9 Blowing air temperature during heating operation

Outdoor temperature conditions	Pattern 1	Pattern 2	Pattern 3
2ºC	-1.7ºC (▲3.1)	-1.3ºC (▲2.8)	-2.2ºC (▲2.9)

( ) Indicates the difference between the blowing air temperature and the suction air temperature

3. Field Test

3.1. Test Method

In this test, we used two packaged air conditioners installed in a building of Mie University. By measuring the blowing air temperature, suction air temperature, outdoor air temperature, etc. of the outdoor unit, the occurrence of the short circuit was examined. We also examined the installation conditions of outdoor units where short circuits are likely to occur. The measurements were conducted mainly in September and October to avoid the cooling capacity shortage in midsummer that might be caused by the short circuit.

The air conditioner used for the measurement was a packaged air conditioner with a rated cooling capacity of 8 kW (manufactured in 2009). As shown in Figure 6, the left side (air conditioner No.1) of two adjacent outdoor units was the main measurement target. As for the air conditioner on the right side (air conditioner No.2), we measured only power consumption in order to understand its operating state.

As can be seen from this figure, there were building walls on the back side of these outdoor units, but there were no walls on the side and front. Therefore, as shown in Figure 7, a partition wall (height 2.0 m, width 1.0 m) simulating the building wall was put on the side and/or front of the outdoor unit of air conditioner 1 to generate the short circuit artificially. An experiment was conducted based on the air conditioner installation manual, and the distance between the outdoor unit and the partition wall was set at 0.15 m when the wall was installed on the side of the outdoor unit and 1.0 m when it was installed on the front.

Figure 8 shows the positions of the thermos-sensors installed in the outdoor unit of air conditioner 1. The temperatures of the blowing and suction air were measured at 1 minute intervals. In addition, the outdoor air temperature was measured at a position away from the outdoor unit, and the power consumptions of both air conditioners were also measured.

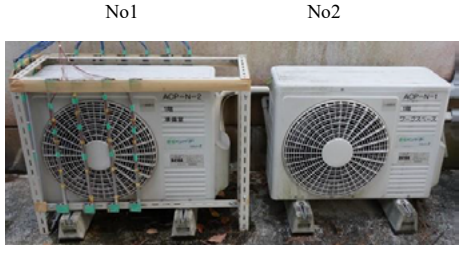

Fig. 6 Air conditioner installation condition (the air conditioner 1 to be measured is on the left)

Fig. 7 Wall installation conditions (left: Side, right: Side + Front)

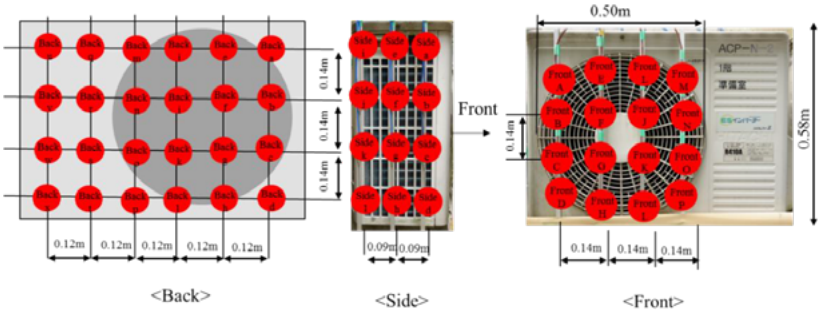

Fig. 8 Measurement position of suction (Back and Side) and blowing (Front) air temperature

3.2. Results

3.2.1. Influence of Wall

Table 10 shows the results of temperature measurements. When the adjacent air conditioner 2 was not operating and the wall was installed on the side, the suction air temperature on the side face increased by 4.6 ºC. On the other hand, the temperature rise on the back face was not so much. The same tendency is observed when the wall was installed in the front. These results are very similar to those of the laboratory tests.

When the air conditioner 2 was operating, the temperature rise in the side and back faces is remarkable. The situation when the air conditioner 2 was operating is described in detail in the next chapter.

Table 10 Rise of average suction air temperature under each condition

Wall	Air-conditioner 2	Side suction temperature – Outdoor air temperature	Back suction temperature – Outdoor air temperature
None	OFF	-0.2ºC	-1.1℃
	ON	0.7 ºC	0.8℃
Side	OFF	4.6 ºC	1.0 ºC
	ON	6.1 ºC	3.2 ºC
Side + Front	OFF	5.0 ºC	1.4 ºC
	ON	4.3 ºC	2.4 ºC

3.2.2. Influence of Adjacent Air-Conditioner

Figure 9 shows the temporal change of the suction air temperature at the representative point "Back 1" on the back of the air conditioner 1 when the air conditioner 2 was operated without any walls. Here Δt on the ordinate denotes the difference between the suction air temperature and the outdoor air temperature. For comparison, the suction air temperature of “Back 1” when the air conditioner 2 was stopped is also shown. The suction air temperature at “Back l” with the operation of air conditioner 2 is 2 ºC higher than that without the operation of air conditioner 2. From this result, it is presumed that when the adjacent air conditioner 2 is in operation, the air blown from the air conditioner 1 wraps around the back of the outdoor unit due to the influence of air blown from air conditioner 2.

Next, let us describe the case where the wall was installed on the side of the outdoor unit. Figure 10 shows the blowing air temperature and the suction air temperature on the back face ("Back a" to "Back d") when the air conditioner 2 was operating. Figure 11 shows changes in the power consumption of the air conditioner 2 and the suction air temperature at the back of the air conditioner 1. The rise of the suction air temperature at the back of the outdoor unit increases compared to the results without the wall (Figure 9). In addition, the influence of air conditioner 2 is more noticeable.

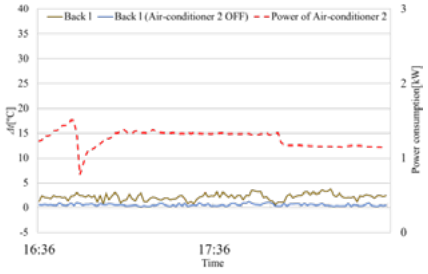

Fig. 9 Comparison of suction air temperature on the back-face and power consumption of air conditioner 2 (No walls)

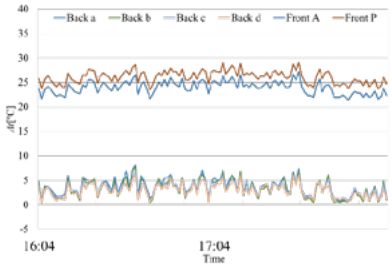

Fig. 10 Comparison of blowing air temperature and back-face suction air temperature (Wall: side installation)

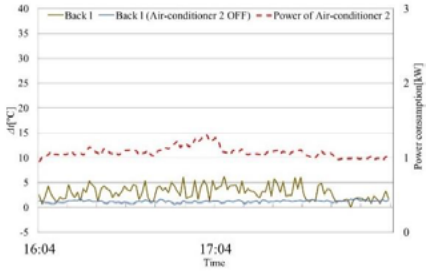

Fig. 11 Comparison of suction air temperature on the back-face and power consumption of conditioner 2 (Wall: side installation)

Table 11 Example of correlation coefficients between blowing air temperature and suction air temperature

Wall	Blowing position	Suction position	Correlation coefficient (Air-conditioner 2 OFF)	Correlation coefficient (Air-conditioner 2 ON)
None	Front D	Side a	0.147	0.258
		Side b	0.128	0.464
		Side c	0.509	0.437
		Side d	-0.008	0.760
Side	Front D	Side a	0.239	0.896
		Side b	0.454	0.832
		Side c	0.020	0.746
		Side d	0.091	0.780
Side + Front	Front D	Side a	0.540	0.775
		Side b	0.535	0.718
		Side c	0.413	0.523
		Side d	0.272	0.715

3.2.3. Correlation Coefficient between Blowing Air Temperature and Suction Air Temperature

In this study, we obtained the correlation coefficient of the time-series changes of the blowing air temperature and the suction air temperature. Based on this correlation coefficient, we can estimate the position at which the air blown from the front of the outdoor unit was easily sucked.

As an example of the correlation coefficient calculation results, Table 11 shows the correlation coefficient calculated between "Front D" (blowing air) on the front face of the outdoor unit and "Side a" to "Side d" (suction air) on the side face. The correlation coefficient between the blowing position "Front D" and the suction position "Side a" is expressed as follows.

$$\text{Correlation coefficient} = \frac{\overline{t_D' \cdot t_a'}}{\sqrt{\overline{t_D'^2}} \cdot \sqrt{\overline{t_a'^2}}} \quad , \quad t_D' = t_D - \overline{t_D} \quad \text{and} \; t_a' = t_a - \overline{t_a}$$

Here t_D and t_a are instantaneous air temperatures at "Front D" and "Side a" measured at every one minute, and overbar means time-averaged values. Therefore, t_D' and t_a' designate the temperature fluctuations of blowing and suction air with time. The value of the correlation coefficient was calculated based on air temperatures measured in two hours.

The correlation coefficient with the wall installation is generally higher than that without the wall. In addition, when the air conditioner 2 was in operation, the correlation coefficient further increases. This suggests that a short circuit tends to be strengthened due to the synergistic effect of the wall and air blown from air conditioner 2. When there were no walls, the correlation coefficient tends to be higher on the lower side face, whereas when the wall was installed, the correlation coefficient on the upper region of the side face tends to be higher. It is thought that the air tends to go to the upper side by the influence of the wall.

4. Conclusions

In this report, in the environmental test laboratory and in an actual building, a wall simulating a building wall or an obstacle was installed near the outdoor unit of the air conditioner, and the relationship between the outdoor air temperature, load factor and the performance degradation were investigated. Due to the influence of the wall installation, SCR and power consumption increased, and COP decreased. The main results are shown below.

1. In the cooling operation, when there are walls near the back and side faces of the outdoor unit, the suction air temperature becomes higher than the case of no wall installation. The increase in the suction air temperature is particularly remarkable on the side face of the outdoor unit.
2. Short circuit is more likely to occur when the wall is installed on the side than when the wall is installed on the front of the outdoor unit.
3. COP decreased by 6.5% in the case of patern3, high outdoor air temperature and the load factor in cooling operation.
4. In the cooling operation, a short circuit may occur in 100% load operation even at low outdoor air temperatures, but the influence of the short circuit is reduced under lower load operation.
5. Under the partial load operation, the influence of the short circuit is large in the cooling operation, whereas the influence of the short circuit is small in the heating operation.
6. In the cooling operation, the suction air temperature also increases on the back face of the outdoor unit, and the temperature rise becomes more remarkable when the adjacent air conditioner is operating.

Disruption to heat business models: from shifting boxes to selling comfort

Cate Lyon [a*], Lindsay Sugden [b], Roxanne Pieterse [c]

[a]Delta-EE Ltd, Argyle House, 3 Lady Lawson Street, Edinburgh, EH3 9DR, UK

Abstract

While heat pumps are gaining ground in the new build market in Europe, the replacement market remains challenging. Emerging alternative business models - like 'Heat as a Service' – tackle key consumer barriers and promise to open up new market opportunities in retrofit for technologies like heat pumps. The authors assess how alternative propositions are gaining traction in Europe, assess customer response to such models based on our own primary research, and discuss what this trend means for the heat pump industry.

Keywords: heat pump; Europe; business model; alternative propositions; heat as a service; asset leasing; services; consumers; overcoming barriers; market opportunities; replacment market; retrofit.

1. Introduction

The heat pump market in Europe has shown >10% growth per year for the past 4 years [1] but it is far from reaching its potential. There are ~12 million heat pumps installed in Europe [1], a number dwarfed by the more than 100 million fossil fuel boilers installed [2]. This is primarily because of limited success in the retrofit (existing buildings) market, where heat pumps continue to struggle to gain traction against "traditional" heating systems (primarily fossil fuel boilers). Alternative, service-based customer propositions for heat are emerging, in particular Heat as a Service, which promise to overcome some of the retrofit challenges, and could enable heat pumps to capture a greater share of the existing buildings market.

Such propositions typically involve a residential building occupier signing up to a contract for heating provision and/or heating equipment (plus related services and maintenance) for a fixed (or variable) monthly fee, rather than purchasing their heating appliance outright. Similar heat contracting business models based on ongoing rather than upfront fees are already common in the commercial and industrial sectors, where heating and hot water demand is relatively more predictable than in the domestic sector, reducing the risk to the provider.

1.1 Heat pumps are established in new build – but existing buildings remain the biggest challenge

Heat pumps are already the heating system of choice for housing developers in many markets – in markets such as France and Germany, heat pumps account for 40-50% of heating systems in new single family homes (and in Sweden this is >90%) [2]. Tightening building regulations, and political goals to phase out the use of fossil fuels in new homes promise a bright future for heat pumps in new build, even in gas-dominated markets such as the Netherlands and UK [3]. But the majority of heating systems are installed in existing buildings, and it is here that heat pumps need to gain traction. In some of Europe's biggest heating markets (UK, Netherlands, Germany) heat pumps capture just a 1 - 5% share of the retrofit single family home market – which should be the initial target for heat pumps. This is compared to a >90% share for fossil boilers. A combination of low end-user awareness of heat pumps, lack of end-user trust in heat pumps and entrenched

E-mail address: cate.lyon@delta-ee.com.

preference for 'like-for-like' replacement, and economic concerns, make gaining traction in retrofit very challenging.

1.2 What are the challenges to the growth of heat pumps in existing buildings, and how can 'Heat as a Service' help to overcome these?

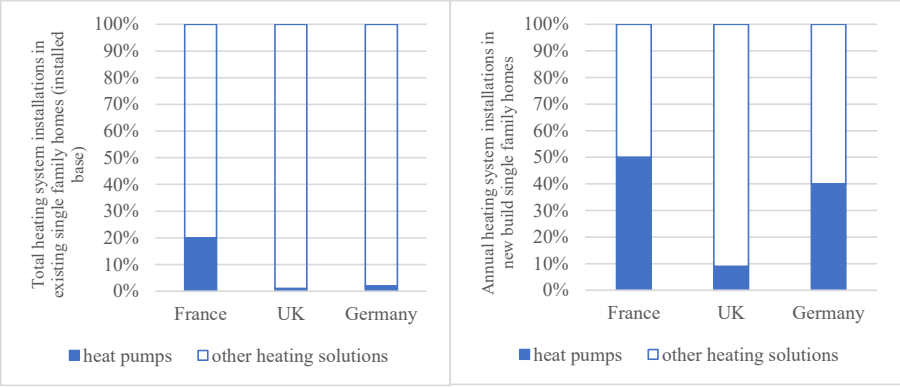

Figure 1: Share of heat pumps in existing (left) and new (right) single family homes

Source: [2], [1]

There are many barriers for heat pumps in displacing traditional heating systems (usually fossil boilers) in existing homes, in particular:

- Upfront cost of heat pump to end-user (can be 2-4 x the upfront cost of a new boiler, and more if heat distribution systems need to be replaced)
- Running costs compared to a boiler (varies by market, but high electricity prices versus gas & oil is a critical issue in many markets, and uncertainty about future energy prices make the idea of switching fuel risky for the end-user)
- End-user confidence/trust in heat pumps' ability to perform (though there are exceptions in markets such as Sweden and Switzerland, end-users are still cautious about switching from a familiar heating system like a boiler, to an 'unknown' system like a heat pump – despite the fact the technology is well-established)

'Heat as a Service' type models, by reducing the amount of risk taken on by the end-user, can potentially help to overcome some of the retrofit barriers:

- Upfront cost of heat pump to end-user: 'Heat as a Service' removes – or reduces - the upfront cost barrier, as the cost is borne by the service provider rather than the end-user. The service provider can get better economies of scale, and potentially get volume discounts for purchase of many heat pumps at once.

- Running costs compared to a boiler: 'Heat as a Service' usually gives a fixed rate heat cost to the end-user, meaning there is less uncertainty about running costs. There are also various ways the service provider might reduce heat pump running costs – through for example including microgeneration for self-consumption such as PV, and through optimisation of the heat pump running times to run when electricity is cheaper.
- End-user confidence/trust in heat pumps' ability to perform: 'Heat as a Service' removes the risk of poor heat pump performance and break-downs from the end-user, by providing maintenance, remote monitoring, and guaranteeing the heat outcome

'Heat as a Service': A definition

'Heat as a Service' usually means either/both of the following:

- *Paying an ongoing monthly fee rather than a one-off upfront fee* (the monthly fee usually includes payment for the heating system, the heat delivered, and the ongoing servicing)
- *Paying for outcomes rather than inputs* (paying for heat or comfort delivered rather than fuel input)

Delta-EE defines 'Heat as a Service' as a service where the provider takes on the following 'risks' usually borne by the end-user:

- *financial risk* – The service provider takes on credit risk by providing a heating appliance for a monthly fee and little or no upfront payment.
- *technical risk* – The monthly fee charged by the service provider includes: routine maintenance, repairs, and appliance replacement if necessary within the contract period.
- *performance risk* – The service provider charges per unit of output (heat) or for the outcome (warmth) provided by the heating appliance (or guarantees savings on heating costs).
- *energy price risk* – The service provider offers a fixed price per unit of heat or warmth generated for a period of time, typically a year.
- *behaviour risk* – the service provider charges for the outcome (warmth) provided, thereby taking on the risk that customers use heating inefficiently by, for example, opening windows.

Sub categories of 'Heat as a Service' exist, where the provide takes on only some (but not all) of the above risks. These include:

- Asset leasing
- Efficient asset leasing
- Energy payment plan
- Warmth payment plan

There are also further developments possible, beyond 'Heat as a Service', including:

- Comfort as a Service: where the outcome is a level of year-round thermal comfort in a home, including providing cooling in summer, when needed
- Energy as a Service: where the offer to the customer includes energy use for other appliances (e.g. including other electricity needs).

2. The 'Heat as a Service' landscape in Europe – who is doing what?

Over the past 3-5 years, an increasing number of new 'Heat as a Service' type offerings have emerged in the domestic sector, being offered from providers including energy suppliers, heating manufacturers and specialist start ups. The majority of these are still pre-commercial and at trial stage, but several have been commercialised successfully, and we estimate that the number of customers currently using a Heat as a Service type model is in the low 1,000s across Europe [4]. Figure 2 highlights some of the main activity in Heat as a Service offerings in the domestic sector. Heating systems employed in these offerings include heat pumps, hybrids (heat pump & boiler), and traditional heating systems, sometimes packaged together with building fabric renovation, PV and other technologies. It should be noted that heat contracting business models, based on ongoing rather than upfront fees, are already common in the commercial and industrial sectors (where heating and hot water demand is relatively more predictable than in the domestic sector, reducing the risk to the provider).

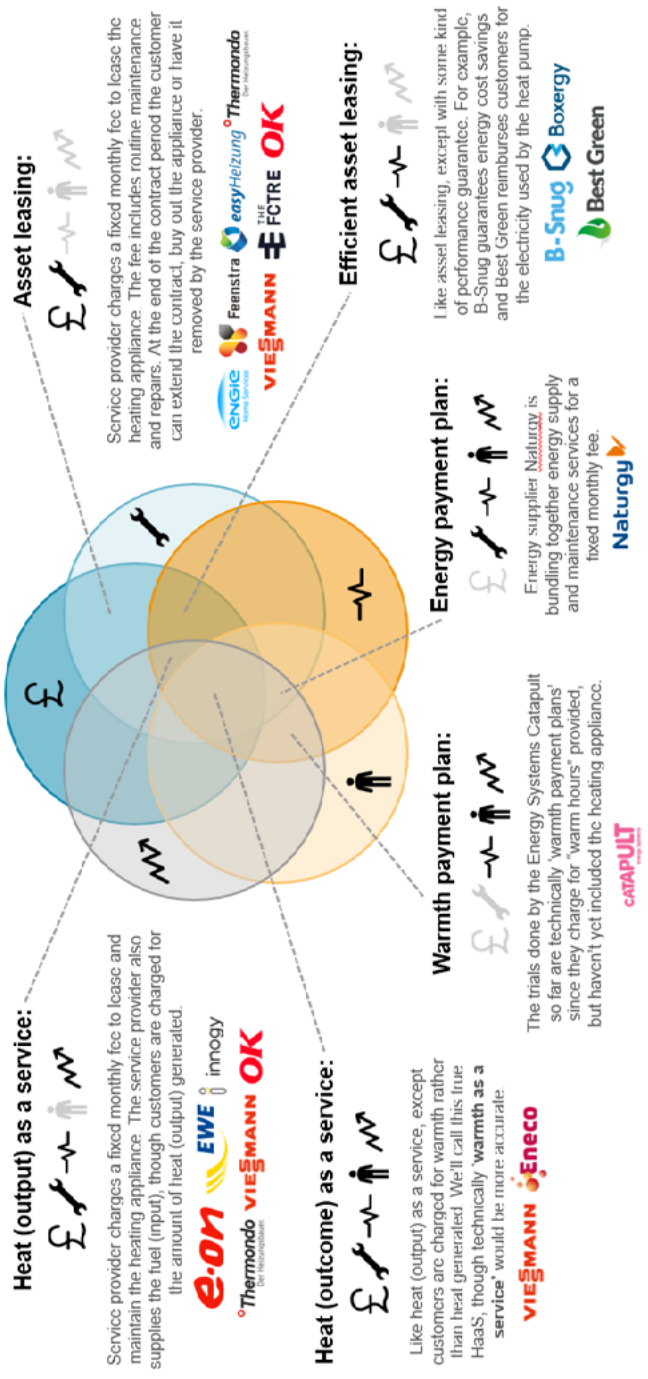

Figure 2: The 'Heat as a Service' landscape. Source: [4].

We highlight examples of three of these models in the case studies below – from specialist service provider The FCTR E in the Netherlands, oil supplier OK in Denmark, and heating manufacturer Viessmann in Germany. (Please note that the use of these examples does not represent an advertisement for any of the companies mentioned, or show any form of endorsement).

CASE STUDY: The FCTR E "e-home" package – Efficient Asset Leasing, moving towards Energy as a Service
Type of provider: Independent service provider
Stage of development: Commercial
Location: Netherlands
Heating appliance: Air-to-water heat pump with water tank and solar PV
Initial target customers: Larger, privately-owned homes (typically 150m^2 or above)
Number of installations: Aiming for 1,000 in 2019

The FCTR E is a Dutch company established in 2016. It replaces gas heating with a package of electric technologies for a fixed monthly fee, at no upfront cost.

The FCTR E could ultimately offer relatively low-risk 'Energy as a Service'. With its customers needing little to no residual electricity* from the grid (as the solar PV is sized to match the heat pump's expected needs), the FCTR E has limited electricity price risks, so user behaviour risks are less of a concern. If it can include electricity supply at a fixed fee as planned, it will be an example of true Energy as a Service.

Key details:

FCTR E e-home package	
Price:	Fixed monthly fee, typically ~€250, properly dependent. No upfront cost.
Contract:	1 year, automatically renewed unless cancelled more than 3 months before contract ends. On cancellation, customers can: ▪ Pay the residual value to purchase the equipment; ▪ Pay for the equipment to be removed; ▪ Transfer the contract free of charge.
Includes:	1) Design and installation of "e-home" system, including a NIBE heat pump, water tank, solar PV (optional) and smart controls. 2) Routine maintenance and repairs.
Savings:	Total cost ~25% less than current energy bill (not guaranteed).

The average system equipment costs ~€35k. This is financed by banks and the company founders.

Contracts are calculated based on a 15 year equipment lifespan, but are **effectively indefinite.**

EV charging and battery storage options are also available.

Residual electricity supply is not currently included, but the FCTR E is planning to white label electricity supply in 2019/20 to meet customer demand. **

The FCTR E is looking into **additional services** it can provide, such as home energy management and grid services.

* Residual electricity means the additional electricity required from the grid, on top of that produced by onsite PV.
** White labelling is where the service supplier has an agreement with another company e.g. the electricity supplier, to sell electricity on its behalf. In this case, the service supplier (The FCTR E) would buy electricity from the electricity supplier and sell it on to the end-user – so the end-user relationship remains with the service supplier.

CASE STUDY: OK – Leasing and Heat (output) as a Service
Type of provider: Oil supplier
Stage of development: Commercial
Location: Denmark
Heating appliance: Air-to-water heat pump
Initial target customers: Privately-owned homes; often those currently using oil for heating
Number of installations: 500/year for leasing model (launched in 2012), 200/year for Heat as a Service model (launched in 2017).

OK offers heat pump leasing and subscription packages, including energy supply for a fixed monthly fee (revised annually based on heat use) and a complete end-to-end service for heat pumps including the design, planning and installation of heat pumps. Customers are offered the options to:

- Buy the heat pump upfront, for a cost of around 100k-120k DKK;
- Lease the heat pump from OK
- Get the heat pump on a subscription service that includes energy supply.

Key details:

	Heat pump leasing	Heat pump subscription
Price:	▪ Upfront fee of DKK 25,000 or DKK 50,000 for installation. ▪ Monthly rental fee from DKK 995, depending on contract length and heat pump capacity.	▪ Upfront fee of DKK 20,000 for installation. ▪ Fixed monthly usage fee for kWh heat consumed, around 2,000 DKK.
Contract:	Flexible contract period, up to 10 years.	15 years. Contract can be transferred to a new owner if moving house, or customers can buy themselves out by paying the residual value of the heat pump.
Includes:	1) Installation of a heat pump. 2) Routine maintenance and repairs.	1) Installation of a Vølund or Vaillant air source heat pump. 2) Routine maintenance and repairs. 3) Energy supply for the heat pump.
Savings:	Can be calculated.	Can be calculated.

The leasing model has been popular, particularly for distress purchases.

The monthly usage fee is **revised annually** based on actual heat use.

OK has a Heat Pump Calculator that shows customers the cost to buy and operate a heat pump, and the energy cost savings over 15 and 20 years (including a 30% discount on electricity prices that customers can apply for).

CASE STUDY: Viessmann –Heat (output) as a Service
Type of provider: Heating manufacturer
Stage of development: Commercial
Location: Germany
Heating appliance: Gas boiler
Initial target customers: Privately owned homes, and private landlords
Number of installations: Offer launched in late 2019; trial of 200 homes already completed.

Viessmann's Heat Fix package is the first commercial offering taking on all five 'risks' by offering a fixed price for energy, albeit with gas boilers rather than low carbon alternatives. As part of Viessmann's aim to realign itself as an "integrated solutions provider for the entire living space", the company has launched three new heat packages in Germany:

- Heat Basic: gas boiler and maintenance for a fixed monthly price (asset leasing);
- Heat Flex: Heat Basic + gas supply with variable billing;
- Heat Fix: Heat Basic + gas supply for a fixed monthly price (Heat (output) as a Service).

Key details:

Viessmann Heat Fix	
Price:	No upfront cost; fixed monthly base price for appliance and maintenance; fixed monthly price for gas consumption.
Contract:	10 years, automatically extended for a further 5 years unless customer gives notice. If notice is given, the customer can: ▪ Pay the residual value to buy the appliance; ▪ Have it removed; or ▪ The contract can be transferred to a new property owner/tenant
Includes:	1) Installation of new gas boiler. 2) Routine maintenance and repairs, including chimney sweep costs, and replacement if necessary 3) Gas supply.
Savings:	Example shows lifetime cost savings of 30%.

The fixed monthly price is calculated on a **case-by-case basis** by the installer at the start of the contract. Changes in consumption are likely accounted for in annual price adjustments.

Installation services are delivered through Viessmann's strong network of **independent installers**, who also handle the subsequent maintenance work. This way installers earn the same for installation and maintenance as they would normally.

Installers find they can also achieve higher conversion rates by offering the heat packages as financing options.

Viessmann sources gas from both local and national energy suppliers, enabling it to get the **best gas prices**.

3. Will 'Heat as a Service' offerings engage end-users and fulfil their potential in driving the growth of low carbon heating such as heat pumps?

Experience from the market and feedback from customer research indicates a strong potential role for 'Heat as a Service' in driving decarbonisation in existing buildings – though there are barriers to implementation to overcome, and considerations to be made regarding how to manage the risk(s) borne by the provider.

Offerings currently being trialled and commercialised show generally positive responses from participants (with no known cases where a customer has asked to end the contract early). But the numbers of customers currently using Heat as a Service-type offerings across Europe is in the low 1,000s, compared with the tens of millions of customers across Europe who have bought heating systems upfront.

Delta-EE has carried out primary customer research across ~800 end-users in the UK, France, Germany, Italy and the Netherlands [5], who currently do not have such a service, assessing their attitudes to different heat propositions (Figure 3). This research shows that, while the majority still prefer the traditional payment upfront option, around 30% of all participants stated that they would be likely to take up a 'Heat as a Service' proposition if available, and this proportion increases with younger participants (to closer to 50%). This is a positive indication of the potential attractiveness of such models – and their growth potential.

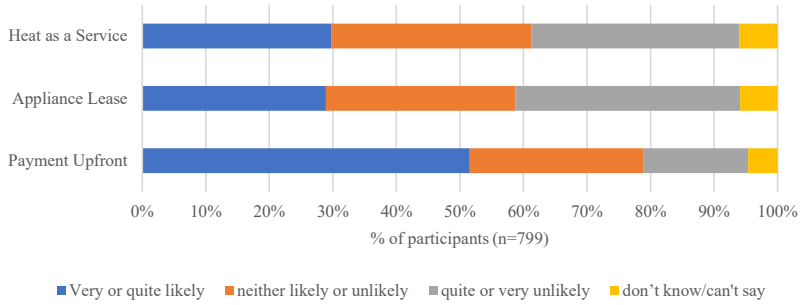

Figure 3: How likely would you be to take up one of the following propositions if it was available to you?

Source: [5]. Based on a sample of 799 domestic customers in the UK, France, Germany, Italy and the Netherlands. (Survey restricted to those who own their home outright or with a mortgage, and make decisions jointly or solely about the heating system in the household).

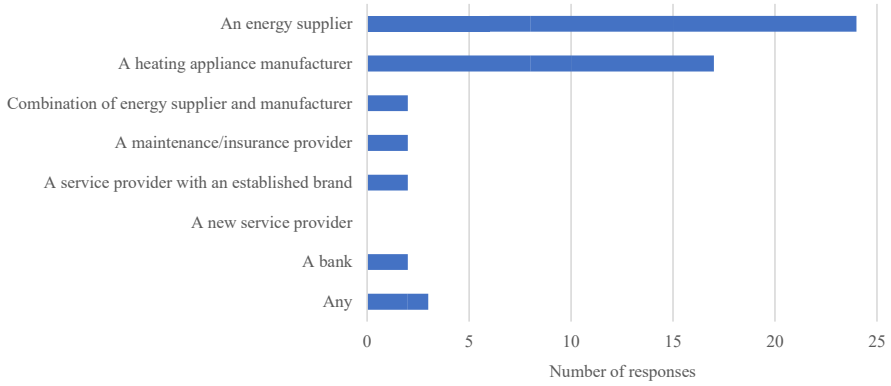
To develop a more detailed view of the optimal proposition designs, Delta-EE carried out Focus Groups with participants in the UK, the results of which are highlighted in Table 1 below. Ultimately, a flexible approach to proposition design is necessary, to meet the widest range of customer needs and expectations. But the research indicates that key pillars of the proposition should - ideally – be:

- a heat contract length of under 5 years
- offer bundled with maintenance and repairs plus an energy supply contract
- and guaranteed running cost savings, or lowest tariff guarantee.

Table 1. High level results from Delta-EE Focus Groups exploring proposition design

What participants liked in a proposition	What participants did not like in a proposition
• Having maintenance and insurance included in the monthly fees	• Long contract periods – over 5 years is not appealing to many customers
• Bundling in other services/solutions like solar panels or insulation	• Being tied into an energy supply contract so it could be difficult to switch energy supplier
• Paying a fixed monthly fee for energy/heat	• Paying extra to use heating outside of pre-set hours

Source: [6]. Based on focus groups with 38 domestic customers in the UK (all home-owners).



4. What does Heat as a Service mean for the heat pump industry?

'Heat as a Service' shows promise as an enabler of growth for low carbon technologies like heat pumps in the existing building market, for the following reasons:

- The concept is already well-proven: many have been commercialised for a number of years, and trials are yielding further insights into the ideal proposition designs.
- Such service models can overcome some key end-user barriers to uptake of new technologies, such as the relatively high upfront cost compared to the typical heating appliance, and concerns over performance or running cost.
- The concept is appealing to a significant share of end-users, according to our customer research. Awareness of these concepts is currently low (due to the limited number of commercial offerings available today in each country), so familiarity is also low. It is conceivable that as familiarity with these offerings rises, the appeal could also grow.

'Heat as a Service' offers a new opportunity for manufacturers, either as equipment suppliers to a service provider, or as a service provider themselves. While the majority of offerings on the market today are from energy suppliers (and specialist start ups), Delta-EE's focus groups research indicate that a heating manufacturer could be an appealing provider, along with energy suppliers (Figure 4).

Figure 4: Who would you choose to purchase a 'Heat as a Service' type package from?

Source: [6]. Based on focus groups with 38 domestic customers in the UK (all home-owners).

5. Recommendations & Conclusions

There is a huge opportunity for innovative 'Heat as a Service' models to enable real growth in the heat pump market – particularly in retrofit, where heat pumps generally still struggle to compete. To capture this opportunity, the heat pump industry can prepare by, for example:

- Identifying a 'Heat as a Service' provider to supply – potentially taking part in trials. This would provide manufacturers with additional equipment sales, and could potentially offer additional opportunities to installation & maintenance partners.
- Considering the product functionalities which will best meet the service providers needs - e.g. connectivity, interoperability of the heat pump and other appliances/controls in the home, minimising maintenance requirements and costs, and providing remote diagnostics. Focussing on these aspects could provide heat pump manufacturers & suppliers with a competitive edge over rivals, in securing equipment supply contracts with service providers.
- Making a strategic decision to become the organisation offering Heat as a Service-type offerings - providing a service to end-users, rather than shifting boxes. This will likely require action on some or all of: identifying partners; strengthening installation and maintenance networks and supply chains; arranging necessary financing and developing customer-facing

tools like billing and support. While this option requires the most effort (and involves the most risk) it also has the potential to bring the highest rewards (through providing the most opportunities for revenue generation, and strengthened brand positioning).

The implementation of 'Heat as a Service' models could be a critical step in unlocking parts of the extensive European domestic retrofit heat pump market to heat pumps, because it would overcome some of the biggest end-user barriers for heat pumps – high upfront cost, risk of high running costs, and lack of trust in the technology. The concept is well-proven, and is gaining ground in the domestic heat pump market, with several large players engaging. We expect this type of model to become much more widespread in the future heating market – and heat pumps can be one of the key beneficiaries.

Electrification of heat and decarbonisation of the electricity system: Sector coupling is creating opportunities for heat pumps

Cate Lyon [a*], Lindsay Sugden [a]

[a]Delta-EE Ltd, Argyle House, 3 Lady Lawson Street, Edinburgh, EH3 9DR, UK

Abstract

As the electricity sector decarbonises, the need for energy system flexibility is rising – and electric heating and cooling have a role to play in providing this flexibility. The flexible operation of residential electric heating and cooling products – including heat pumps – is beginning to move from trial stage to commercial reality in some European markets, potentially creating value for customers, networks and energy suppliers. Where are the opportunities today, how will these change in the future, and how can the heat pump industry be part of a future world of flexible energy? The authors present their latest research into the emerging opportunities and business models for heat pumps arising from 'sector coupling', home energy management, and demand-side response.

Keywords: heat pump; Europe; sector coupling; decarbonisation; flexibility; home energy management; demand-side response; business models; opportunities; customers; networks; energy suppliers; aggregators.

1. Introduction

As the electricity sector in Europe decarbonises, the need for energy system flexibility is rising, due to the greater share of electricity coming from intermittent renewable sources such as solar PV or wind generation (versus traditional, dispatchable fossil-fuel based generation). Smarter control of the level and timing of demand-side electrical loads (so-called demand-side response) can provide an important source of this flexibility, and one which can also generate value for a number of players in the energy system.

At the same time, the penetration of electrically-driven heating and cooling in homes and businesses in Europe is also increasing, driven by: a desire for forms of heating that are more efficient and lower carbon than traditional forms using fossil fuels; rising average summer temperatures; and increasing consumer expectations on year-round thermal comfort in buildings.

This convergence of the heating and electricity sectors in Europe (so-called 'sector coupling') – and the growing need for energy system flexibility – therefore presents an opportunity for heat pumps in Europe to become a more attractive technology to end-users, energy suppliers, aggregators, network operators, governments and other players, through their role in providing demand-side response. The flexible operation of residential electric heating and cooling products – including heat pumps – is beginning to move from trial stage to commercial reality in some European markets today.

However, as this is a space which is still in development, there are challenges associated with understanding the exact nature and timing of the opportunity, and the associated developments needed to realise it. It is therefore pertinent for those involved in the design, development, manufacture and sale of heat pumps (and related components & services) to understand where these opportunities are today in Europe, how they might change in the future, and what role heat pumps can play in a future world of flexible energy, in order to make the right strategic decisions for their businesses.

Delta-EE here presents its latest research into the emerging opportunities and business models for heat pumps arising from 'sector coupling', home energy management, and demand-side response in Europe.

2. Heat pumps and other HVAC loads represent an important potential source of flexibility

2.1 There is a growing need for energy system flexibility in Europe, leading to greater consideration of the potential for demand-side response

As the electricity sector in Europe decarbonises, the need for energy system flexibility is rising, due to the greater share of electricity coming from intermittent renewable sources such as solar PV or wind generation (versus traditional, dispatchable fossil-fuel based generation). This flexibility could be provided by various means, including additional dispatchable generation or electricity storage solutions.

Smarter control of the level and timing of demand-side electrical loads (so-called demand-side response) can also provide an important source of this flexibility, and one which can generate value for several different players in the energy system – plus end-users.

2.2 Heat pumps and other electric HVAC loads could provide many GWs of energy system flexibility – if appropriately connected

Delta-EE estimates that within Europe in 2019, the installed base of electrical heating, cooling and hot water appliances within residential properties represents over 220GW of installed capacity (table 1). We also estimate that the expected replacement of older electric HVAC appliances – or installation of new appliances – within Europe will likely represent 10's of GWs of 'new' capacity in the next five years, in the markets studied [1].

Table 1. Electrical heating, cooling and hot water loads in Europe in residential properties in 2019. An estimate of installed capacity, % of installed based with connectivity enabled, and potential for flexibility of timing of use. (Markets considered: UK, Germany, France, Italy, Norway, Sweden, Denmark and Finland).

	Space Heating	Hot Water
Capacity of installed base (GW)	110	110
% of installed base with connectivity enabled	<1%	<1%
Potential for flexibility of timing of electricity demand (qualitative)	Low to medium	Medium to high

Space heating loads – including heat pumps – offer low to medium potential to be flexible with regards to the timing of electricity demand. This can be increased by the provision of additional thermal storage, and/or smarter control regimes.

In order to be used to provide demand-side response to the wider energy system, it is necessary for an electricity-using appliance (such as a heat pump) to have the ability to receive signals from an external source which can influence the operation of the appliance (e.g. turn off, turn on, modulate power usage up or down). Delta-EE estimates that today, a very low percentage of the installed base of heat pumps in Europe (<1%) has the necessary connectivity installed - and enabled - in order to allow them to be used for demand-side response. However as new appliances are installed and sold, we expect that this percentage will rise, as it is easier for new appliances to be sold with the necessary equipment and control protocols already installed (preventing the need for costly retrofitting). We also expect to see a growing number of commercial offerings to residential customers emerging in the coming years, which will increase the user awareness and acceptance of such models.

3. How this flexibility can create value for energy system players, and end-users

3.1 There are several potential sources of value from sector coupling

Transmission system operators (TSOs), distribution system operators (DSOs) and electricity suppliers all benefit from having flexibility in the energy system. The value to these players of demand-side flexibility (demand-side response) includes the opportunity to avoid costs, or to generate revenue (figure 1).

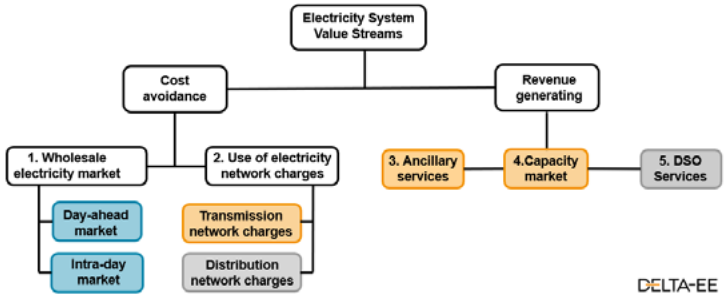

Fig. 1. Value streams typically available in European countries from demand-side response [2].

Demand-side flexibility can help market players to avoid costs by improving their trading in the wholesale electricity market, and/or avoiding charges arising from the use of the electricity networks.

- **Wholesale electricity market:** the majority of electricity on the wholesale market is traded by generators, suppliers and traders, on the day-ahead and intra-day markets. In the day-ahead market, trading takes place one day ahead of when the electricity will be delivered. The intra-day market is used by market members to fine-tune their market positions and account for any unforeseen circumstances which occurred once the day-ahead market has closed. Energy market players can choose to use demand-side flexibility to reduce the costs associated with this trading, by – for example – shifting the time of electricity use by their customers into a time period when it is cheaper for them to generate or purchase that electricity.
- **Electricity network charges**: are fees charged to network users (e.g. end customers) to recover costs associated with building, operating and maintaining the electricity transmission and distribution systems. The fees are related to the volume of electricity consumed, the connection capacity, or the timing of the electricity consumption (with higher charges often associated with periods of peak demand on the networks). Energy market players can use demand-side flexibility to reduce these charges – especially where the flexibility can be used to shift consumption into times of lower demand on the networks.

Alternatively, demand-side flexibility can be used to generate revenue from ancillary services payments, capacity market payments, or providing services to distribution system operators (DSOs).

- **Ancillary services payments:** are payments made by the Transmission System Operator to energy market players on the agreement the player provides services which maintain the proper function of the electricity system, by helping to maintain grid frequency, or enable the efficient handling of imbalances or congestion. Traditionally, these payments have been awarded to energy market players who can turn on or turn up electricity generation assets in order to provide the necessary services. However, in an increasing number of markets in Europe, these payments can now be awarded to players who can provide the necessary services via demand-side flexibility.
- **Capacity market payments**: are market subsidies paid to owners of electricity generation assets to ensure they can provide electricity generation to meet peak demands. As with ancillary services payments, an increasing number of European markets are allowing energy market players to use demand-side flexibility to bid to provide this service.
- **DSO services**: some distribution system operators (DSOs) are beginning to pay energy market players for demand-side flexibility, where this can help the DSO to avoid costs such as reinforcing their network or paying for constraint management.

Heat pumps can – in theory – be used to access all these value streams. In reality, the opportunity to access them is dependent on several factors in each European market, including:

- Minimum load size needed to access each stream (residential heat pumps will normally need to be aggregated into a larger portfolio of assets than individual appliances)
- Whether regulations permit the value stream to be accessed by residential loads in that country

- The penetration of smart meters, which are often a key enabler of residential demand-side response offerings.

In addition to the above value streams, heat pumps can also be used to provide value to end-users by optimizing heat pump operation within the building itself - e.g. by improving the self-consumption of electricity and/or integrating with other loads within a building. This can be done either using intelligence within the heat pump itself, intelligence off-site (within a cloud computing service) or intelligence within a home energy management unit – or a combination of several of these.

We have illustrated these potential uses for heat pumps (and other electrical heating and cooling loads) within a residential property in figure 2.

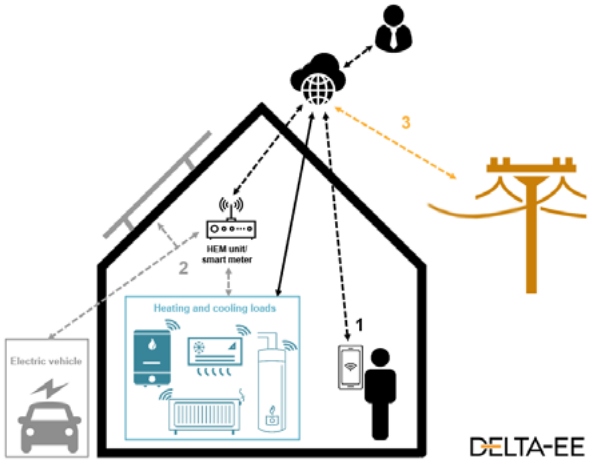

Fig. 2. Illustration of different uses for connected heat pumps (and other electrically-driven heating and cooling loads). 1: connected individual appliance providing greater control & visibility to end-user. 2: integration with other loads, at building level, for optimizing self-generated electricity. 3: providing services to the wider energy system (demand-side response).

3.2 Over time, more value streams are expected to become accessible, in more European markets

Delta-EE has surveyed a number of major European energy markets, using a mixture of desk-based research, and conversations with relevant industry experts and players. Delta-EE has found that today in Europe, the number of demand-side response value streams which are open to residential loads – including heat pumps – varies by country (table 2).

Based on our observations, and conversations with industry experts, Delta-EE expects that in the coming years, more markets within Europe will open an increasing number of value streams to residential loads, driven by increasingly favourable policy and improving regulation. This will open up a growing commercial opportunity for players in the energy market to use aggregated fleets of residential heat pumps for demand response.

Table 2. Number of demand-side response value streams which can be accessed by residential loads in selected European markets in 2019. (Excludes improved self-consumption within one residential property). [1].

3.3 End-users can gain value from sector coupling in a number of ways

In-home optimization of the heat pump operation can bring value to the end-user (as above) via improving self-consumption of electricity, and/or integrating with other building loads. In addition to this, the end-user of a heat pump (or other HVAC appliance) can also benefit from the appliance being used for demand-side response.

Depending on the value stream(s) being accessed and the business model used, companies wishing to influence heat pump operation in order to provide demand-side response may choose to offer one or several of the following financial benefits to the heat pump end-user:

- Access to a lower-cost electricity tariff
- Access to a time-of-use electricity tariff, where the cost of electricity (price per kWh) varies by time. These can be fixed time periods within each 24yr period (static time-of-use tariff) or variable (dynamic time-of-use tariff). Time of use tariffs allow the heat pump end-user the opportunity to change their times of electricity consumption, in order to lower their electricity bills.
- Some companies offer an additional service whereby they will provide an optimization service to the end-user, automatically shifting the heat pump operating times into periods of lower cost electricity (where possible without affecting user comfort).
- A small number of companies will reward end-users with a financial payment for allowing their heat pump to be used for demand response, either in the form of a direct payment, or a discount on their energy bill.

As well as financial rewards, companies can also choose to reward the end-user of the heat pump through offering non-financial rewards, such as:

- Improved controls, such as via a smartphone app
- Improved visibility of energy usage (energy insights provision) via a smartphone app, or website
- Optimising the heat pump to run at the times of lowest electricity carbon dioxide intensity, thereby helping to reduce the end-user's 'carbon footprint'
- The positive emotional benefit from explaining that their heating appliance is helping to decarbonize Europe's electricity supply, by helping to accommodate more renewable sources of electricity.

4. Commercial examples and learnings from using heat pumps in Europe to provide demand-side response

4.1 Commercial examples already exist in Europe, and more are likely to emerge in the coming years

Our review of the European market has revealed several commercial offerings in Europe which use residential heat pumps to provide demand-side response, generating value for the company providing the offering, and also financial and/or non-financial rewards to the end-user. The key metrics are provided in table 3, and the following sections give three commercial examples available in Europe today. (Please note that the

use of these examples does not represent an advertisement for any of the companies mentioned, or show any form of endorsement).

Table 3. A summary of commercial offerings using residential heat pumps for demand response in Europe in 2019. There are numerous further projects which are in pre-commercial or trial stage; information for these is not presented here. [3].

Metric:	
Number of fully commercial offerings with heat pumps as the main asset:	7 offerings
Number of countries:	5 countries
Number of assets being steered for demand-side response (majority of which are heat pumps):	>20,000 assets
MWs of capacity provided by these assets:	>160MW

4.2 Commercial examples 1 & 2: Time of use tariff optimization in Sweden & Austria

In 2017, the Swedish government passed a law requiring energy suppliers to offer half-hourly electricity tariffs (with prices tied to market spot prices). A similar law has now been passed in Denmark. This has given rise to heat pump manufacturers such as NIBE and IVT (Bosch) introducing a service whereby the heat pump can automatically respond to price signals and generate heat to store when it is cheapest to do so. Customer savings are in the range of 5-10% on the variable part of their electricity bill. While this may have minimal impact in the Nordic countries, where wholesale prices are relatively stable, in countries such as Germany and the UK, where wholesale prices are more variable, the saving could be much greater. A dynamic time of use tariff for residential customers was recently launched in the UK, from supplier Octopus Energy.

In Austria, an energy supplier called aWATTar offers hourly time-of-use electricity tariffs to residential end-users. The company also offers end-users an additional hardware and software package which can automatically shift their heat pump operating hours into lower-priced hours, where this is possible without reducing their comfort. End-users pay a fee of around €149 for this additional package, and the company claims it will reduce the end-user's yearly energy bills by around 10%, through this load-shifting

4.3 Commercial example 3: heat pumps for ancillary services in Switzerland.

In Switzerland, company TIKO gains revenue from the ancillary services market. It controls the operation of a fleet of residential heat pumps throughout the country to provide grid balancing services to the Swiss electricity network. The offer to the end-user is reduced-price access to a smart phone app, which allows them to remotely adjust their preferred heating times, view their heat pump's energy consumption and performance, and alert them to possible faults.

5. Further development of several enabling factors would help the heat pump industry fully realise the opportunity across Europe provided by sector coupling

Our research has shown that only a small share of today's installed base of heat pumps in Europe is being used for demand-side response. There remains an - as yet - largely untapped potential for residential heat pumps to be used for sector coupling, allowing such appliances to be fully part of a future world of flexible, low carbon energy.

The further development of a number of enabling factors would help to increase the number of commercial offerings available, including (but not limited to):

- Greater wholesale & retail energy price variation
- Increased value from electricity system revenue streams, in order to mitigate the associated costs of aggregating and managing the assets
- Regulatory frameworks allowing residential assets to be (more easily and more commonly) used to provide demand-side response
- Reduced cost of associated hardware (including cost of retrofitting, where applied to an existing installed heat pump)
- Greater standardization of communications protocols among devices
- More use of real load profiles by energy suppliers to settle residential customer electricity bills

- More wide-spread use of home energy management systems, to control and optimize electricity loads within residential buildings

Creating a compelling proposition for the end-user was voted as being the most important area for development, in a poll of energy & heating industry professionals conducted by Delta-EE (figure 3).

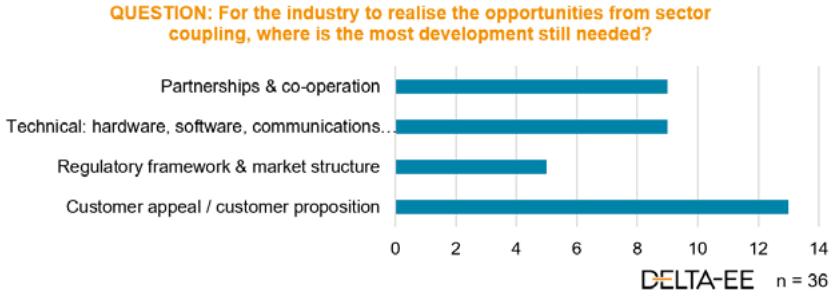

Fig. 3. Results of a poll among energy & heating industry experts by Delta-EE in September 2019. Respondents could select one of the four possible options shown.

Abstract

This paper describes the design and experimental analysis of a steam producing industrial heat pump system. The heat pump is a two-stage flooded system with a thermal capacity of 150 kW_{out}, capable of producing medium pressure steam (4.8 bar_{abs}, 150°C) with up to 90°C temperature lifts. The heat pump takes up heat at two distinct temperature levels and in this way can take advantage of temperature glides, typical of waste heat streams in industrial processes. It has been tested with a single working fluid, namely the hydrocarbon Pentane. The heat pump is tested using a specially designed test rig, capable of simulating conditions typical of numerous industrial processes. Experimental results are presented for various operational conditions (temperatures, powers) using both the single-stage and dual-stage cycle. The heat pump is shown to be capable of producing steam temperatures at the design point of 150°C. The results demonstrate that steam producing heat pumps are a feasible technology option for industrial applications. There are however steps needed for mass uptake, especially related to upscaling powers to the 1-5 MW range.

1. Introduction

The European Union and its 28 member states (EU28) have set the ambitious target of reducing greenhouse gas (GHG) emissions by 80-95% relative to 1990 levels by 2050. In order to achieve this, there is the requirement to transform the current energy system, primarily by switching to renewable energy sources and implementing energy efficiency measures. This will be particularly relevant for the industrial sector in the coming years, which at present (2018) is responsible for 11,590 PJ or 25% of final energy consumption in EU28 [1].

* Corresponding author. Tel.: +31 (0) 6 5000 9632.
E-mail address: andrew.marina@tno.nl.

Industrial energy usage in EU28 is dominated by the demand for thermal energy, which is estimated to be responsible for 73% of total consumption (2012) [2]. The heating demand is at present covered almost entirely by fossil sources, namely natural gas, oil and coal. The remaining energy demand, covered by electricity, is mostly required for mechanical work, for example to drive fans, compressors, pumps and other machinery. Based on this, it can be determined that large reductions in GHG emissions from industry will only be achievable through radical changes in the supply and use of heat, implying the need for significant changes to existing processes. The challenge for industry to transform their heat supply is made greater by the requirement for heat use at different temperature levels, from below 100°C, to well above 1000°C, depending on the given process or sector.

The use of heat pump technology in an industrial setting is an option which has the potential to cover a large share of the low temperature (<200°C) heat supply, estimated to be 45% of total industrial heat demand (incl. space heating) [3]. Heat pumps are a technology which take waste heat, typically discarded to ambient due to the low temperature level, and upgrade this to temperatures required by the process. This is done with the input of electricity. When renewable electricity is used as an input source, the GHG emissions from the process can be reduced to zero. In any case, the electricity input required is less than the original energy input (gas, oil, etc.) to the process, meaning that implementing heat pumps will necessarily lead to reductions in the final energy consumption.

One of the main drivers currently prohibiting heat pumps in industry, is the fact that the majority of commercially available heat pumps are currently limited to supplying process heat up to temperatures of approximately 90°C. There is currently a limited demand for heat in industry up to this temperature level. Increasing the maximum heat supply temperature of heat pumps above 100°C such that they have the capability to produce steam will increase the market potential of the technology significantly. Further increases in the maximum temperature towards 200°C will lead to further application potential, making the technology appropriate for numerous processes particularly in the chemical, paper and food sectors.

Whilst there has recently been increased focus in industrial heat pump technology in both academia and the refrigeration and heat pump sectors, the developing nature of the market ensures that further demonstration of the technology is needed. In the Dutch nationally funded project 'Sustainable sTEam Production for induStry' (STEPS), a pilot scale, steam producing industrial heat pump was designed, constructed and tested. The goals of this development project were as follows:

- To demonstrate that an industrial heat pump, producing steam at temperatures up to 150°C (4.8 bar_{abs}), can be manufactured from components which are currently available in the market
- To identify if there are necessary developments needed from component and equipment manufacturers as well as system suppliers
- To accelerate acceptance and uptake from industrial end-users of heat pump technology

The project was carried out with a consortium of partners consisting of a research institute, equipment manufacturers and system suppliers, as well as industrial end-users of the technology from multiple industrial sub-sectors (paper, chemical, refinery, food and beverage). Of this consortium, the design and construction of the heat pump was realized by refrigeration and heat pump system supplier IBK, whilst testing and subsequent analysis of results was conducted at the industrial heat pump test centre at TNO. This remainder of this paper provides details relating to the design of the heat pump system (section 2) as well as results from testing under representative industrial conditions (section 3).

2. Heat Pump Design

Details relating to the design and technical characteristics of the heat pump are given in this section. Firstly, a description is given on how design conditions for the heat pump were determined and the effect this has on the system requirements. Following this, information is provided on the physical system itself, including the process scheme and component information. Finally, details are provided on the specially designed test rig, which was connected to the heat pump to simulate the conditions that would be imposed on the heat pump by an industrial process.

2.1. Design Conditions

Full scale industrial heat pump systems will be characterised by large thermal powers, typically in the range of 1-5 MW_{out}. With the intention in the project to develop a pilot scale heat pump system, a nominal thermal power of 150 kW_{out} was targeted.

Design conditions for the constructed industrial heat pump were selected based on input received from the multiple industrial end-users involved in the project. The end-users were requested to provide data relating to typical conditions (process and waste heat quantities as well as temperature levels) whereby a heat pump could be applied within their process. On the basis of the information received, the design conditions and requirements of the heat pump were determined.

It was determined that to satisfy the requirements of the multiple end-users, the heat pump should be designed to function with three operational concepts:

1. Single evaporator, single compressor
   The evaporator temperature varies between 52°C and 97°C, whilst the target steam temperature varies between 120°C and 150°C. The use of a single compressor ensures this operation mode is most suitable for low to moderate temperature lifts.
2. Single evaporator, two compressors
   The evaporator temperature varies between 52°C and 97°C, whilst the target steam temperature varies between 120°C and 150°C. The use of two compressors in series ensures this operation mode is most suitable for moderate to high temperature lifts. Furthermore, this cycle implementation provides efficiency (coefficient of performance - COP) enhancement when compared with the single compressor cycle.
3. Two evaporators, two compressors
   The single system operates with two evaporators which have two distinct pressure (temperature) levels. The low temperature evaporator varies between 52°C and 97°C, whilst the high temperature evaporator varies between 97°C and 111°C. The target steam temperature in this case is also in the range of 120°C to 150°C.

Whilst conventional heat pump cycles consist of a single source and sink, the requirements of the end-users have necessitated a multi-temperature heat pump whereby waste heat can be input at two locations. There are two main scenarios whereby a multi-temperature (source) heat pump is advantageous for use in a process:

1. Where multiple waste heat sources are available at differing temperature levels.
2. Where the waste heat source has relatively low energy content, leading to a large temperature glide on the waste heat stream in order to produce the required thermal power on the sink side of the heat pump.

The efficiency of a heat pump cycle, also known as the COP relates the heat output in the condenser to the electrical work input. The theoretical maximum COP that can be achieved is determined by the temperature of the heat sink as well as the temperature lift required to be achieved by the heat pump (see section 2.4). Increasing the temperature lift has a detrimental impact on the maximum achievable COP. By implementing a multi-stage (single evaporator, two compressors) or multi-temperature (two evaporators, two compressors) cycle, the COP is enhanced as the entirety of working fluid in the heat pump cycle does not need to be compressed from lowest temperature (pressure) level to highest temperature (pressure) level, therefore limiting the temperature lift for part of the system. This leads to a lower electrical energy input for a given process heat output.

Whilst multi-temperature heat pumps impose additional complexity on the system design and associated control system for operation, their use is not uncommon. There are numerous cycles which can be used to implement multi-temperature heat pump cycles. A comprehensive review of the various multi-temperature heat pump cycles is given by Arpagaus [4].

2.2. High Level Design

The heat pump construction was based on a previously designed, constructed and tested system, an overview of which can be given in the works of Wemmers et al. [5]. The original heat pump design was based on a single stage system (single evaporator and compressor) and used Butane as the working fluid. To fulfil the requirements of the end-users, a number of modifications had to be made to the unit, namely to convert it to a multi-stage and temperature unit, as well as adapt the system to operate with a new working fluid. The new working fluid was needed as the critical temperature of Butane is 152°C, making it unsuitable to operate at the desired sink temperatures of 150°C in a sub-critical cycle.

Pentane was chosen as the new working fluid in the system for the following reasons:

- It is a natural working medium which has zero ODP and low GWP (~4), adding to the sustainable credibility of the technology
- It has a high critical temperature (197°C) and low boiling point (36°C) relative to the range of design and operation conditions (52°C – 150°C) to be tested
- It has good thermal stability, up to the temperatures of interest

As was the case with the heat pump described in [5], the modified unit was constructed inside a container, which allows it to be easily transported and placed at various industrial sites as needed. Rather than test the heat pump directly at an industrial site, the heat pump was tested on a specifically constructed heat pump test rig, also placed within a container unit. There are a number of benefits to this approach, the most important being:

- Issues and delays associated with start-up and commissioning can be resolved without affecting or interfering with the production process
- The heat pump in the first instance is decoupled from the process, making it much simpler to troubleshoot performance or reliability issues
- The performance of the heat pump can be characterised in a controlled environment for numerous operational conditions

An image of the containers housing the heat pump, as well as the test infrastructure can be seen in Figure 1 which follows. These are provided to give the reader an indication of the physical sizing of the systems.

Fig. 1. Containers which house the heat pump (white container) and test infrastructure (blue container) and associated connections

2.3. Process Flow Diagram

A process flow diagram of the heat pump system is seen in Figure 2. As indicated previously, the heat pump is a two-stage system, which allows heat input at two locations. The heat pump is characterised by the two piston compressors as well as the two separator vessels which feed liquid refrigerant to the evaporators in a thermosiphon type arrangement. Additional notable characteristics of the system are described as follows.

Suction Gas Superheaters

A notable characteristic of the working fluid Pentane is that isentropic compression from a (near) saturated vapor will result in the compressed fluid entering the two phase region. Liquid droplets in the compressor can have a large impact on the longevity of the system and may even lead to complete failure. Two suction gas superheater heat exchangers make use of the high temperature liquid from the condenser and middle pressure (MP) separator vessel, transferring heat to the gas in the compressor suction lines. These heat exchangers move the compressor suction gas sufficiently away from the two-phase region, therefore ensuring a limited amount of superheat in the discharge gas for both compressors.

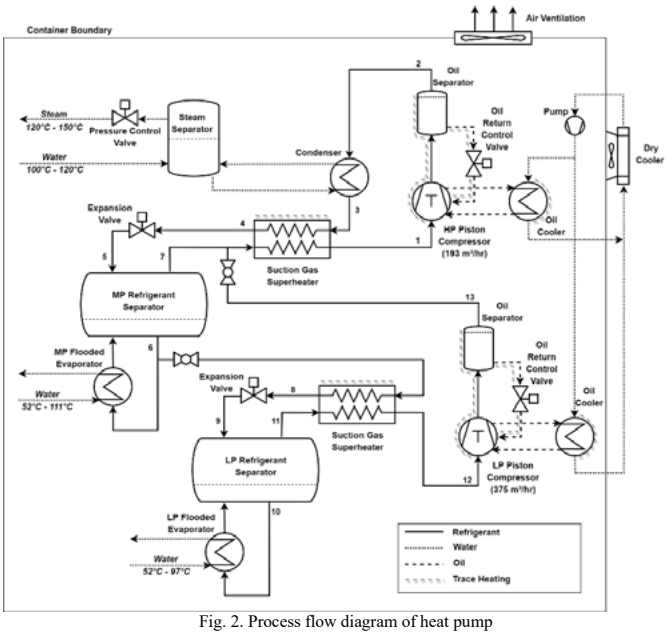

Fig. 2. Process flow diagram of heat pump

Condenser and Steam System

The heat pump utilises a split condenser system (only a single condenser pictured), located parallel to one another. On the water side of the system, the condensers are fed by a steam separator vessel in a thermosiphon type arrangement, with a two phase mixture returned to the vessel from the heat exchanger. The steam separator vessel is fed by the test rig to maintain a fixed liquid level, whilst pressure (and therefore temperature) is controlled by actuating a control valve on the steam return line to the test rig.

Oil Management

Oil discharge from the compressor is separated from the compressor discharge gas in oil separator units. The oil is returned to the compressor through a control valve, which is actuated to limit the return flow rate. Additional oil which manages to pass through the oil separators will make its way to the pentane separators whereby it will accumulate without proper management. Therefore a small amount liquid from the refrigerant separators is entrained intermittently into the suction gas lines, prior to the suction gas superheaters such that it can be evaporated and any residual oil returned to the compressors (feature not pictured in process flow diagram).

In addition to managing the return of oil to the compressors, the high temperatures which characterise this system necessitate external cooling of the oil. This is conducted through two heat exchangers coupled to an external cooling circuit which discards the heat to ambient through use of a dry cooler. The oil is circulated using a pump which is internally located within the compressor housing.

Trace Heating

Trace heating is employed at numerous locations throughout the heat pump, utilised when the heat pump is not in operation. The majority of trace heating in the system is located in the vicinity of the compressor oil system. Trace heating is located on the oil separator and the compressor housing, as well as the lines (both oil and refrigerant) between these components. In addition, trace heating is placed on the oil coolers. The purpose of this trace heating is to prevent refrigerant condensing and mixing with the oil during shut down periods. This can lead to oil foaming on start-up, limiting the oil pressure in the compressor. Trace heating was also placed on both suction gas superheaters to prevent liquid condensing in the suction line when the system is not in operation. Without this trace heating, it is probable that significant amounts of liquid refrigerant would be entrained into the compressor on start-up.

2.4. Theoretical Performance

As indicated in section 2.1, the COP of a heat pump relates the heat output in the condenser to the electrical work input as seen in equation 1. This is valid for both single evaporator and multi-evaporator cycles, in the latter case, the electrical energy from both compressors must be summed.

$$COP = \frac{\dot{Q}_{th-out}}{\dot{W}_{elec-in}} \tag{1}$$

The theoretical maximum COP that can be achieved by a heat pump cycle containing only internally reversible processes is known as the COP_{Carnot} and is defined by the second law of thermodynamics. For a heat pump with a single heat source, the COP_{Carnot} can be simply expressed as a function of the source and sink temperatures, as given in equation 2.

$$COP_{Carnot} = \frac{T_{sink}}{T_{sink} - T_{source}} \tag{2}$$

For a multi-temperature heat pump system, calculation of the COP_{Carnot} becomes non-trivial. The value is dependant not only on temperatures, but also on the fraction of heat input from each evaporator in the system. The equations which define the second law efficiency (COP_{Carnot}) for a multi-temperature heat pump have been defined by Arpagaus [4] and are reproduced in equations 3 to 7 below.

$$COP_{Carnot(LT)} = \frac{T_{sink}}{T_{sink} - T_{source(LT)}} \quad , \quad COP_{Carnot(MT)} = \frac{T_{sink}}{T_{sink} - T_{source(MT)}} \tag{3), (4}$$

$$\beta = \frac{\dot{Q}_{th-in(MT)}}{\dot{Q}_{th-in(MT)} + \dot{Q}_{th-in(LT)}} \quad , \quad \alpha = \frac{\beta}{1-\beta}\frac{COP_{Carnot(LT)} - 1}{COP_{Carnot(MT)} - 1} \tag{5), (6}$$

$$COP_{Carnot(multi-temp)} = \frac{1}{1+\alpha}COP_{Carnot(LT)} + \frac{\alpha}{1+\alpha}COP_{Carnot(MT)} \tag{7}$$

To determine the true efficiency of a heat pump, the COP achieved is related to the thermodynamic maximum through equation 8. For the current project, a η_{Carnot} of 50% was targeted for both single stage and dual stage cycles, which should be feasible for a well designed heat pump system.

$$\eta_{Carnot} = \frac{COP}{COP_{Carnot}} \tag{8}$$

2.5. Component Selection

The system utilises industrial open type piston compressors manufactured by Mayekawa (HP compressor pictured Figure 3). The specifications of these compressors are given in Table 1. Piston compressors were chosen as they match well with the system size requirements (150 kW) and can easily adjust to the differing pressure ratios required for testing. These compressors were able to operate between 900 RPM and 1600 RPM and were lubricated by a polyalkylene glycol (PAG) lubricant with an ISO viscosity grade of 100.

Table 1: Compressor specifications

Component	Type	Swept Volume (cm^3)	Displacement (m^3/hr @ 1450 RPM)
LP Compressor	Mayekawa F8WA	4310	375
HP Compressor	Mayekawa B6HK	2218	193

The heat pump is equipped with numerous sensors to measure physical quantities which combined give the performance of the cycle. The data from the unit is collected at an interval of 1 second using a Siemens SCADA system. There are pressure and temperature sensors at numerous locations, both of which are generally located in each vessel as well as between the major components. Mass (or volume) flows are not measured within the heat pump itself, rather they are calculated from data gathered from the connected test rig (see section 2.7).

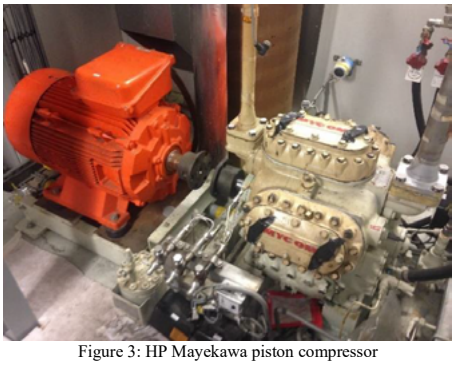

Figure 3: HP Mayekawa piston compressor

2.6. Safety Systems and Measures

The heat pump system inside the container conforms with relevant ATEX requirements. The container is placed in the open air, with the internals ventilated with approximately 2000 m³/hr of fresh air. Pentane detectors in the ventilation ducts will detect leaks at 1400 PPM, roughly 10% of the lower explosive limit.

2.7. Test Rig

A process flow diagram of the test rig used to simulate the industrial process can be seen in Figure 4. The buffer vessel is the central component, with all flows originating from this location. The buffer vessel contains a water steam mixture which is heated in the range of 100°C – 120°C (1 bar_{abs} – 2 bar_{abs}) using an electrical heating element prior start-up. Liquid from this vessel is fed to the steam separator (which subsequently feeds the condenser) as well as the two evaporators. The flow rate for all three circuits are set by a speed controlled pump, whilst the temperatures of the flows to the evaporators can be controlled by recirculating the cooled flows from the exit of the evaporator back to the inlet. The return flows from both the evaporators (liquid) as well as the steam separator (vapor) are returned to the buffer vessel. The heat added to the vessel from the flow from the condenser is greater than that removed from the evaporators, in theory, by the power of the compressors. Therefore, to maintain the temperature of the buffer vessel at a fixed level, it is necessary to remove heat, which is done by condensing steam at the top of the vessel using a simple U tubed heat exchanger. A water glycol mixture is circulated through the heat exchanger with the heat discharged to ambient using a dry cooler. The test rig is equipped with numerous instrumentation (pressure, temperature, flow) to determine the thermal power from the heat pump and fully characterise the process.

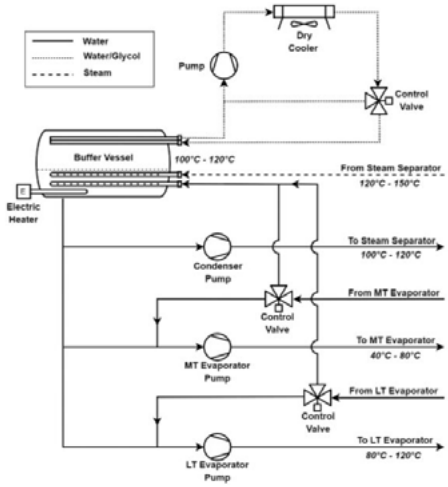

Fig. 4. Process flow diagram of test rig which simulates the industrial process on the heat pump

Figure 5 shows an image of the internals of the test rig system. The buffer vessel is clearly distinguishable in the foreground on the right side of the figure. The connections for the U-tube heat exchanger are located at the top of the vessel, whilst the return lines for the condenser and evaporators are located below. In the background on the left side of the figure, the pumps as well as general flow apparatus (valves, flow meters) are present. After this figure was taken, and prior to testing, the buffer vessel, piping and components were thermally insulated.

Fig. 5. Internals of test rig showing the buffer vessel and ancillary components

3. Experimental Results

This section outlines experimental results obtained from the unit. Firstly, two measurement results (one single stage, one dual stage) are analysed. Following this, a full list of results from the experiments is presented.

3.1. Analysis of Single Stage Results

Single stage results are presented for the heat pump producing steam at 130.6°C from a source heat temperature of 84.9°C cooled to 79.7°C. The measured cycle state points are presented on TS and PH diagrams in Figure 6 and 7 respectively. The numbered points on the diagram make reference to the location in the cycle as seen in Figure 2. Overlaid on the TS diagram is the temperature of the external source and sink to give an indication of the ΔT in the evaporator and condenser heat exchangers. It is noted that the specific entropy information is not relevant to this data.

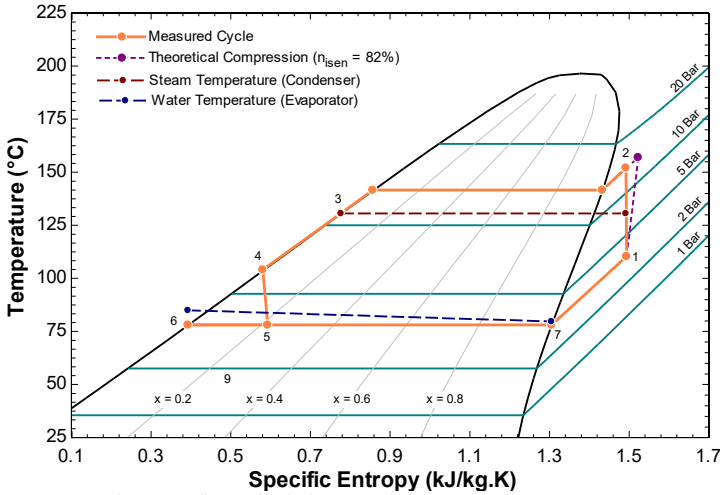

Fig. 6: TS diagram for single stage cycle (T_{steam} = 131°C, T_{source} = 85°C)

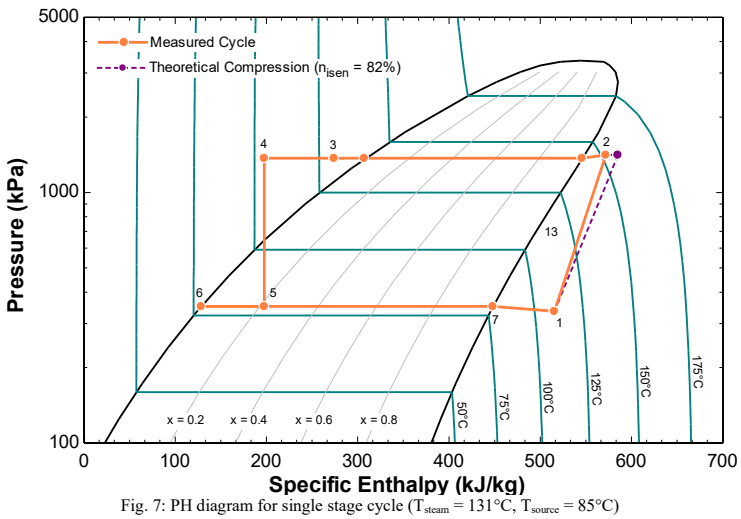

Fig. 7: PH diagram for single stage cycle (T_{steam} = 131°C, T_{source} = 85°C)

The heat pump produced 97.5 kW of heat (steam) with an electrical energy input of 36.3 kW, leading to a COP of 2.69. Based on the maximum/minimum external temperatures of 130.6°C and 79.7°C respectively, the COP_{Carnot} for these conditions is 7.92, leading to a value of η_{Carnot} of 34%. The low efficiency of the system is attributed to three (3) reasons described below with the assistance of the TS and PH diagrams, as well as Figure 8, which presents an energy balance for the cycle.

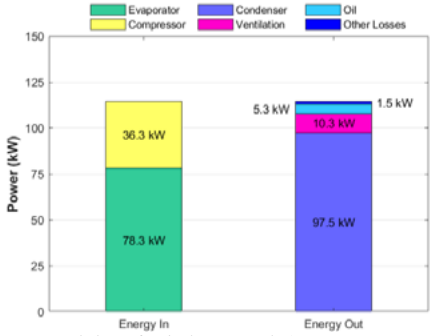

Fig. 8: Energy balance for single stage cycle (T_{steam} = 131°C, T_{source} = 85°C)

1. *Compressor and Electric Motor*

As stated, the measured electrical power to the compressor was 36.3 kW. At the given conditions the compressors should be expected to operate with an isentropic efficiency of 82%. Based on the calculated mass flow for the cycle, the power input is expected to be in the range of 22.2 kW, which obviously varies greatly (10.1 kW) from the measured value. The reason for the large electrical power input is difficult to determine due to the limited sensors which may give a conclusive answer. Likely it is a combination of a lower than expected isentropic efficiency of the compressor, combined with a low electrical motor efficiency, estimated to be in the range of 60%.

2. *Large Temperature Difference in Condenser*

For this experimental condition, the measured condenser temperature was 141.6°C (13.7 bar) whilst the measured evaporator temperature was 78.1°C (3.5 bar). Whilst a small ΔT was measured throughout the evaporator (1.6°C-6.8°C), this was not the case in the condenser (~11°C). The large temperature differences act to increase the work required by the compressor, therefore reducing the total efficiency of the machine.
The large mean temperature difference which acts to reduce the efficiency of the heat pump, has been attributed to air ingress occurring whilst the system is shut down and below atmospheric pressure. This air trapped in the condenser section could not be easily purged.

Thermal Losses

A large amount of heat produced in the system was lost to oil cooling (5.3 kW) as well as the ventilation air (10.3 kW). These thermal losses are visible through inspection of the theoretical compression process overlaid on the measured cycles in Figure 6 and 7. Whilst it would be expected that the theoretical process brings the compressor discharge state closer to the two-phase region than the measured cycle, this is not the case due to the thermal losses which are present. This result emphasizes the case for proper thermal insulation of the heat pump unit and correct selection of the oil temperature when operating at high temperatures. It is noted that a small portion (1.5 kW, 1.3%) of the total heat input could not be accounted for in the energy balance.

3.2. Analysis of Dual Stage Results

The results of the dual stage cycle implementation are presented for the heat pump producing steam at 150.4°C from two heat sources; one cooled from 105.1°C to 102.0°C, and the other from 64.9° to 60.1°C. Once more, the measured cycle state points are presented on TS (source and sink temperatures overlaid) and PH diagrams, seen in Figure 9 and 10 respectively.

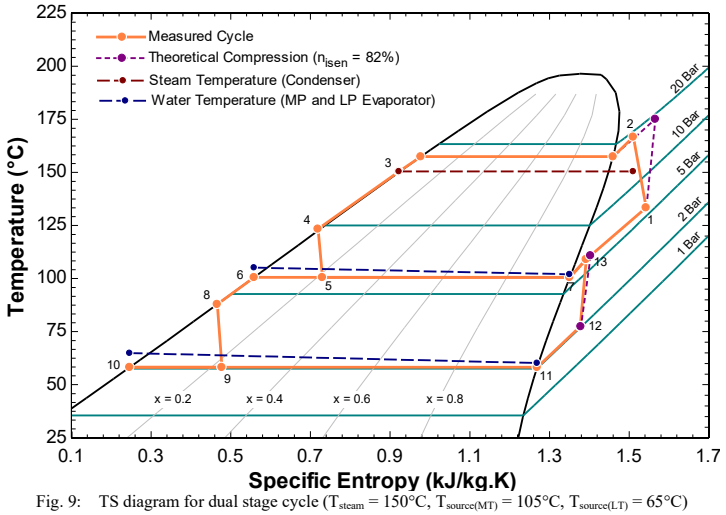

Fig. 9: TS diagram for dual stage cycle (T_{steam} = 150°C, $T_{source(MT)}$ = 105°C, $T_{source(LT)}$ = 65°C)

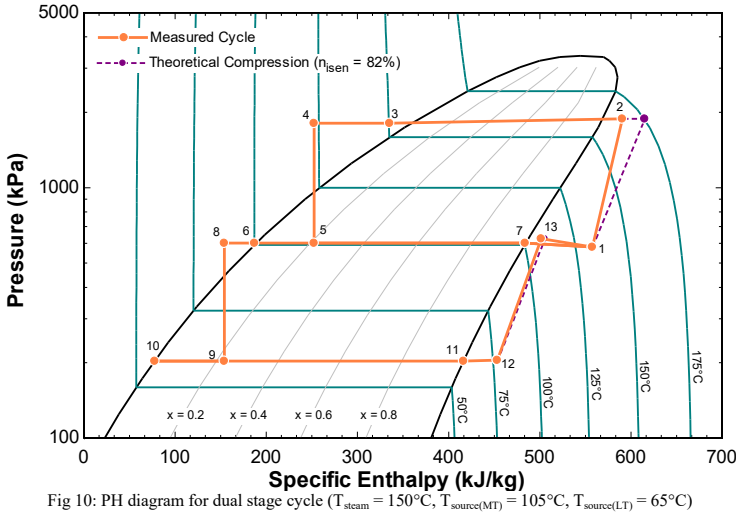

Fig 10: PH diagram for dual stage cycle (T_{steam} = 150°C, $T_{source(MT)}$ = 105°C, $T_{source(LT)}$ = 65°C)

The heat pump produced 144 kW of heat (steam) with an electrical energy input of 63 kW, leading to a COP of 2.06. Utilizing equation (3) through (7), the COP_{Carnot} was calculated to be 5.63 for the dual stage cycle, leading to a η_{Carnot} of 36.5%. Whilst still relatively low, the dual stage cycle performs relatively better than the single stage cycle.

Insights can be gained into the performance of the cycle from the supplied TS and PH diagrams (Figure 9 and 10) as well as the energy balance for the system provided in Figure 11. The theoretical compressor work required for this cycle was 31.2 kW (59% of measured) and 14.3 kW (83% of measured) for the HP and LP compressors respectively. This gives evidence to suggest that the combination of compressor and electrical motor performs better in terms of isentropic and electrical efficiency in the low stage compared to the high stage. Further to this, from the TS and PH diagrams, when viewing the theoretical compression process, it can be seen that for the low stage that the theoretical and actual lines are almost overlapping. This is not the case for the high stage. This indicates that the thermal losses on the low stage are significantly lower than that of the high stage. This could be expected on the basis that the low stage operates at much lower temperature levels than the high stage. These factors, particularly the higher electrical efficiency of the motor, are likely the reason for the slightly higher η_{Carnot} when compared to the single stage cycle. Like the single stage cycle though, thermal losses from the system are still significant, with 12.1 kW lost to the ventilation, 14.0 kW lost to the oil system, and 18 kW being unaccounted for. Similarly, large temperature differences were seen over the condenser, which also increases the internal temperature lift of the heat pump and acts to reduce the COP of the system.

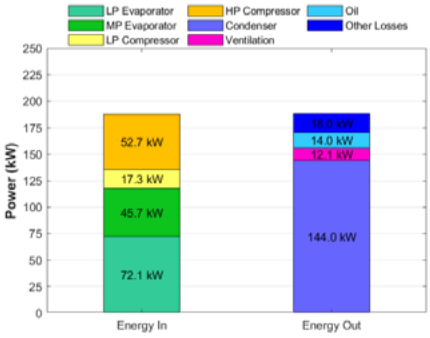

Fig 11: Energy balance for dual stage cycle (T_{steam} = 150°C, $T_{source(MT)}$ = 105°C, $T_{source(LT)}$ = 65°C)

3.3. Summary of Additional Results

A summary of the measurement results from the pilot scale heat pump unit is given in table 2. As was the case with the reference measurements, the system was characterised by low values of η_{Carnot}. Once more, in general, two-stage cycles performed better relative to the single stage cycle.

Table 2: Summary of additional measurement results from the heat pump

LT Evaporator		LP Compressor	MT Evaporator		HP Compressor	Steam Production		Heat Losses		COP	η_{Carnot}
T (°C)	Q̇ (kW)	Ẇ (kW)	T (°C)	Q̇ (kW)	Ẇ (kW)	T (°C)	Q̇ (kW)	Oil (kW)	Air (kW)	(-)	%

4. Conclusions and Future Works

This paper gave an overview of the design and experimental analysis of a pilot scale industrial heat pump, designed with a thermal capacity of 150 kW_{out}, able to produce medium pressure steam of 150°C (4.8 bar_{abs}). The heat pump was able to take up heat at two distinct temperature levels through the use of separate flooded evaporators. Pentane was used as a working fluid, allowing the range of evaporating and condensing

temperatures (52°C – 150°C) required by end-users involved the project to be covered with a single working fluid.

To perform an experimental analysis of the heat pump, it was connected to a specially designed test rig, which contained the necessary instrumentation to determine thermal powers and characterise the process. Results were presented for the heat pump operating with both a single heat input as well as a dual heat input at two distinct temperature levels.

The heat pump was in general characterised by low values of η_{Carnot}, in the range of 32-38%. The low efficiencies were attributed to three factors: combined low electrical efficiency of the electrical motor and isentropic efficiency of the compressor; large temperature differences between fluid streams in the condenser and higher than expected thermal losses. In general, the two-stage cycle showed higher values of η_{Carnot} than the single stage cycle, which was demonstrated to be a result of the lower thermal losses in the low (temperature) stage, combined with a compressor and electrical motor performance which better matched to theoretical values. With the absence of the large temperature differences in the condenser, and use of electrical motors with efficiencies in the range of 90%, it is feasible that values of η_{Carnot} exceeding 50% would be feasible.

Despite the lower than expected efficiencies, the results of the experimental analysis demonstrate that it is indeed possible to build an industrial steam producing heat pump utilising equipment currently available in the market. Using this standard equipment, the heat pump demonstrated a maximum steam temperature of 150°C, corresponding to a saturation pressure of 4.8 $bar_{(abs)}$. The condensing temperature in this case exceeded 157°C suggesting higher steam temperatures should be feasible with a better functioning condenser. Another notable result was a maximum external temperature lift of 90°C, achieved using the dual stage cycle with heat input at an intermediate temperature level.

Further work on this topic will involve attempting to gain clarity on the lower than expected performance of the system, particularly determining the exact reason for the higher than expected electrical energy input for the high pressure compressor. Additionally, the unit will be tested with a synthetic working medium, namely, the non-flammable synthetic R1336mzz(Z). The experiments conducted will focus on other process conditions relevant for end-users not yet tested, as well as characterising the heat pump using a single evaporator combined with two-stage compression. Follow-up projects on compression heat pumps will focus on upscaling the technology to full-scale sizes (1-5 MW) relevant for industrial end-users. The focus will be on achieving heat pump units with low specific investment costs (€200/kW_{th}), giving a higher likelihood of mass uptake in the market.

5. Acknowledgements

The project is partially funded by subsidies of the Topsector Energy from the Ministry of Economic Affairs (EZ) – project number TEEI115010.

Abstract

Since the last 5 years the European heat pump market is showing an accelerated growth of outdoor air source heat pumps. The noise emitted by heat pumps is recognised as a drawback of the technology, especially during non-steady state operation of the heat pump.
Within Annex 51 "Acoustic Signatures of Heat Pumps" of the IEA HPT TCP, a dedicated task is the experimental investigations on acoustic performance of air-to-water heat pumps. The measurements of several laboratories on a unit, according to several operating conditions, on standard conditions (EN 14511), part-load conditions (EN 14825) and ERP (EN 12102-1) are compared. Under some conditions, some frost/defrost cycles occur, and a focus is set on the spectrum and sound level changes that can be observed between these cycles. The paper also presents some data about the acoustic directivity of the unit.

Keywords: acoustic emission; inter-laboratory test; heat pump; acoustic test;

1. Introduction

The primary aim with Annex 51 "Acoustic Signatures of Heat Pumps" of the IEA HPT TCP is to further increase the acceptance of heat pumps for comfort purpose with respect to the noise and vibration emissions.

The overall objective of this collaborative work is to gather the knowledge and expertise of the participants in order to forward this knowledge with dedicated recommendations for low-noise heat pumps to different target groups such as manufacturers, acoustic consultants, installers, standardization bodies and policy makers.

To reach this goal, different reasons to reduce sound emissions depending on countries (regulation), locations and applications have to be gathered and understood. The main influencing factors to the acoustic signature of these units will be identified. Collecting and combining research results in these fields on the different implementation levels (component, unit and application level) will finally lead to directions for improved components, units and control strategies including guidelines, as well as training and inputs to future standards.

The work of Annex 51 is divided into six tasks, from standard and legislation aspects to acoustic behavior of individual heat-pump sources (components) and noise synthesis, noise emission for neighborhood, psychoacoustics, etc. One of these tasks is dedicated to the measurement of the heat-pumps noise levels: water heater, air-to-air and air-to-water heat-pumps.

This paper focuses on the acoustic measurement of a split air-to-water unit circulating in six European laboratories, and running on several operating conditions, leading to different sound power levels which are analyzed and compared. In addition, the unit polar directivity is also measured and the effects on the noise between the defrosting phases and the consequences of frosting on the sound level is addressed.

* François Bessac. Tel.: +33 (0)4 72 44 49 00 *E-mail address:* francois.bessac@cetiat.fr

Regarding the expertise in terms of testing of heat pumps, as Annex 51 gathers experts from the major testing laboratories as well as the convenor of the European standardization committee on acoustics for HP (CEN/TC 113 WG9) and considering the new standard EN 12102-1 which is applied in this project, no specific bibliography was conducted for that task.

It has to be noted that many round robin tests are regularly performed within laboratories for ISO 17025 accreditation but without any public data. The European project ECOTEST, aiming at assessing the reproducibility of the standards used for Ecodesign regulations by means of round-robin tests on different types of heat pumps was conducted exactly at the same time than the Annex 51 task. The results of ECOTEST on the acoustic tests will be considered once publically available, if any relevance for this Annex.

2. Sound power levels of heat-pumps in steady-state conditions

2.1. Program

The EN 12102-1 standard specifies the main rules for implementing an acoustic measurement, especially on the installation aspects of the unit, whatever the operating conditions. A measurement program (cf. Table 1) has been defined for the unit, and each laboratory carried out all or part of this program, with thermodynamic measurements in parallel to the acoustic measurement.

The EN 12102-1 Annex A.4 gives the conditions to determine the sound power level of variable speed units for compliance with Ecodesign and Energy labelling regulations (cf. configuration #5 of Table 1).

Table 1. program of tests with the thermodynamic settings and specific settings for the selected air-to-water heat pump

Nr.	Standard	Condition	Air dry bulb (wet bulb) temperatures (°C)	Water inlet/outlet temperatures (°C)	Setting from manufacturer table	Set temperature	Fan	Mode	Liquid circulator setting

10	EN 14825	E (TOL)	-10(-11)	*/35	15	25	Medium (3 bars)	Heat (Sun)	max.

2.2. Heat-pump under test

A split air-to-water heat-pump was selected as it is representative of a large share of the European market. The unit under test was provided by an European manufacturer: this inverter unit using R410A has a rated heating output of 8 kW according to its label. The outdoor unit size is approx. 800 x 600 x 300 mm.

2.3. Laboratories

This unit circulated in 6 European laboratories, carrying out acoustic and thermodynamic measurements:

- AIT (Wien, Austria),
- CETIAT (Lyon, France),
- DTI (Aarhus, Denmark),
- Fraunhofer ISE (Freiburg im Breisgau, Germany),
- Politechnico Milano (Milan, Italy),
- RISE (Borås, Sweden).

These laboratories implemented the heat pump in different measuring environments, some in a reverberant room, some others in a climatic chamber used as a hard wall room or as a free field room. The measurement

techniques are various, from ISO 3741 in reverberant room and ISO 3743-1 or ISO 3747 (with engineering grade) in hard-wall room (usually a climatic chamber), and ISO 3744 for other environments. They all fulfilled the EN 12102-1 “class A” measurement requirement, which implies ambient conditions to be controlled, and the use of an acoustic standard with at least engineering grade.

One of the laboratories uses a mesh of 55 microphones around and above the unit, allowing directivity measurement.

Several laboratories investigated short time steps acoustic measurements (with less than the 30 seconds average used for standard measurement) to observe the noise variation when frosting and defrosting cycles occur.

Fig. 1. Examples of the heat-pump installation in a test room
(left: reverberant room, right: climatic chamber)

2.4. Inter-comparison results and analysis

Even though the tests results for all the conditions listed in Table 1 can not be presented, it can be said that in most of the cases, the laboratories found similar results. The differences that can occur are acceptable, given the variety of test environment and acoustic test methods. When some larger difference appeared, it was often due to a difficulty of adjusting operating condition rather than an acoustical measurement problem.

The first condition to be tested by 6 laboratories is the standard rating condition, as given in EN 14511 condition (configuration #1) which results are presented in Fig. 2

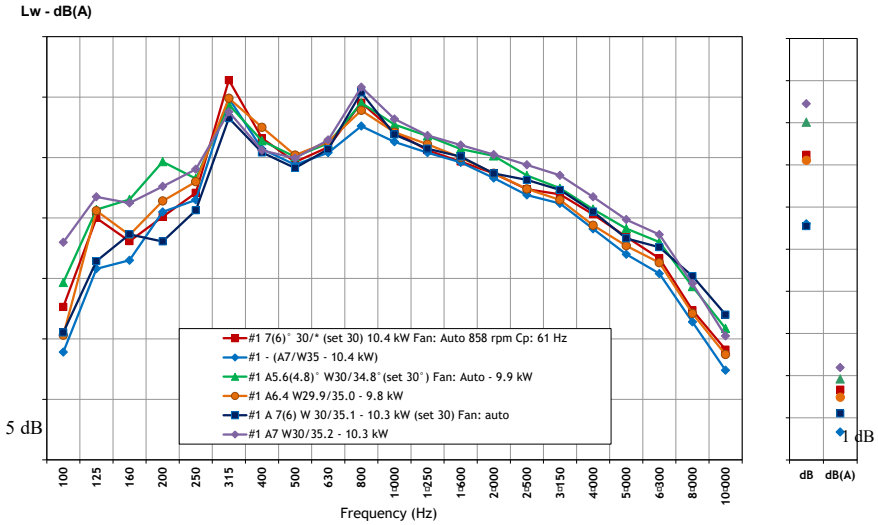

Fig. 2. Spectrum of A-weighted sound power levels for Standard rating conditions EN 14511 (#1) from 6 laboratories

For this operating condition, the spectra are close in the middle range of the spectrum, and the peaks at 315

and 800 Hz are well observed by all laboratories (their origin has not been studied, not being part of this work). As usual, larger differences appear at low frequencies, due to modal behavior of the rooms. The overall dB(A) value remains in a range of 1.4 dB(A). The thermodynamic results are also in a narrow range, from 9.8 to 10.4 kW.

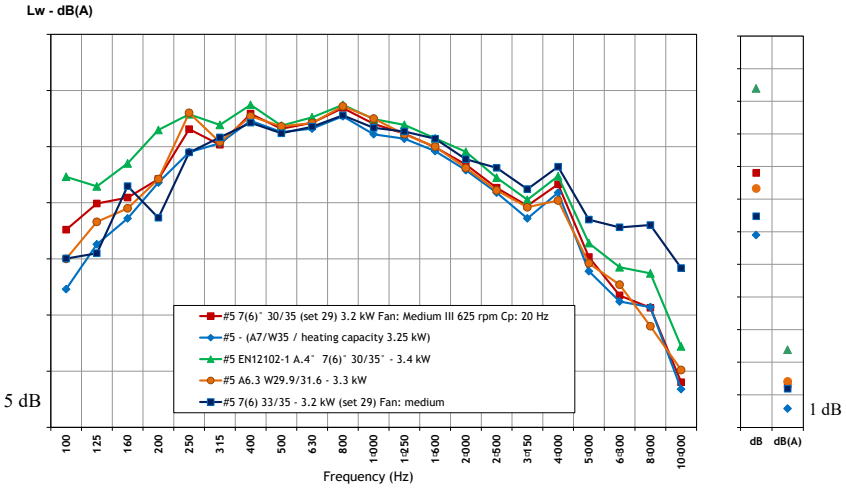

Fig. 3. Spectrum of A-weighted sound power levels for EN 12102-1 7(6)° 30/35° same capacity as for the previous EN 14825 (C) from 5 laboratories

The EN 12102-1 condition requires to set the unit to the same heating capacity as observed for the C point of EN 14825, by reducing the compressor frequency and/or the water temperature difference ΔT if necessary. This procedure is sometimes difficult to achieve as the setting parameters are not reachable, or even though, the requested capacity can not be achieved.

The Fig. 3 shows results from 5 laboratories, leading to convergent results, for the middle range of the spectrum. The low and high frequency ranges exhibit some discrepancies for some laboratories (not investigated in the scope of this study), but the overall dB(A) value remains in a 1.5 dB(A) range. The measured capacity remains in a 0.2 kW range, from 3.2 to 3.4 kW.

2.5. Operating conditions vs sound power levels

The results of one laboratory which measured the rotation speed of compressor and fan are used to show the differences in sound power levels according to the operating conditions.

Different operating conditions lead obviously to variable sound power level and different spectrum shapes. In the present case, the standard rating condition (configuration #1) has a peak at 315 Hz band which disappears for the same condition but with the max frequency setting of compressor and fan. In spite of an average difference of 1.5 to 2.5 dB over the spectrum, the overall value only differs by 0.8 dB(A).

The noise levels for the configuration #6 and configuration #5 are significantly lower, respectively -13 and -10 dB(A) compared to the standard rating conditions (#1).

The noise is more linked to the rotation speeds of the compressor and the fan, than to the heating capacity of the unit, for which no linear relationship can be found for all the laboratories. Fig. 4 shows that configuration #5 is louder by 2.8 dB(A) than #6, due to the higher fan rotation speed (625 vs 558 rpm), despite a lower capacity. Although the two configurations have the same fan rotation speed, configuration #3 is louder by 1 dB(A) than #7, because compressor rotation frequency is 81 Hz instead of 34 Hz.

For all laboratories, configuration #3 (EN 14551 at maximum frequency) gives the highest observed sound power level from all configurations. The negative outdoor air temperature conditions lead to a sound level very close value to the value obtained with configuration #3. For the sake of simplicity, and to avoid acoustic measurement at negative temperatures, this easy-to-implement condition could be considered if the highest sound level would have to be declared. It has to be noted that this value would only be representative of a short period of the heat pump operation.

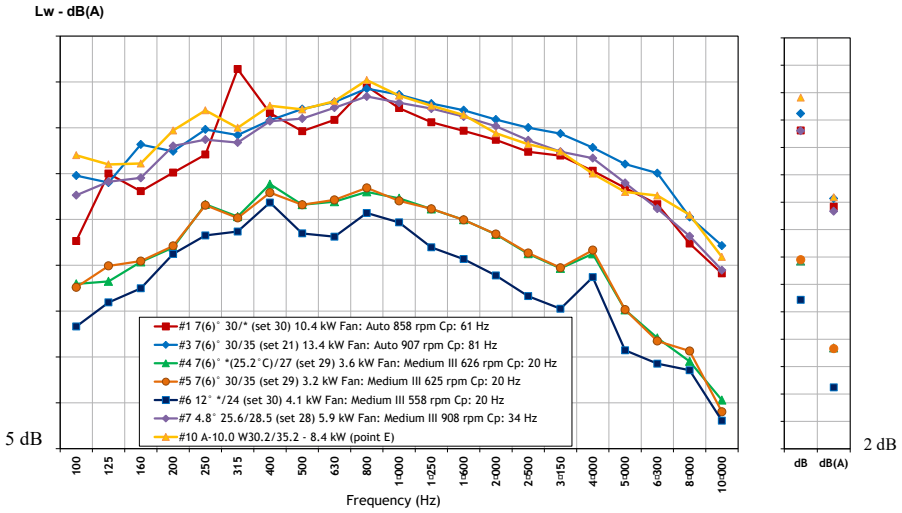

Fig. 4: Spectrum of A-weighted sound power levels for different operating conditions of the heat pump

For the acoustic value measured according to EN 12102-1 Annex A.4 (configuration #5), laboratories found out the procedure difficult to understand and not easily implemented for setting the unit (the heating capacity has to be same than for C point, the compressor frequency being the main parameter to adjust, then the outlet water temperature if necessary). The sound power level obtained is very close to the one obtained for EN 14825 point C (configuration #4). For the 5 laboratories that perform both tests, the overall difference is between 0 and -0.3 dB(A) only. A proposal could be to replace configuration #5 by the configuration #4 for achieving better reproducibility among laboratories.

3. Directivity

One laboratory implemented measurements with a dodecagonal polar frame (approx. diameter 2 m) around the outdoor unit, with 55 microphones. The data from 12 microphones, height 75 cm (third row from the floor, see the yellow arrows for 2 microphones on Fig. 5), allows the plot of the relative directivity diagram, presented in A-weighted overall level on Fig. 6 (an offset was applied to the acoustic data to show directivity values centered on zero).

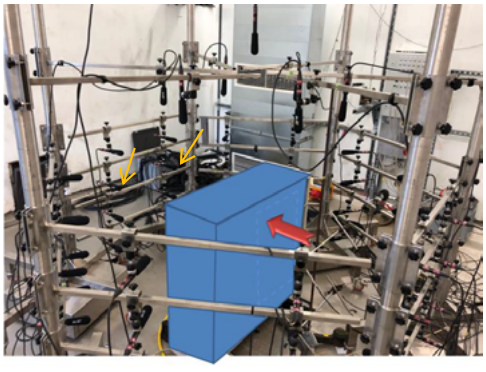

Fig. 5.Dodecagonal frames around the units with microphones

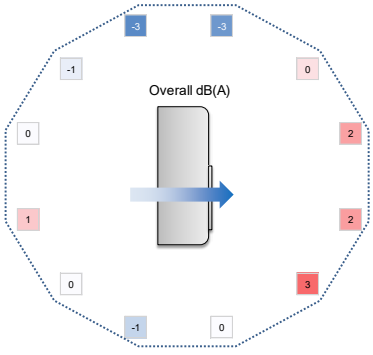

Fig. 6. Directivity for the overall A-weighted sound pressure level at 75 cm height

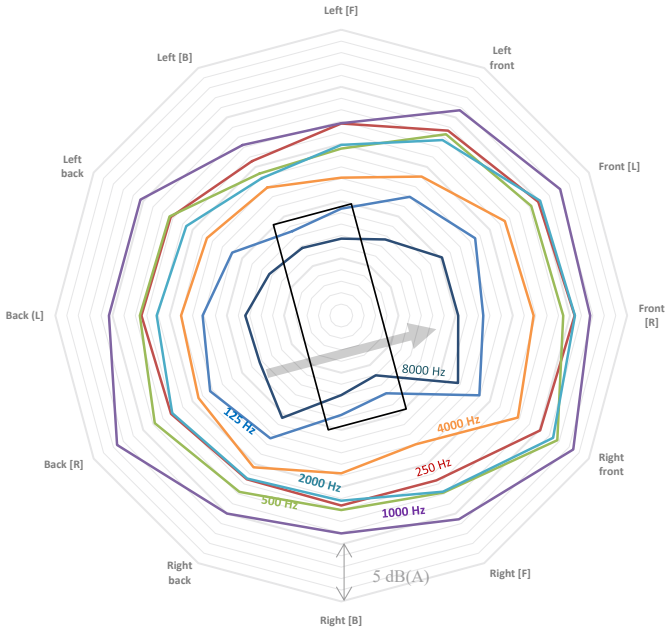

Fig. 7. Directivity for each A-weighted octave band

The directivity diagram in Fig. 7 shows the acoustic radiation directivity of the unit for each A-weighted octave band. Due to the fan located on the right of the casing, the maximum sound level is emitted in this direction ("right front"), and a little bit less on the rear side. The minima can be found on right and left sides, where there are only blind faces. For each octave band, Table 2 gives the amplitude of variation, and the position of the loudest and the quietest microphone.

Table 2. Amplitude of variation of sound pressure level around the unit

Freq.	**125 Hz**	**250 Hz**	**500 Hz**	**1000 Hz**	**2000 Hz**	**4000 Hz**	**8000 Hz**	**Overall**
Max – Min (dB)	6.1	4.8	7.5	6.6	7.5	5.8	5.7	6.2
Max position *	Right front	Front [R]	Right front	Right front	Right front	Right front	Right front	Right front
Min position *	Right [F]	Left [B]	Left [B]	Left [F]	Left [B]	Left [F]	Right [F]	Left [B]

** according to Fig. 7*

As expected the radiation is not omnidirectional, but the directivity amplitude is not huge, with a maximum range of 7.5 dB, meaning a ± 3.75 dB(A) around the mean arithmetical value. The octave bands for which the directivity is the most important are also those which contribute the most to the overall level. Overall range (including the full band) is ± 3.1 dB(A) around the mean arithmetical value.

In the case of an outdoor unit installation close to a neighborhood, this directivity should be considered in order to orientate the quietest side in front of the neighbor. Nevertheless, the effect of this directivity tends to reduce at longer distance.

4. Transient effects (spectral, sound power level)

The experiments also focused on the variation of sound power level when the heat pump operates with frost/defrost cycles. The sound level is rarely measured during this phase as it is generally out of the scope of standardised condition required for national legislations or certifications. In this condition, it is then continuously measured with a short time step (around 1 s) over a series of frost/defrost cycles. According to the temperature conditions, these cycles may have different duration, from 75 minutes to 120 minutes. The variation of acoustic emissions during these phases seems to be repeatable in shape as shown in Fig. 8.

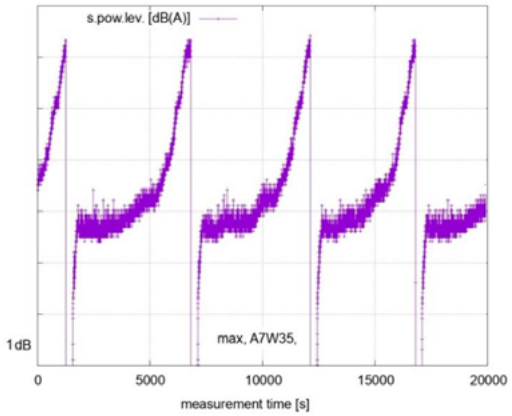

Fig. 8. Time dependent A-weighted sound power levels over 5h30 – configuration #3: EN 14511 freq. max

The simplest analysis for this unit shows that its sound power level measured (averaged over a few seconds) is always lower than the one measured during frosting (almost-steady state operation), without consideration of annoyance which would be studied using a psychoacoustic approach. That is why the acoustic behaviour during the defrosting phase is not investigated in the present paper.

Fig. 9 shows the variation of A-weighted sound power level according to time in seconds, for each octave band and for the overall levels during the frost and the defrost cycle. It can be seen that the overall value slightly increases with the frosting, for almost all frequency bands, except 4000 and 8000 Hz. The most contributing bands to the overall A-weighted value are 1000, 500 and 2000 Hz.

The frosting of the unit leads to an increase up to 3.5 dB(A), before the unit switches to the defrosting cycle. The spectrum at the end of frosting (arrow D) can be compared to the "dry" heat exchanger configuration (arrow H) on Fig. 10. The spectra of Fig. 10 correspond to the arrows time positions on Fig. 9.

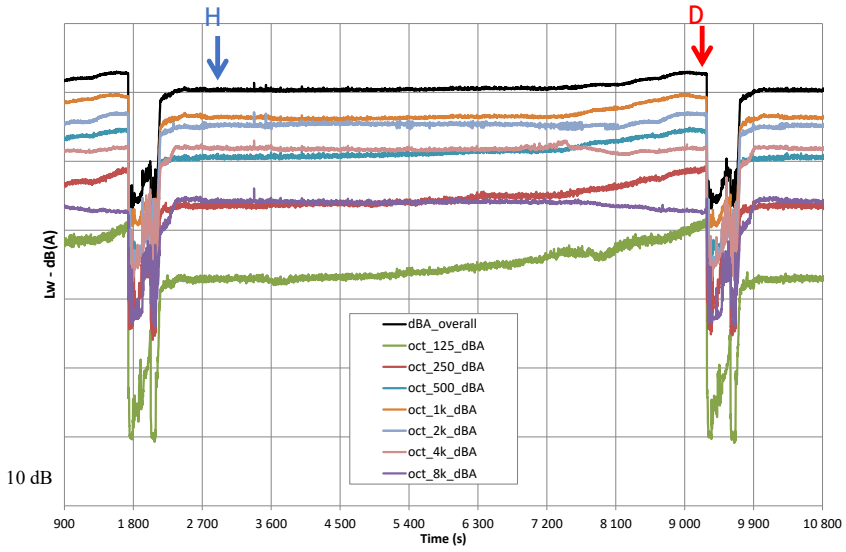

Fig. 9. Time dependent A-weighted sound power levels (in octave bands) between two defrosting phases configuration #3: EN 14511 frequency max

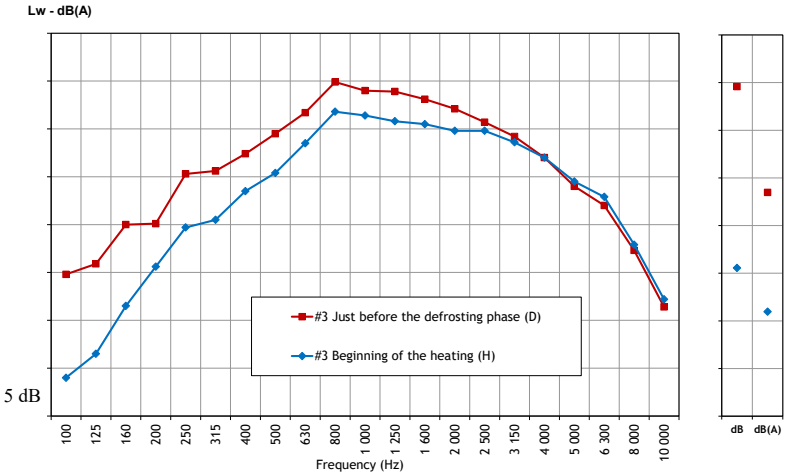

Fig. 10. Comparison of sound spectra before and after defrosting phase (cf. arrows on Fig. 9)

A similar increase of sound power level was observed for the configuration #7 (EN 14825 point B) condition, with a smaller effect on the overall increase, which is around 2 dB(A).

Fig. 11 shows the same quantities as Fig. 9, for negative outdoor air temperatures, leading to different behaviors of the sound power level. These levels are steadier, without noticeable increase before the defrosting starts, even though some accidents on frequency band may occur, but without larger influence on the overall level (see changes at 1800 s). However, this overall level quickly reaches the same magnitude than the one observed at the end of heating of Fig. 9 - arrow "D").

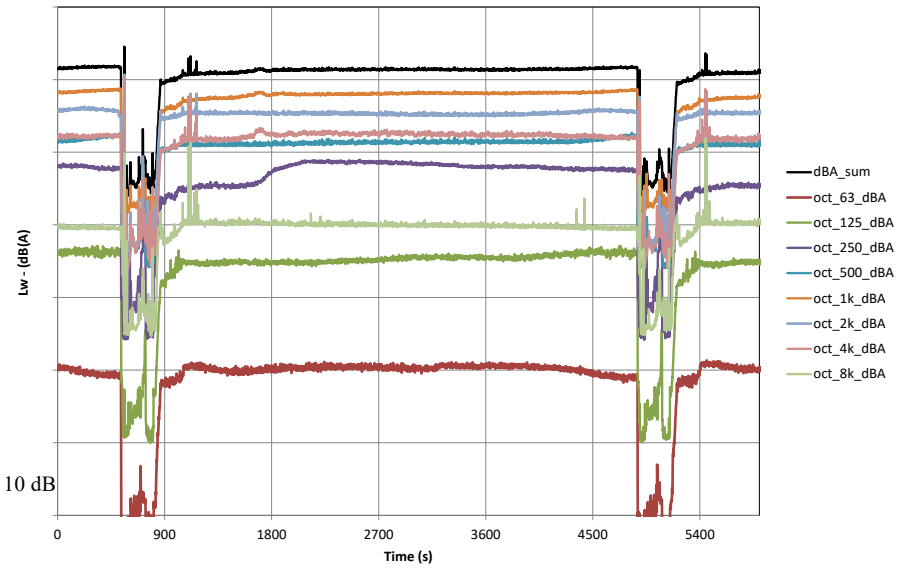

Fig. 11. Time dependent A-weighted sound power levels (in octave bands) between two defrosting phases configuration #8: EN 14825 -7(-8) */34

Conclusions

Acoustic tests have been performed on a split air-to-water heat pump, circulating through six European laboratories, for several operating conditions. The comparison of sound measurements shows a good agreement between results for standard operating conditions (EN 14511 and EN 12102-1). The EN 12102-1 Annex 4 used for Ecodesign compliance requires a unit setting not easy to understand and a clarification from the European Commission could be helpful.

The polar directivity appears to exist with a moderate amplitude (6.2 dB(A) for the overall A-weighted value, and 7.5 dB(A) for middle frequency octave bands), which can be used for an optimized orientation of the outdoor unit in order to limit the noise for the neighborhood. Additional measurements done on the non-steady period between the defrosting phases show that the frosting may increase the sound power level by 3.5 dB(A) for positive outdoor temperatures.

As part of the Annex 51, the results from these round robin tests will be of much help for:

- achieving a better understanding by the manufacturers of the acoustic behaviour of heat pumps in relation with climate conditions
- providing input for the revision of acoustic product standards such as EN 12102-1
- preparing recommendations for installers, namely on the sound directivity
- a better understanding by the policy makers of the complexity to tackle sound power level as it is often a compromise with energy efficiency of the heat pumps.

The results will provide input in order to select the most relevant operating point of the heat pumps and to define corresponding sound power level requirements in ErP regulations.

Abstract

Heat pumps are a promising building technology, especially in nearly Zero Energy Buildings (nZEB), which is believed to be the future building standard in many countries. In IEA HPT Annex 49, participants of nine countries are investigating design and integration options for heat pump application in nZEB. In Task 1, current implementations of nZEB are analysed and a methodology to compare ambition levels in the countries is developed. In Task 2, improvements of the heat pump performance by system integration are investigated by simulations, which are also coupled to the evaluation of real world performance of monitored heat pumps in nZEB in Task 3. In Task 4, the design and control is investigated, which also covers control for demand response. Besides single buildings, also clusters of buildings are included.
Results indicate that heat pumps reach a high performance in nZEB, which is necessary to reach ambitious nZE targets in particular in larger buildings. Furthermore, by simulation and monitoring, further optimization potentials of the heat pump operation have been identified. It is also confirmed that adapted controls can improve self-consumption and grid interaction of on-site electricity generation.

Keywords: Integrated heat pumps; nZEB, system design; energy flexibility; field monitoring

1. Background of nZEB

The recast of the Energy Performance of Buildings Directive [1] in Europe sets the objective that all new public buildings shall be built as nearly Zero Energy Buildings (nZEB) from 2019 on and all new buildings from 2021 on. Also in the USA and Canada Net Zero Energy Buildings (NZEB) are in the focus of the political strategy for high performance buildings, in order to be widely introduced between 2020 and 2030 and in Japan, NZEB are planned to be the standard building by 2030.

Even though political strategies strongly refer to the nearly or Net Zero Energy objectives, there is limited available knowledge and experiences about standardised cost- and performance optimized building technologies to reach nearly or Net Zero Energy consumption. While low- and ultra-low energy houses, e. g. according to the passive house standard, already show considerable market penetration and growth in several European countries and worldwide, nZEB are rather in the pilot and demonstration phase in order to prove a nearly zero, net zero or even plus energy balance. In plus energy buildings a surplus of produced energy compared to the consumed energy is achieved by installed renewables on-site on an annual basis. Especially in the non-residential sector, the nZEB balance can be challenging. Residential buildings have rather moderate energy loads and consumptions, and in particular for single family buildings, there is enough space in the building envelope to reach the balance by on-site renewable production.

In larger buildings, though, both loads may be higher and building envelope may be limited regarding the on-site renewable production, challenging the achievement of the balance and emphasizing the application of high performance components and operation.

Due to the common understanding, an NZEB is a grid-connected building with highly reduced energy needs where the weighted consumed energy can be produced by weighted renewable production on-site on an annual basis. However, this definition is incomplete, e.g. regarding the system boundary (what does on-site mean,

* Corresponding author. Tel.: +41 55 222 43 25
E-mail address: carsten.wemhoener@hsr.ch.

since the EPBD also considers nearby energies), the energies taken into account (including plug loads or just building technology, including mobility, life-cycle consideration) and the weighting system. Moreover, with a broad introduction of the concept as intended in the political objectives, aspects like load match between locally produced and consumed energy as well as interaction with energy grids, in particular the electricity grid should also be considered and buildings should be designed to work in line with the needs of the connected energy grids. Last but not least, the definition of the nZE building has an impact on design and the system configuration.

2. Project outline IEA HPT Annex 49

IEA HPT Annex 49 entitled "Design and integration of heat pumps for nZEB" is carried out in the Heat Pumping Technologies (HPT) Technology Collaboration Programme (TCP) of the International Energy Agency. It deals with integration options and design/control of heat pump application in nZEB, which is investigated both by simulation and monitoring of realized nZEB. Moreover, prototype developments of new integrated heat pumps are included in the Annex 49.

The IEA HPT Annex 49 started in October 2016. The nine countries Austria, Belgium, Estonia, Germany, Norway, Sweden, Switzerland, UK and the USA have joined the Annex 49. The Annex 49 is dealing with a more in-depth evaluation of integration options as well as the design and control of components. Moreover, the building technology may get new tasks, e.g. the provision of flexibility to the connected energy grids, in particular the electricity grid. This may have an impact on future system design and on storage integration. But not only a short-term flexibility, but also the seasonal mismatch has to be taken into account for a holistic assessment of the system solutions.

Furthermore, also the economic boundary conditions are rapidly changing. For instance, PV prices and subsidy schemes are changing, which affects the design and layout of systems and reduction of feed-in tariffs lead to a higher importance of the self-consumption to guarantee an economic operation of the PV system. Decreasing prices of electrical batteries due to e-mobility may additionally have an impact on self-consumption and demand response.

As a further aspect, the investigations in Annex 49 extend the system boundary to clusters of buildings or neighbourhoods. For instance, collective systems connected by micro-grids and load balancing between buildings are implemented.

The work in Annex 49 has been structured into the following tasks:

- Task 1 deals with the state-of-the-art of heat pump application in nZEB in the participating countries. Thereby, the impact of the national definitions on the ambition level in the countries is a topic. Furthermore, implications of the definitions on heat pump use shall be characterized by comparing system solutions and characterizing favourable system layouts and configurations.
- Task 2 is dedicated to an in-depth analysis of integration options of heat pumps in nZEB both on the source side like the ground and active components in the building envelope as well as thermal and electric storage. Moreover, also the integration and coupling to electric and thermal grids shall be considered in terms of load management and grid supportive operation. Thereby, also clusters of buildings and neighbourhoods are evaluated regarding their integration potential for load shift between buildings.
- Task 3 is dedicated to the development of prototype systems and the monitoring of heat pump operation and performance in nZEB, which also includes larger buildings like multi-family houses and non-residential buildings like office buildings, a school and a kindergarten, a hotel and a supermarket in Germany and Norway.
- Task 4 is dedicated to the design and control of heat pumps in nZEB and is closely linked to the system integration in Task 2. Both the on-site control as well as design implications for higher self-consumption of solar energy produced on-site and demand response for grid-supportive operation are aspects of the control. Thereby, potentials of model predictive control are partly assessed, as well.

An overview of the different participating institutions in the countries and the national project contributions is given in Table 1.

Table 1. Overview of contributions of the participating countries to Annex 49

Country/Institution	Contribution to IEA HPT Annex 49
Austria Unit EE building Univ. of Innsbruck, IWT TU Graz, AIT	• Monitoring and simulation of two nZEB buildings for performance optimization • Development of a prototype of a façade integrated heat pump • Evaluation of larger nZEB buildings and districts
Belgium Free Univ. Brussels	• Evaluation of heat pump in office nZEB with sewer heat recovery heat source
Estonia Tallinn Technical Univ.	• Modelling and simulation of ground-coupled heat pumps (energy piles, horizontal collectors) • Design of heat pumps and heat emission systems for the nZEB application
Germany TH Nürnberg, IGS of Univ. of Braunschweig, TEB GmbH	• System integration, design and field monitoring of different nZEB building types • Development of control strategies for smart grid integration
Norway SINTEF, NTNU, Cowi AS	• Developments of heat pumps with natural refrigerants • Investigation/monitoring of nZE demonstration buildings and neighbourhoods in Norway
Sweden RISE	• Monitoring and comparison of heat pump systems in two equal test houses
Switzerland IET HSR	• Integration and design options of solar and heat pump systems • Field monitoring of nZEB with façade integrated PV
UK Glen Dimplex	• Evaluation of design and control of nZEB model houses
USA ORNL, NIST, CEEE Uni Maryland	• Field monitoring of integrated heat pump variants (IHP) • Technology testing and comfort evaluation in NZEB test facility (NZERTF) • Evaluation of a prototype of a personal cooling device to reduce loads in NZEB

In the following, specific results of the single Tasks and national contribution are given as overview of the outcomes of the IEA HPT Annex 49.

3. Results of the different Annex 49 Tasks

3.1. Task 1 on the state-of-the-art of nZEB

In Task 1 the state-of-the-art of nZEB in the different participating countries of the Annex 49 is analyzed. nZEB definition in Europe is elaborated by the EU-member states (MS) and current definitions in the EU-MS vary both in system boundaries, metrics, limits and rating systems as outlined in [2], [3] for different states of implementation. Thus, in the first step, there will not be a common definition of nZEB, even though the EU institutions REHVA and CEN have prepared different documents to support a harmonized definition and implementation of nZEB in the EU. In the USA, a similar system boundary as of the REHVA definition has been proposed by US-DOE [4].

However, current implementations of nZEB may still updated before requirement for all new buildings are enacted on January 1, 2021, even though the deadline for the requirements for all new public buildings is already passed and thereby, definitions are in application.

The different definitions of nZEB are also related to national rating procedures, which use national calculation methods in order to approve compliance with the nZEB requirement according to the national implementation. As consequence, even with a common definition, the implementation in the single countries would vary due to different national boundary conditions, national climate data and calculation methods. Thus, it is hard to compare the ambition level of the different countries to achieve high building performance values in the new sector, which would be a useful information for policy makers to set high ambition levels in the new built sector.

Therefore, in the Task 1 of Annex 49, a methodology to compare the ambition levels of different nZEB definitions is worked out. The term ambition level refers to the ambition of the nZEB rating to reach very high energy performance of the building. For instance in Denmark, there is an ambitious requirement to reach a building envelope in the range of passive house level for the nZEB implementation, thus for the building envelope, Denmark has a high ambition level. The development of the methodology is still in progress, thus in the following, the current state is shortly summarized, details on the state of the methodology can be found in [6]. The methodology is based on a single family building as outline in [5] with some modification in order to turn the building into an nZEB. Since a heat pump is applied as heat generator for space heating and DHW operation, the building corresponds to an all-electric building. As next step, based on the common design, boundary conditions and site of the reference building, the building is transferred to the local conditions.

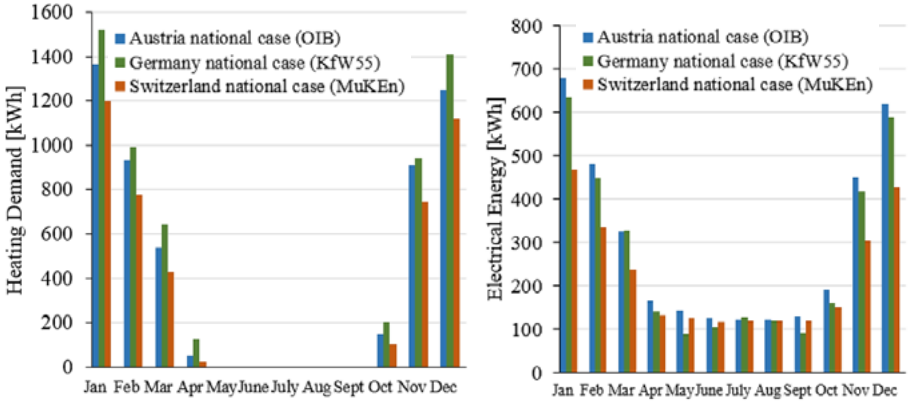

Fig. 1. Comparison of the space heating demand (left) and the electrical energy (right) for the nZEB requirements in the D-A-CH countries Germany, Austria and Switzerland

Thereby, the national nZEB layout related to the national boundary conditions by the rating procedure in the different countries can be evaluated. Afterwards, the building parameters are transferred to a simulation model of the buildings, and boundary conditions and climate data are changed back to the common ones.

This enables the comparison of the national buildings for common boundary conditions regarding internal loads, climate and DHW tapping profiles. Finally, the space heating demand and the delivered energy can be compared in order to get a ranking of the ambition level in different countries. Fig. 1 shows a comparison for the D-A-CH countries Germany (D), Austria (A) and Switzerland (CH), which are in the same climate zone, for the space heating demand on the left and the delivered electrical energy on the right according to the national definitions. It can be seen, that requirements for the nZEB rating in Switzerland results both in a lower space heating demand and in a lower electricity consumption than in the two other countries. Thus, a relative order of ambition levels among the three countries can be evaluated. However, present limitations of the methodology are that only countries in the same climate zone have been compared and the method focuses on the building envelope, while for the nZEB concept, also the on-site renewable production shall be included for the ranking. Thus, the methodology shall be further developed and extended to other examples.

3.2. Task 2 on heat pump integration for nZEB

Task 2 is dedicated to the integration options of heat pumps for nZEB application. The work in Task 2 is carried out by simulation, but is also linked to monitoring projects carried out in Task 3. An example for this link of the implementation of optimization potentials derived by simulations in monitored buildings is a project contribution of the Unit for Energy Efficient Building of the University of Innsbruck

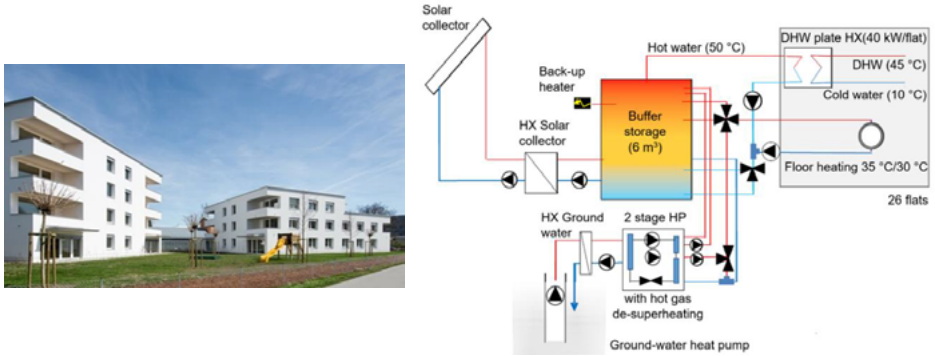

Fig. 2. Two multi-family houses in passive house standard of the project Innsbruck Vögelebichl (left, photo: "NHT Tirol") and principle sketch of the installed system technology (right)

An example for this link of the implementation of optimization potentials derived by simulations in monitored buildings is a project contribution of the Unit for Energy Efficient Building of the University of Innsbruck.

The case study deals with two multi-storey multi-family buildings in passive house standard of the social housing company NHT in Tyrol, Austria (see also [8] for more details). In the following, the main facts are summarized. Fig. 2 left shows a photo of the two buildings in Innsbruck Vögelebichl and Fig. 2 right depicts a principle sketch of the building system technology.

The buildings consist of 10 or 16 flats, respectively, with a total treated area of 2149 m^2 and are designed for a Net Zero Energy balance in terms of space heating, domestic hot water (DHW) production and auxiliary energies for the building technology (i.e. without taking into account appliances and plug loads). The design heat load for both buildings is 24 kW (according to the Passive House Planning Package – PHPP) and additional 12 kW for DHW. The buildings are equipped with 73.6 m^2 solar thermal collectors and a solar PV installation, which covers the entire roof of the one building with an area of 99.8 m^2 and a part of the other roof with 52.5 m^2 besides the solar thermal installation. The system consists of a ground-water source two compressor heat pump of a nominal heating capacity of 58 (52) kW at W10/W35 (W55) and respective COP values of 6 (3.7). The heat pump and the solar thermal system supply heat to a central 6 m^3 thermal buffer storage. The storage is charged at the top in DHW mode and at a relative height of 67% in space heating mode. The combined return flow enters the storage at a relative height of 33% or at the bottom depending on the temperature level. The installed direct electrical back-up heater is currently not in use. The storage delivers the heat to a floor heating system in the flats and the decentralized fresh water systems with plate heat exchangers for the DHW supply at use temperatures of 45 °C, using a primary inlet temperature of 50 °C from the storage.

Additionally, the heat pump is equipped with a de-superheater for simultaneous heating and DHW preparation. The de-superheater is located between the compressor outlet and the condenser inlet and uses the higher temperature of the refrigerant discharge gas for a DHW production at lower condenser pressure level in simultaneous space heating operation (e.g. for a floor heating with typical design temperature of 35 °C/30 °C) instead of the higher pressure level of the DHW-only mode. Thereby, the higher DHW temperature can be produced at high efficiency and no interruption of the space heating operation is necessary. However, the heat extraction is limited to the de-superheating fraction before the condensation begins, see also Fig. 4 below. Furthermore, the actual hydraulic integration is not optimal, see [8] for more details.

The investigations by simulation comprises different aspects of the system as operation modes of the two-compressor heat pump including the evaluation of the performance map, which is not available for all operation modes by the manufacturer. Furthermore, the de-superheater operation, the monitoring system, the nZEB balance including the auxiliaries, the storage stratification and the control of the building technology are investigated. For a detailed analysis, a system model has been set-up, which consists of a simplified refrigerant cycle model of the two-compressor heat pump. Using the model, the performance maps of the missing operation modes have been identified with the monitoring data. Moreover, a model of the central storage has been set-up and compared to monitoring data. There are some deviations, but for the use of investigating the configuration, design and control of the system, the model is applicable. Using the developed system models, the integration of the system functions and the respective control can be simulated and optimized. Selected results are presented in the following, more details are found in [7, 8].

Fig. 3. Monitored heat balance (left) and electrical energy (right) of the three year measurement period of the multi-family buildings Vögelebichl Innsbruck

Results of the monitoring a three-year period are shown in Fig. 3. Operation of the buildings started in winter 2015. The demand for space heating of the buildings was 20.5 kWh/(m²yr) in 2017 and 18.5 kWh/(m²yr) in 2018 and thereby slightly higher than the planned 15 kWh/(m²yr) according to the passive house standard.

The DHW demand was 25 kWh/(m²yr) and thereby in the expected range. Both the space heating demand and the electricity consumption could be successively decreased from year to year.

However, the thermal losses slightly increased in absolute numbers leading to an increased relative contribution of 14%, which is one of the major reasons, why the NZE balance related to the balance boundary of the building technology and the onsite PV production could not be fulfilled, yet. In 2018, for instance, the electricity consumption of the HP was 21 MWh and auxiliary energies were responsible for 14 MWh. The PV field produced in average around 27 MWh, as shown in Fig. 3 right of the electric energy balance for the years 2016 to 2018.

Despite the reduced total energy demand in 2018 (mainly because of the decreased heating demand), the NZE balance was not achieved. Thereby, the PV production was 24.5 MWh in 2018 due to a technical failure of the inverter of the PV field of the north building. A yield between 26.6 MWh and 27.2 MWh can be predicted based on data of 2016 and 2017 for the case without the failure.

Fig. 4, left hand side, shows a more detailed theoretical estimation of the system operation by de-superheating. Potentials for electricity savings are dependent on the ratio of DHW heat demand and space heating demand, which depends on the building standard. While in low energy houses (LEH) the space heating demand is still dominating, the fraction can increase to 50% of the total heat demand in single family passive houses (PH SFH) and even reach a ratio of about two in multi-family passive buildings (PH MFB). The given curves are parametrized by the DHW share produced by de-superheating, which might range from 7.5% to 15%. With increasing DHW fraction, the potential electricity saving decrease from 8% in the best case to about 1% to 2%, since with dominating DHW demand, the simultaneous operation with space heating decreases and thereby also the potential for combined heat production for both building services. In this configuration, the de-superheater could always supply the heat to the buffer storage in the top zone.

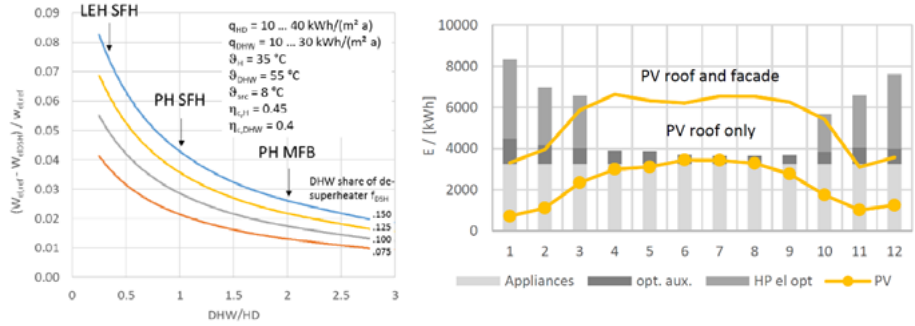

Fig. 4. Theoretical potential of the DHW electrical energy saving by desuperheating for different building types and DHW shares (left) and simulated annual energy balance with improved control and reduced auxiliary losses (right)

Fig. 4, right hand side, depicts a prediction of the monthly energy balance with reduced auxiliary energy consumption for the building equipment (e.g. pumps, fans etc.) and optimized control strategy. A multi-dimensional performance map was developed in Matlab/Simulink environment and is integrated in a system model that allows to simulate different heat pump operation strategies with and without de-superheating, single and double-stage operation as well as optimized hydraulic integration. In this optimal case, the nZE balance for heating, DHW and auxiliary energy for the building equipment can be met with the yield of the PV on the roof. However, it is noteworthy that PV in the façade is required, if also household appliances and plug loads are considered, too, as shown in Fig. 4 right. It is obvious, that the contribution to the winter load is not significant if the annual energy balance is met. A monthly net balance could only be achieved by integration of (very cost intensive) long term energy storage. This demonstrates the importance of reducing the winter load.

3.3. Task 3 on heat pump prototyping and monitoring of heat pumps in nZEB

Task 3 is dedicated to the development of prototype technologies and monitoring of nZEB with heat pumps. Different participating countries in the Annex 49 perform field monitoring projects in order to evaluate the real performance of heat pumps in nZEB.

Fig. 5: Building Black & White with roof and façade integrated PV system in the city centre of Pfäffikon SZ (left) and building use (right, orange – commercial use, green – office use, blue – residential use) (source: AWIAG)

In the following results of a monitoring project in Switzerland are given, which refers to a 5-storey building with mixed commercial (basement, 615 m^2), office (1st and 2nd floor, 615 m^2) and residential use (3rd and 4th floor and attic, 1520 m^2) energy reference areas in the city centre of Pfäffikon (SZ), that has been monitored for one year. The building and the uses are depicted in Fig. 5.

Fig. 6 shows a sketch of the building technology system. As counterpart to the efficient building envelope on passive house level also an efficient building technology was planned and an active solar electricity production was designed to high yields of a net zero energy balance. Therefore, a major part of the building outer surface is used for the solar PV-production. In order to meet a nZE balance, the roof comprises 26 kW$_p$ of monocrystalline PV modules. In the south, east and west direction, thin-film PV modules of a total installed capacity of 48 kW$_p$ are integrated in the façades. The efficiency of the roof modules is with 21% notably higher than the thin film CIS-module in the façade with an efficiency of 11%. Moreover, the building is integrated in the city centre, so that the facades are temporarily shaded by surrounding buildings.

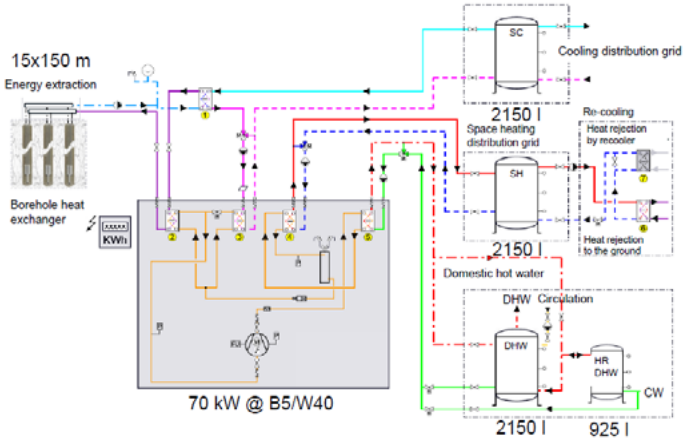

Fig. 6: Building technology concept of the Black & White with ground-coupled heat pump and waste heat recovery in space cooling operation (source: Andy Wickart Haustechnik AG)

As innovative building technology concept, the core component of a 70 kW (B5/W40) ground coupled heat pump has been planned, so that the building corresponds to an „All-electric building“. The heat source is a borehole heat exchanger field of 15 Duplex-ground probes of 40 mm diameter and a depth of 150 m each, which guarantees an efficient space heating and DHW operation, but is also integrated in the cooling concept. For the space cooling operation, a 5-phase-concept is considered: The system is planned in that way, that both the ground and a heat recovery for the DHW and space heating operation cover the re-cooling of the heat pump in cooling operation, i.e. also for the active cooling operation, no re-cooler to the outside air is required.

However, the focus of the cooling concept is a high degree of coverage in ground-coupled free-cooling (phase 1), and only at higher cooling loads, the active cooling with reverse operation of the heat pump is used. The maximum cooling capacity in active cooling mode is 53 kW. Thereby, the re-cooling heat is transferred primarily into the DHW preheating storage (phase 2). At simultaneous space heating and cooling demand, the recooling heat is transferred into the heating buffer storage (phase 3), and only in case of a surplus heat, which cannot be used in the heating buffer or DHW storage, the ground is regenerated (phase 4). If the ground cannot absorb the surplus heat anymore, a re-cooler to the outside air has to be operated (phase 5). For balancing the load and production a heating and cooling buffer storage of each 2,150 l are installed. Additionally, two DHW storages are installed, a preheating storage of 925 l for the use of re-cooling heat and a DHW storage of 2,150 l.

Moreover, for the different uses, ventilation systems with heat recovery are installed, which supply the building with an overall volume flow rate of 8,450 m^3/h. The commercial areas are cooled by cooling ceilings, which enhances the free-cooling use due to the higher possible temperature levels, and henceforth the reverse operation of the heat pump for space cooling can be limited to peak loads in summer. Additionally, the ground probes are used to preheat the ventilation air in wintertime in order to avoid ice formation on the heat recovery heat exchangers.

The year-round monitoring was evaluated from Oct. 2016 – Sept. 2017 and the balance is depicted for the single energy uses in Table 2. The measured energy consumption mainly corresponds to the calculated design values of the building. The space cooling demand is yet a bit lower, since one of the server rooms has not been operated as planned.

The projected production did not reach 20 $kWh/(m^2yr)$ energy reference area (ERA), which would have balanced the energy consumption of the building technology. Reasons are the different type of modules, so the façade could deliver more energy with higher efficiency of the modules. The system performance factors reaches high values of 4.97 in space heating operation and 3.1 in DHW operation at 60 °C charging temperature of the storage. The space cooling operation reaches a seasonal performance of 5.9, whereby the re-cooling heat is entirely used in the space heating and DHW storage or for the regeneration of the ground, so no re-cooler to the ambient air is installed. The PV yield of the façade-integrated modules, though, has not reached the projected values, since different modules than considered in the planning have been used in the real building.

Table 2. Yearly balance of the Black & White building with mixed use in urban environment

Balanced energy	Calculation/Design value	Monitoring value
Space heating and DHW	11.4 $kWh_{el}/(m^2yr)$	9.9 $kWh_{el}/(m^2yr)$
Ventilation	3.2 $kWh_{el}/(m^2yr)$	5 $kWh_{el}/(m^2yr)$
Space cooling	5.2 $kWh_{el}/(m^2yr)$	2 $kWh_{el}/(m^2yr)$
Total electricity building technology	19.8 $kWh_{el}/(m^2yr)$	16.9 $kWh_{el}/(m^2yr)$
Total electricity consumption	49.1 $kWh_{el}/(m^2yr)$	44.4 $kWh_{el}/(m^2yr)$
Electricity yield solar PV	20 $kWh_{el}/(m^2yr)$	13.4 $kWh_{el}/(m^2yr)$
nZEB balance (weighted with 2)	-0.4 $kWh_{el}/(m^2yr)$	7.0 $kWh_{el}/(m^2yr)$

Thus, despite a building envelope on ultra-low energy house level and a good system performance with an overall seasonal performance factor of 5.2 including free-cooling, the net balance based on the system boundary building technology (excluding plug loads) is not entirely reached. Nevertheless, 95% of the energy for the building system is produced on-site on an annual basis including the ground source. The reasons for not reaching the nZE balance is the PV yield of the façade modules, which is below the design values. With an increased efficiency of the façade modules, though, the nZE balance for the boundary of the building technology could be reached, while it would be hard to reach the nZE balance including plug load, which would require a total on-site production of 44.4 $kWh/(m^2yr)$. Since already a large fraction of the façade and roof is covered with PV and the system performance is already high, it would be hard to reach the balance including plug loads for this type of building, since the building envelope is limited and PV yields are also affected by the urban environment due to temporary shading by surrounding buildings.

3.4. Task 4 on Design and control of heat pumps in nZEB

Task 2 on the integration of nZEB building technology and Task 4 on the design and control of heat pumps for the application in nZEB are interlinked. If integrated systems are considered, also the design and control is an important feature to achieve the maximum performance.

The integration also includes the integration of nZEB into connected energy grids in terms of thermal grids or the electrical grid. As example of grid integrated nZEB, a project contribution of Germany is presented which consists of a new built neighbourhood.

At the energy campus of the TH Nürnberg, Germany, the electric and thermal integration is considered for the example of eight single family terraced houses of each 150 m^2 energy reference area, which is called "Herzo Base". The system concept contains two modulating central ground-coupled heat pumps, which are equipped with inverter control and are distributing the space heating energy by a low temperature grid on the level of the supply temperatures for the space heating operation, which is thereby centrally supplied. In contrast, the domestic hot water (DHW) is produced in decentralised 200 liters DHW storages in each house, which are supplied each by decentral 2 kW booster heat pumps, that use the low-temperature grid as heat source.

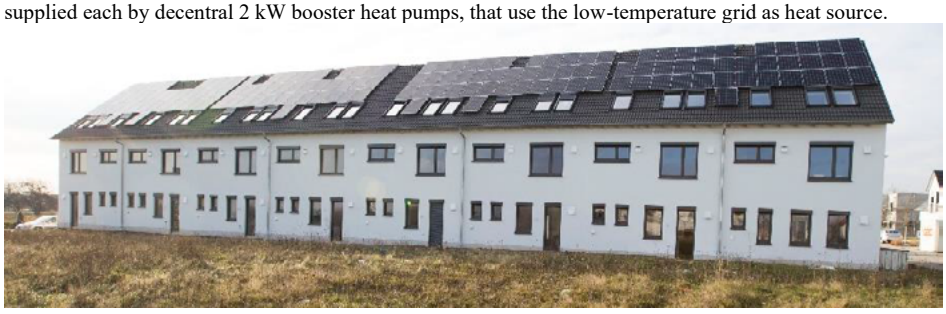

Fig. 7. Terraced houses of the project "Herzo Base" in Germany

In summertime, the ground source is used for free-cooling. The system is also equipped with an electrical battery storage that is installed centrally at the two modulating ground-source heat pumps. Fig. 7 shows a picture of the eight terraced houses.

At daytime, the PV mainly covers the household appliances and plug loads. In case of PV surplus, the battery is charged to mainly cover the illumination of the buildings and electric consumers in the evening.

Additionally, also central thermal buffer storages are installed. Besides a monitoring of the system, it is also investigated by simulations. One task of the simulation study is to evaluate control concepts, how the different storage options and heat pump modulation enhances self-consumption of the on-site generated PV electricity, since thermal storage and electric storage can be combined to increase on-site PV use and diminish grid interaction and grid import as well as to reduce peak loads. Details on control strategies are found in [9].

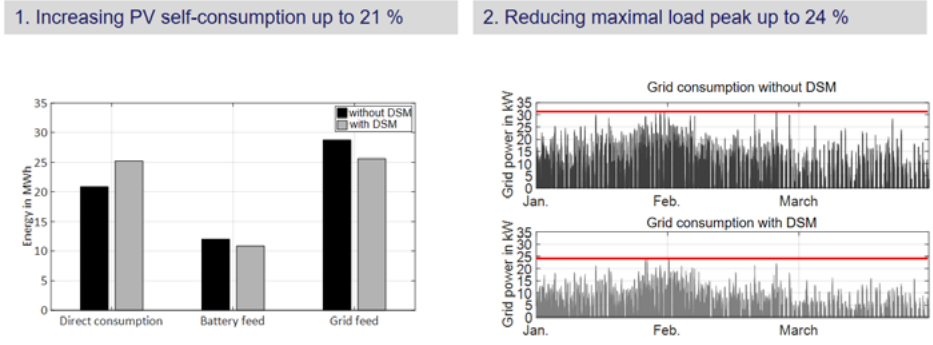

Fig. 8. Simulation results of Demand Side Management (DSM) to increase self-consumption and decreased load peaks and grid import

In Fig. 8, simulation results for the increase of self-consumption are depicted. The direct consumption could be notably increased by 21% due to the control optimisation. Thereby, also the battery feed-in could be decreased by 10%, while grid import is reduced by 11%. Moreover, the impact of the DSM on the grid also led to a reduction of the load peaks in the grid, which were reduced by 24% in the three winter months January to March.

Monitoring results of the system for the year-round monitoring period of April to March confirm the plus energy design of the building. The measured energy for space heating is with 33.2 kWh/(m²yr) slightly higher than the design value of 23.4 kWh/(m²yr) and also the measured DHW energy of 21.8 kWh/(m²yr) surpasses the design value of 18.5 kWh/(m²yr).

The space cooling, though, is with measured 7.3 kWh/(m²yr) a bit lower than the calculated 8.6 kWh/(m²yr). The overall balance in terms of delivered energy, primary energy and CO_2-emissions is given in Fig. 9. In the annual balance a surplus of the delivered energy by the PV production of 26.6 kWh/(m²yr) is achieved, and weighted values of primary energy and CO_2-emissions lead to 47.9 kWh/(m²yr) and 14.0 kg/(m²yr), respectively. This surplus can also be explained by the good performance values of the installed heat pumps, which is depicted in Fig. 10 for different system boundaries.

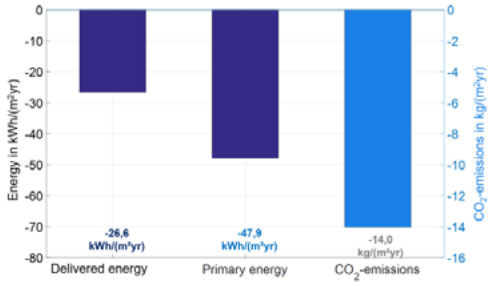

Fig. 9. Annual monitoring results for the Herzo Base system in terms of delivered energy, primary energy and CO_2-emissions

Even higher values than in the simulation have been measured. The two central heat pumps reach values of 5.4 and 6.0 in the boundary of the COP, and including the source system a value of 5.6. The source system by itself reaches a measured performance of an ETA of 175, where ETA refers to the electro-thermal amplification by extracted heat related to pumping energy. The booster heat pumps for the DHW operation reach performance values around 4.

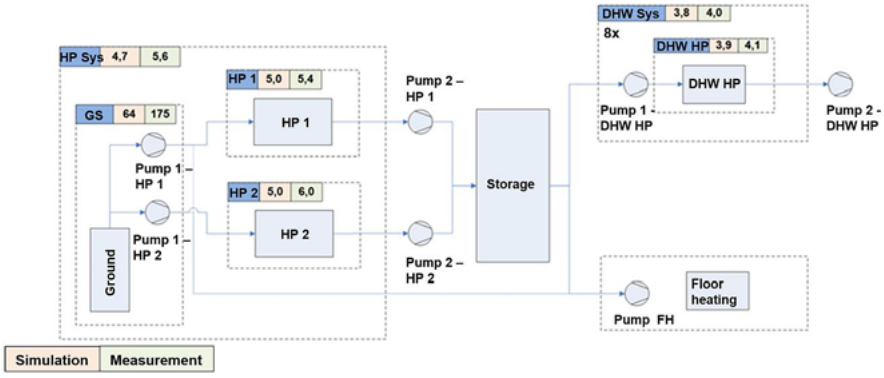

Fig. 10. Seasonal performance factors based on produced energy of the heat pumps

4. Conclusions

IEA HPT Annex 49 has the objective to perform investigations and analysis of the integration options and adapted design and control of heat pumps for the application in nearly Zero Energy Buildings, which are considered as future building standard in many countries around the world. nZEB requirements have already been introduced in the EU member states by Jan 1, 2019 for all new public buildings, which will be extended to all new buildings by the beginning of 2021. Nevertheless, despite different attempts for a harmonisation among countries, the implementations presently differ in metrics, limits and rating procedures, which impede a comparison of ambition levels and the development of standardised system solutions.

Moreover, in this step, not all countries require the nZE balance, but some countries only set requirements on the building envelope or primary energy consumption or have separate requirement for on-site renewable production without explicitly requiring a balance between energy consumption and on-site production.

IEA HPT Annex 49 has set a scope on integration options of the heat pump for nZEB. Regarding the monitoring, integration option yield positive results regarding the energy performance. The monitored integrated heat pumps reach high seasonal performance factors in the range of 5-6, which is also due to internal waste heat recovery by combining different building service in simultaneous operation of the heat pump as well as the integration of sources for free-cooling and regeneration. However, despite a high system performance and a high-performance building envelope, reaching an annual nZE balance may still be challenging in larger buildings, where the building surface area is limited for the renewable production on-site. Thus, a high system performance and an optimised system operation is a prerequisite for approaching the nZE balance in these buildings.

Regarding the design and control, besides the conventional aspects of performance and cost, additional aspects may affect the design of the building technology in nZEB, namely the energy flexibility, which becomes more important in nZEB for two reasons. On the one hand, the economy of on-site PV systems, which are often installed in nZEB to achieve the nearly zero energy balance, is positively affected by a higher degree of on-site consumption of the produced electricity in times of decreasing feed-in tariffs.

On the other hand, with increasing renewable energy in the electricity grids, buildings may also play a role to provide energy flexibility to the grid by reduced or increased consumption according to the grid needs. In this context also the control strategies are an important feature, since future buildings should contribute to a reduction of grid interaction and reduce the stress put on the grid by the increased renewable energy production. Thus, buildings are already seen today as one player for a future smart grid and the nZEB concept of on-site renewable production to balance the building's energy demand can be considered as turning point for buildings from a passive to an active component in the energy system. Design and control of the building technology should thus take into account demand response capabilities. An increase of electrical storage side by side with thermal storage installations raise the question of improved system and building integration of heat sources, generators, storages and sinks, on the single building level as well as on the neighbourhood and district level, where buildings with different use profiles and needs can be integrated by thermal and electrical grids. Presented results of a load shift and peak load reduction, which can be achieved by electric and thermal storage integration are positive from the energy perspective, but it has still to be proven, if this is also economically feasible for the building owners, since currently in most cases the building owner is not refunded for providing energy flexibility. Exception may be found in particular tariff structures, where e.g. a benefit for peak load reduction is granted. However, especially in smaller buildings like single family houses, designing the building technology to larger demand response capabilities, e.g. by larger storage design may not pay off with current electricity tariffs.

Summarising, nZEB are a next step to high performance buildings including renewable energy production, but reaching the balance can still be a challenge in larger building. The high-performance values reached with heat pump integration options and optimised design and control help to achieve ambitious targets of nZEB, and also enhance energy flexibility, which has been proven by the different simulation and field monitoring results of IEA HPT Annex 49.

Acknowledgements

IEA HPT Annex 49 is a collaborative research project and gratitude is expressed for the contributions of all participating countries as well as for the good collaboration within the IEA HPT Annex 49.

The support and funding of the IEA HPT Annex 49 by the Swiss Federal Office of Energy SFOE is highly acknowledged.

Abstract

According to the Paris Agreement (COP21), the increase in global average temperature should be less than 1.5°C. The industry demands to decrease CO_2 emissions; however, the demand for heat at high temperature "more than 100°C" is mostly met by fossil fuels. Therefore, we have studied the process of introducing heat pumps with heating water to 160°C or higher by utilizing exhaust heat. We filtered industrial processes that are highly effective for installing heat pumps and calculated the effect. The installation of heat pumps was confirmed to reduce the primary energy consumption by approximately 14% and running costs 32% compared with using only fossil fuels. Thus, we have been developing 160°C- and 200°C-type centrifugal heat pumps using a low GWP refrigerant and exhaust heat. By 2023, the performance is going to achieve more than a COP 3.5 by heating high temperature pressurized water to 200°C and using heat source water at 95°C with a heating capacity of 600kW. Furthermore, we have selected a refrigerant suitable for high temperature, and the refrigerant candidates have GWPs of 20 or less and stability.

Keywords: Low GWP refrigerant, Heat pump, Industrial use, High temperature, COP ;

1. Introduction

In December 2015, the 21st Session of the Conference of the Parties to the United Nations Framework Convention on Climate Change (COP21) adopted the Paris Agreement, requiring each country to update and submit its own CO_2 reduction goal every five years. For refrigeration and air conditioning equipment, fluorinated greenhouse gases (F-gases) regulations in Europe, and the Act for Rationalized Use and Proper Management of CFCs and HFCs in Japan were designed to reduce the environmental impacts of these gases.

HFC refrigerants that have a high global warming potential (GWP), such as R134a, have been replaced by new types of low GWP refrigerants. Several aspects of these low GWP refrigerants must be verified, including their physical properties, stability, toxicity and flammability. The choice of refrigerant depends on the capacity, compressor type, operating temperature, and conditions of the heat pump; thus, it is necessary to consider the following items when selecting alternative refrigerants [1].

- Environmental factors: GWP ≤ 100, not an Ozone Depleting Substance
- Low toxicity and non- or mild flammability
- Physical properties: Cycle efficiency equivalent to that of existing refrigerants. Design pressure not to be excessively high.

Several double bond olefin refrigerants are candidates. Table 1 shows a comparison of R-134a and olefin refrigerants. The GWPs of the olefin refrigerants are very low, and their cycle efficiencies are equivalent to that of existing refrigerants.

Heat pumps are increasingly being used for supplying of hot water and heating in the household sector,

but their application in the industrial sector has been slower [6]. The adoption of exhaust heat recovery heat pumps offers great potential for improved energy efficiency and a reduction in CO_2 emission in the mechanical and chemical industries. So, investigation of in the mechanical and chemical industries in which high-temperature heat demand and unused exhaust heat exist, and high temperature heat pump systems capable of heating pressurized hot water to 160°C and 200°C with COPs of 3.5 or more, are part of the research and development program of the New Energy and Industrial Technology Development Organization (NEDO).

2. Investigation and selection of the process of introducing heat pumps

The actual conditions of the heat process are not clear for the machinery and chemical industries, such as the existence of heat demand and exhaust heat, the balance between heat and energy, operating hours, and operating methods to introduce heat pumps. First, as shown in Fig. 1, we evaluated the effect of installing a heat pump from simple information, such as the process temperature, heat demand, and existence of exhaust heat. As shown in Table 2, the drying process and the chemical process were indicated to be particularly effective. As a result of the hearing investigation, it was clarified that the data on the heat demand is organized in detail, but only the supply temperature of the heating source is organized, and there is almost no data on the exhaust heat source. Therefore, we measured the actual conditions of the drying process [Company L] and the chemical process [Company B], which are highly effective when install, and we clarified the heat balance with respect to the measured temperature, flow rate, state, operating time, etc. in the system.

In addition, we examined an exhaust heat recovery system and pressurized water supply system, etc. for the existing facilities and studied the economic effect of installing a heat pump. As shown in Fig. 2, we found that the primary energy consumption and running costs could be reduced.

- Paint drying process [Company L]: As shown in Fig. 3, it is possible to reduce primary energy consumption by 14% and running costs by 32% by installing 160°C heat pump with a COP of 4 to a portion of existing burners into the current air circulation heating process, compared with only using burners.
- Chemical process [Company B]: As shown in Fig. 4, it is possible to reduce the primary energy consumption by 7% and the running costs by 23% by installing 200°C heat pump with a COP of 3 to a portion of the existing boilers heating process of the reactor, compared with only using boilers.

Therefore, we have been developing a 160°C heat pump and process system of air drying and thermostatic chamber and a 200°C heat pump for steam generation and chemical processes, by taking the two steps.

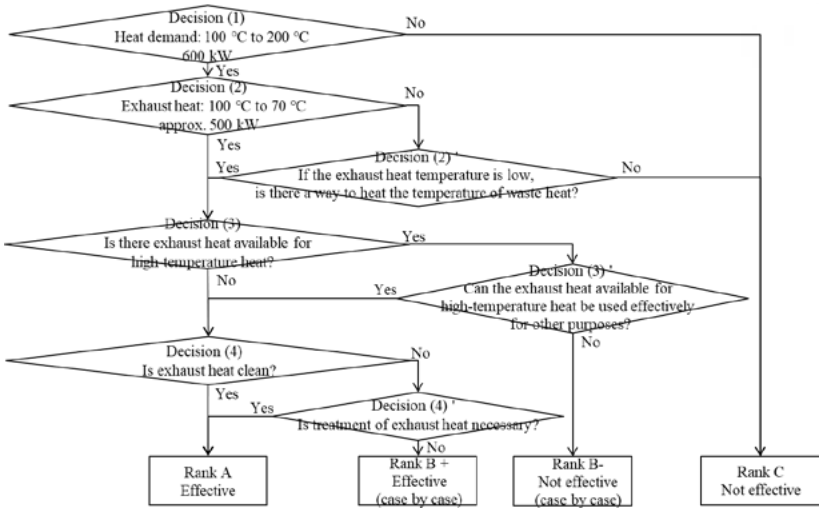

Fig. 1. Flow of assessment of introduction effect

Table 2. Survey results of the process introducing heat pumps

Business Type	Company	Process	Stability of temperature conditions/load		Rank	Remarks
			High temperature heat	Exhaust heat		
Ironmaking	A	Cleaning	200°C	200°C or higher	B -	Suitable heat demand, but too high temperature exhaust heat
Chemistry	B	Heating	135 ~ 190°C	100°C	A	Suitable heat demand and exhaust heat
Refuse incineration	C	Incineration	200°C	200°C or higher	B -	Suitable heat demand, but too high temperature exhaust heat
Sludge incineration	D	Incineration	200°C	200°C or higher	B -	Suitable heat demand, but too high temperature exhaust heat
Chemistry	E	Drying	120°C	35°C	C	Suitable heat demand, but too high temperature exhaust heat
Glass, earth and stone products	F	Drying	100°C or lower	-	C	Too low temperature heat demand
Rubber products	G	Mixing	100°C	40°C	C	Too low temperature heat demand
Chemistry	I	Distillation column	200°C	100°C	A	Suitable heat demand and exhaust heat
Chemistry	J	Rectification [distillation]	100~200°C	100°C	A	Suitable heat demand and exhaust heat
Chemistry	K	Sterilization, drying, distillation	100°C	40°C	C	Too low temperature heat demand
Machinery	L	Paint drying	120°C	100°C	A	Suitable heat demand and exhaust heat

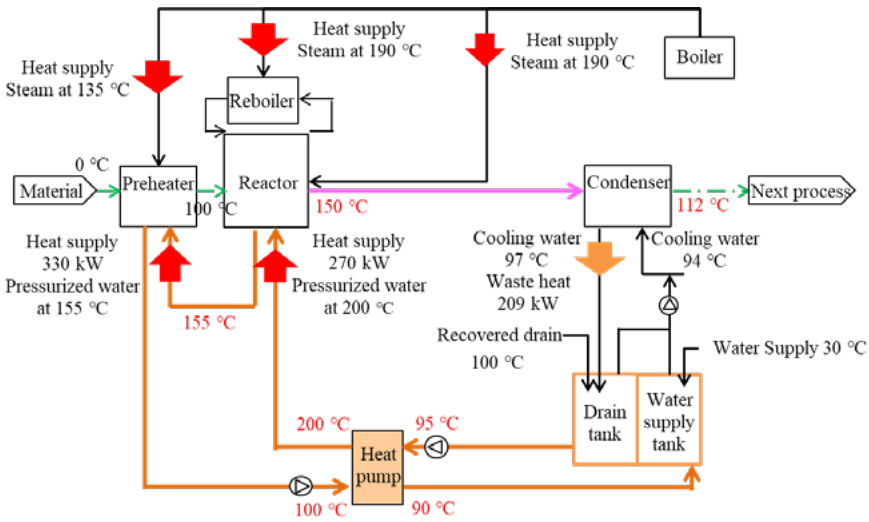

Fig. 4. Proposal for installation into the chemical process

3. Development of centrifugal heat pump heating pressurized water to 160°C

3.1. Selection of refrigerant

For the selection of a refrigerant, the operational temperature range of the heat pump must be considered, and physical properties suitable for the temperature range are required. This requires the following physical properties:

- Stability at high temperature: To prevent of isomerism and decomposition at the operating temperature of the heat pump.
- Standard boiling point: At the operating temperature, it is necessary that the design pressure of the equipment is not significantly high, and the compressor size is not too small to prevent a reduction in the adiabatic efficiency. Therefore, in high temperature, it is better to use a refrigerant which has a high standard boiling point.

R-134a is often used in existing centrifugal heat pumps, and Table 3 shows a comparison between R-134a and olefin refrigerants. If the olefin refrigerants is used for the 160°C heat pump, the refrigerant side pressure of the pressurized water in the heat exchanger can be reduced to approximately 3MPa(abs). It was confirmed that the thermal stability of R-1233zd(E) is poor at 175°C and 200°C. In addition, the internal pressure of the machine using R-1233zd(E) could be below atmospheric pressure when the heat pump is stopped; thus, the incoming air needs to be considered. However, as shown in Table 4, decomposition proceeds in a short period when air is added even at 150°C. Therefore, it is necessary to select R-1234ze(Z) or R-1336mzz(Z) to ensure the stability of the heat pump in the operating temperature range. The pressure on the refrigerant side of the high-pressure water heat exchanger of R-1336mzz(Z) is lower 37% (2.42MPa(abs)), the saturated vapor specific volume at 68°C is 54% higher, and the theoretical heating COP is 3.7% higher (3.61) than that of R-1234ze(Z). Therefore, the design pressure of the equipment is not too high, the compressor size is not too small, and the heat pump performance is expected to be improved. Thus, R-1336mzz(Z) is selected for the 160°C heat pump from the viewpoints of the thermal stability, design pressure, vapor specific volume, and theoretical heating COP.

Moreover, R-1336mzz(Z) is reported to have good stability up to 250°C and suitable for the 200°C heat pump [7].

Table 3. Comparison of R-134a and olefin refrigerants

Refrigerant	HFC	Olefins		
	R-134a	R-1234ze(Z)	R-1233zd(E)	R-1336mzz(Z)
Standard boiling point [°C] *1	-26.1	9.7	18.3	33.5

3.2. Selection of lubricant oil and elastomer materials

As with the refrigerant, the lubricant oil must be stable in the high temperature range, and the solubility and viscosity of the lubricant oil with the refrigerant also need to been evaluated.

As a first step, we investigated lubricant oil for the 160°C heat pump using R-1336mzz(Z). The synthetic oil is commonly used with non-chlorine refrigerants, such as HFCs. The polyol ester (POE) oil was therefore selected because of the stability for R-1336mzz(Z). Therefore, as shown in Table 5, we carried out the accelerated thermal stability testing at 220°C and 200°C in consideration of a 200°C heat pump also, and the stability at 220°C was confirmed. Moreover, kinematic viscosity is 175%, compared with the requirements for the bearings of the 160°C heat pump. Thus, we selected the lubricant oil with sufficient high-temperature stability, lifetime, and lubricating performance for the 160°C heat pump.

The POE oil has a kinematic viscosity of 101%, compared with the requirements for the bearings of the 200°C heat pump.

Table 5. Thermal stability testing of POE oil

Test condition*1		Result
Temperature [°C]	Duration [h]	Acid Value [mg kOH/g]
200	168	0.01
220	168	0.01
220	336	0.23
220	672	0.45
250	168	2.25

*1: R-1336mzz(Z)/oil: 50/50, air/moisture [ppm]: 100/1000

We carried out autoclave testing for suitability of the elastomer material and R-1336mzz(Z)/POE oil. Table 6 shows the change in weight, volume, hardness, and refrigerant hue for the test specimens. Those (PTFE, PEEK, EPDM, FKM, FFKM, etc.) were compatible with the R-1336mzz(Z)/POE oil. Thus, we selected the suitable elastomer materials for the 160°C heat pump.

Table 6. Compatibility testing of elastomer material with R-1336mzz(Z)/POE oil

3.3. Drop-in verification test

To verify the component validity for the 160°C heat pump, we modified the verification machine with R-1336mzz(Z) from 90°C hot water heat pump with R-134a. In addition, we designed and manufactured the verification test equipment, so that it could operate with pressurized water up to 200°C, and we conducted a drop-in verification test. Table 7 shows the specifications of the verification machine, Fig. 5 shows the heat pump cycle, and Figs. 6 and 7 show the external appearance.

The evaluation items were as follows.

- Verification test equipment: The test equipment could be operated stably even at 160°C for a pressurized outlet water.
- Aerodynamic performance of the centrifugal compressor: The performance was equivalent to the estimated performance evaluated for the 90°C heat pump using R-134a, even if the refrigerant was replaced from R-134a to R-1336mzz(Z) and the centrifugal compressor was designed for high temperature.
- Heat exchanger performance: The performance was found to be equivalent to the estimated value, even if the refrigerant was replaced from R-134a to R-1336mzz(Z).
- Mechanical loss: The loss of bearings, motors, etc., was the estimated value.

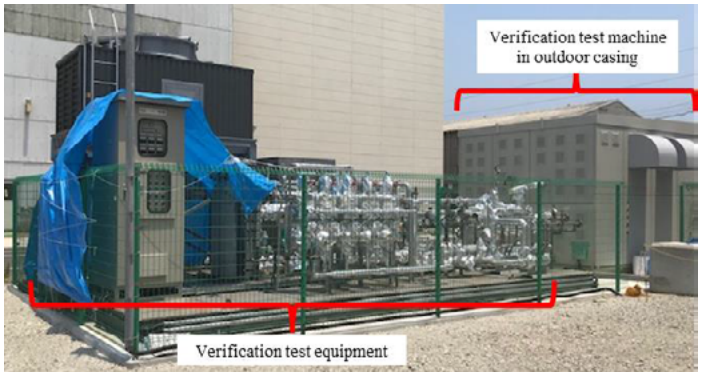

Fig. 7. External view of the verification test machine and equipment

Table 8 shows the result of the drop-in verification test. We confirmed that the verification equipment can be operated stably up to 160°C for pressurized water output, and that the performance of the heat exchanger is equivalent to the estimated value. However, there were discrepancies with regard to the estimated values for the compressor flow performance and the loss of motor. Therefore, after investigating the cause of the discrepancies, we has modified the verification machine as follows, and executed an additional drop-in verification test.

- Centrifugal compressor: To modify the shape, material and assembling method, in order to ensure a flow rate equivalent to the estimated value
- Motor: To modify the cooling system to control the motor temperature properly and the motor with high heat resistance to evaluate the characteristics of the deviation

Table 8. Results of element verification test

Items	Actual measurement value	Estimated value
Heating capacity	267.1 kW	
Hot pressurized water temperature	145.7 °C → 160.1 °C	
Hot pressurized water flow rate	16.9 m^3/h	
Heat source temperature	92.1 °C → 87.9 °C	92.5 °C → 87.9 °C
Heat source flow rate	34.1 m^3/h

3.4. Design of centrifugal heat pump

Heat pumps heating water to 90°C are applied for moderate high temperature, for example, for cleaning and food processes. However, there are thermal demands from 160°C to 200°C in industrial applications, for example, for chemical reactor and drying processes, etc.

160°C heat pumps need drain water as exhaust heat and we estimates exhaust heat (heat source water) temperature is less than 100°C. Therefore, two-stage compressors are planned to be arranged in series, so that one heat pump unit can operate even at the high differential pressure between the condenser and the evaporator.

The 90°C heat pump is adopted a two-stage compression economizer cycle. However, to obtain a higher COP, the two-stage compression bleeding cycle shown in Figs. 8 and 9 is adopted for a high temperature

heat pump [8]. In the case of a process in which the inlet temperature of the hot water can be lowered to the temperature of the heat source water (For example, it is used to raise the temperature of a medium from ambient temperature to high temperature.), the bleeding cycle is highly efficient because it uses some of the refrigerant gas discharged from the low stage compressor for intermediate heating.

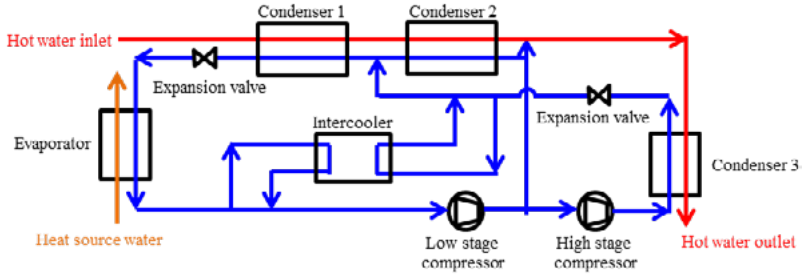

Fig. 8. Two-stage compression bleeding cycle

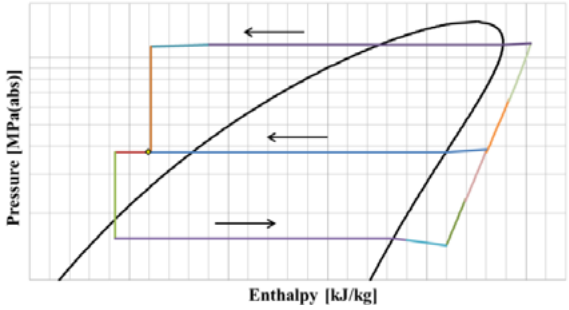

Fig. 9. P-h diagram of two-stage compression bleeding cycle

Table 9 shows the specifications of the 160°C heat pump. Under the conditions of a heating capacity of 600 kW, a hot water inlet/outlet temperature is 70°C/160°C, a heat source water inlet/outlet temperature is 80°C/70°C, and its COP is estimated to be 4.0.

Based on the results of the drop-in verification test, we are going to improve the accuracy of the estimated performance and expand the operational temperature range.

Table 9. Specifications for 160°C heat pump

Rated heating capacity	600 kW
Refrigerant,	R-1336mzz(Z)
Hot pressurized water temperature	70°C to 160°C
Hot pressurized water flow rate	6.0 m^3/h
Heat source water temperature	80°C to 70°C
Heat source water flow rate	40.5 m^3/h
Power consumption	146.7 kW
COP	4.0
Heat pump cycle	Two-stage compression bleeding cycle
Low and high stage compressors	Centrifugal two-stage compressor
Evaporator/condenser 1,2,3/intercooler	Brazing plate heat exchanger
Size L × W × H	3.6 × 2.0 × 2.5 m
Starting method	Inverter

4. Development of elements for centrifugal heat pump heating pressurized water to 200°C

We have been developing step by step 160°C and 200°C heat pumps with low GWP refrigerants. We will try to launch 200°C heat pump with pressurized hot water for practical applications by 2023.

As shown in Chapter 3, R-1336mzz(Z) may be a refrigerant candidate for 200°C heat pumps. A comparison of R-134a and R-1336mzz(Z) is shown in Table 10. The vapor specific volume @ 88°C of R-1336mzz(Z) is smaller at 94% than that of R-134a @25 °C. Under the condition of 200°C pressurized water and heat source water inlet/outlet temperature of 95/90°C, this may lead to be smaller compressor size and reduce in an adiabatic efficiency. Therefore, to prevent a reduction in an adiabatic efficiency, new refrigerant candidates that have a high standard boiling point and proper vapor specific volume for a 200°C heat pump must be selected. The candidates have GWPs of 20 or less and are stable at high temperature. We continue to examine toxicity, cycle characteristics, etc., and will evaluate whether or not to apply to a 200°C heat pump.

For the heat pump cycle of 200°C pressurized high-temperature water, we are going to adopt a two-stage compression bleeding cycle capable of achieving a COP of 3.5 or more, as with the 160°C heat pump.

Table 10. Comparison of R-134a and R-1336mzz(Z)

Refrigerant	Existing		New	
	R-134a	R-1336mzz(Z)	Candidate A	Candidate B
Standard boiling point [°C] *1	−26.1	33.5	During evaluation	
Saturated vapor specific volume @ 25 °C [m^3/kg] *1	0.0309	-		
Saturated vapor specific volume @ 68 °C [m^3/kg] *1	-	0.0496		
Saturated vapor specific volume @ 88 °C [m^3/kg] *1	-	0.0291

5. Conclusion

In response to the industry demands to decrease CO_2 emissions, we are developing 160°C and 200°C heat pumps with pressurized water at 100°C or higher and low GWP refrigerants.

As a result of investigation of the effective process to install the 160°C or 200°C heat pumps, we estimated that primary energy consumption could be reduced by 14%, running costs by 32% for painting drying process, and primary energy consumption by 7%, running costs by 23% for chemical process.

The 160°C heat pump with a heating capacity of 600kW is being developed with an existing refrigerant R-1336mzz(Z), which has a GWP of 2. R-1336mzz(Z) has low GWP, non- flammability and low toxicity, making it a suitable refrigerant for industrial heat pumps. In addition, under the conditions of hot water inlet/outlet temperature of 70°C/160°C and heat source water inlet/outlet temperature of 80°C/70°C, a two-stage compression bleeding cycle in which COP is improved was adopted, it is estimated to achieve COP is 4.0. Furthermore, a drop-in verification test has been started, and the additional drop-in verification test will be executed after modification of the verification machine, and we are going to improve the accuracy of the estimated heat pump performance and expand the operational temperature range.

We are also considering the use of a new refrigerant with a high standard boiling point for the heat pump heating pressurized high-temperature water to 200°C. The refrigerant candidates have GWPs of 20 or less and are stable at high temperature. We are going to continue to examine the toxicity, cycle characteristics, etc. of the refrigerant candidates for the 200°C heat pump. In the future, we will select a suitable refrigerant for the 200°C heat pump. A two-stage compression bleeding cycle has been adopted with the target of COP 3.5 and over, and we will carry out the element design and drop-in test, and proceed with the development of the high temperature heat pump.

Today's one million heat pumps are already in essential role in smart energy transition towards carbon neutral Finland

Jussi Hirvonen*

*Finnish Heat Pump Association SULPU ry, Laivurinkatu 13 as 3, 06100 Porvoo, Finland

Abstract

Finland reached one million heat pump installations in year 2019. Heat pump sales and stock in relation to population of 5.5 million is one of the biggest in the world. Heat pumps produce as much as 15% (>10TWh/a) of Finnish heating. Investments in heat pumps now amount to EUR 6 billion. The decarbonisation impact of heat pumps already over 2 million tons CO2 eq. Reasons behind this success story may be useful to understand. Good circumstances such as cold climate, moderate electricity prices, lack of gas network and good drilling conditions help create a very successful heat pump market without subsidies. But very active lobbying and market creating activities by the national heat pump association cannot be overemphasised, along with taking care of sufficient and appropriate information flow to all parties. The quality issues of products and installation have also been all the time under a critical eye. Finnish success story continues. According to recent studies, in 2030 heat pumps will produce 22 TWh/a with those 2 million heat pumps. The Finnish government has decided recently that Finland will be carbon neutral in 2035. In a large Finnish Smart Energy Transition research project a very challenging 35 TWh/a target has been set for heat pumps in 2040.

Keywords: Heat pump market;Finland;lobbying;Heat pump association;market drivers;Smart Energy Transition

1. Introduction

The significance of heat pumps has grown in Finland in the heating of single-family houses, multi-storey buildings as well as large service-facility buildings such as shopping centres and logistics centres. Also, the use of heat pumps is continuously increasing in heat-recovery and process solutions as well as in the production of district heating and cooling. The role of heat pumps as a producer of Finnish renewable energy is much greater than that of, e.g., solar and wind energy.

This article describes the size, development and structure of the Finnish heat pump market as well as its special characteristics. This market has also been adjusted in line with the heat-pump market in other European countries.

The Finnish heat pump market has increased a thousand-fold over the past couple of decades. Annual heat pump purchases made by individual people, worth EUR 600 million in 2019, form the biggest Finnish investment in renewable energy.

This article looks also at the drivers that have had, and still have, an impact on the success of the heat pump sector, and it considers whether those drivers can be influenced. The experiences of the rapid market development in Finland and an analysis of the market drivers, as well as the possibilities to influence those market drivers, may provide a basis for the development of the heat pump market in countries where the significance of heat pumps is not yet this great.

In 2035 Finland should be carbon neutral. For this purpose a study has been published which estimates that heat production by heat pumps should be increased to 38 TWh/a by 2040. In the Finnish heating system district heating plays a very big role, about 50% of the Finnish heating market. Decarbonisation of the heat market by

* Jussi Hirvonen. Tel.: +358 50 500 2751.
E-mail address: jussi.hirvonen@sulpu.fi.

heat pumps means a lot of heat pumps in the production of district heating but also saving district heating and other heat production by enormous amounts of heat pumps installed locally in individual houses.

2. The Heat Pump Market in Finland

2.1 Special Characteristics of the Finnish Heat Pump Market

On a European scale, the Finnish heat pump market is big and quite unique. When looking at the number of heat pumps per type, the heat pump market is dominated by air-source heat pumps, whereas ground-source heat pumps lead the market when looking at the figures in Euros. 75% of single-family house builders choose a heat pump. In over 50% case the choice is Ground Source Heat Pump. Heat is already being extracted from 150 000 geothermal wells, the combined depth of which totals half of the earth's circumference, i.e., 20,000km.

300,000 owners of houses where heating is based on oil and hydronic electricity have not yet replaced their heating with a heat pump even though the return on capital invested is, almost always without exception, 10%/a. More than half a million people who use electric heating are wondering whether the affordable electricity price of 12 cents per kWh will increase.

Efforts have been made to start saving energy also in district heating that has been produced with combined power and heat production (CPH) or other means. This happens more and more often with exhaust-air heat pumps that have been installed in apartment houses and office buildings. Big buildings are also increasingly replacing district heating entirely with ground-source heat pumps. New, large shopping and logistics centres increasingly use large geothermal fields for cooling and heating instead of district heating. The largest geothermal site in Finland, a logistics centre, has 316 geothermal wells, each 300 metres deep, totalling 100km of drill holes.

The role of cooling in the Finnish climate is not great. However, the demand for it in housing, too, has increased due to living-comfort reasons as well as nearly zero-energy buildings. This is beginning to have an impact on the profitability of investments, since heating and cooling is provided through the same investment.

The most important reason behind the success is clear, yet this reason is also distinctive on a European scale. Heat pump systems are a very profitable investment. The return on capital invested is often 10-15%/a. The Finnish government does not offer so far any subsidy to heat pumps apart from the household tax deduction that can be claimed for the installation work of a heat pump.

Heat pumps are easy to use, they are carefree, they require little space and they have a cooling feature. These are arguments that also speak in favour of choosing a heat pump. Affordable electricity, the lack of a gas network, the high consumption of heating energy that is caused by the Nordic conditions, a suitable bedrock for drilling, the customer-friendly heat pump system supply all create favourable preconditions for profitable investments.

2.2. The Finnish Heat Pump Market Is Big, Even on a European Scale

2.2.1 Over 10 TWh per year production with 1,000,000 Heat Pumps

At the end of 2019, the cumulative sales of heat pumps heat reached the limit of one million pumps. We must remember that Finland is a country with a population of only 5.5 million people. A heat pump is by far the most popular form of heating in new single-family houses, and heat pumps are rapidly replacing oil and electric heating as well as district heating in old buildings.

At the end of 2019, as many as 1,000,000 heat pumps have already been sold in Finland. Their total annual output is more than 10 TWh which corresponds to over 15% of the heating of Finland's residential and service building stock. About 7 TWh of renewable energy and waste heat is recovered annually and used in heat pumps [1]. It is noteworthy that this huge investment in the environment and in fighting against climate change has been made mainly by house owners using their own money. The excellent profitability of heat pumps has made consumers' decision-making easier. People have also started to understand the significant role of heat pumps in heat decarbonisation and demand response.

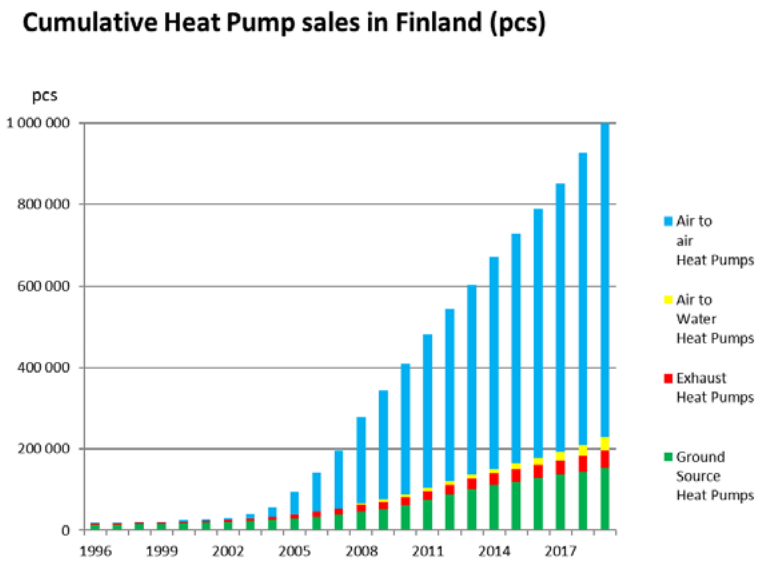

Fig. 1 Number of Heat Pumps Installed in Finland, Cumulative 1996-2019 [1]

75% of single-family house builders choose a heat pump as their main heating system. 53% choose a ground-source heat pump, which apparently is a world record of its own in new construction. Just over 15% of builders choose an exhaust-air heat pump, and approximately 5% choose an air-to-water heat pump. Furthermore, electrically heated houses are most often being fitted with air-source heat pumps as an electricity-saving and cooling fixture.

The greatest potential for heat pumps, however, lies in the already-existing houses. 200,000 oil boilers, more than 100,000 hydronic electric heating users, and 500,000 direct electric heating users most often pay double or triple the price for their heating energy as compared to heat pump heating. With the current interest rates, not making the decision to invest in a heat pump shows only ignorance.

The value of about 100 000 annual heat pump system deliveries is EUR 550 million. When the megawatt-size heat pump systems for district heating/cooling production, industry, shopping centres, and other service buildings as well as other ancillary operations such as planning, delivery supervision, maintenance, and other services (not yet included in the SULPU statistics) are added, the heat pump sector reached annual investment levels exceeding half a billion in 2019. This meant approximately one extra TWh per year to CO2-free heat production. It should be noted that most of this investment consisted of investments made by individual consumers using their own money, as it was a good investment for them.

The heating business concerning residential and service buildings amounts to between 70 and 80 TWh per year. Of this already 15%, over 10 TWh per year, is clean, individual heating generated by heat pumps. This has been achieved through Finland's close to one million heat pumps, in which consumers have invested EUR 6 billion. Heat pump investments in the production end of district heating and cooling as well as in industrial waste heat recovery are also growing.

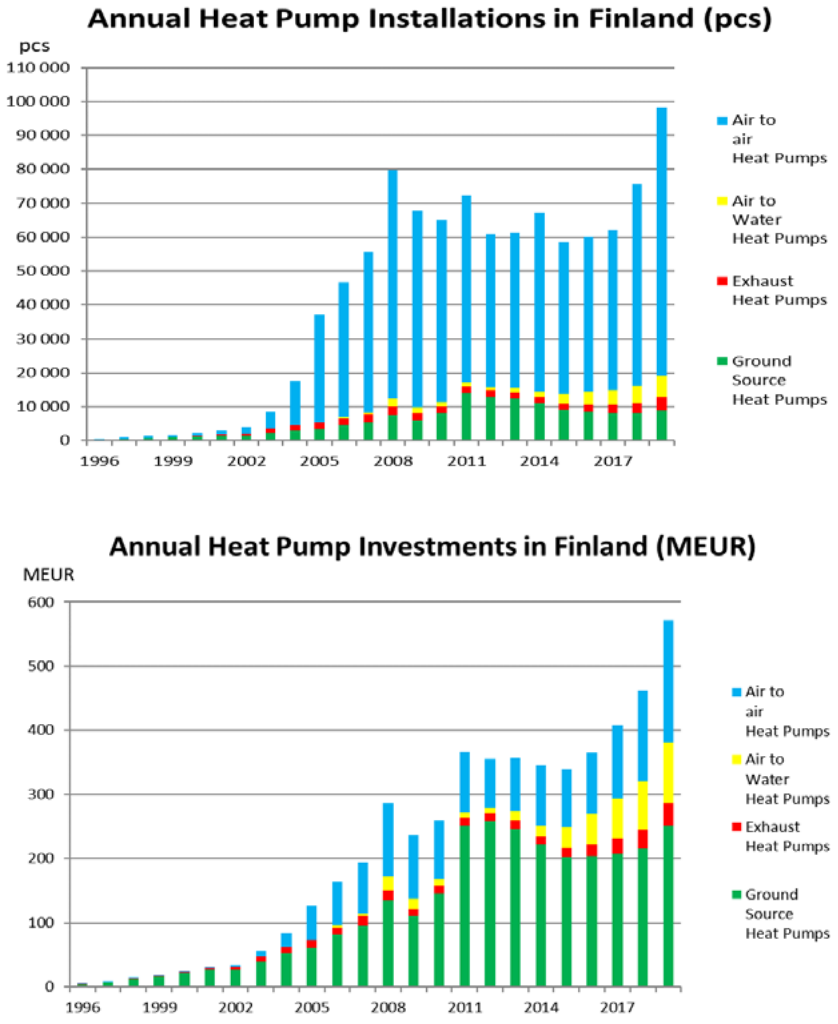

Fig. 2 Heat Pumps Installed in Finland per Type of Heat Pump; Quantities and in Euros, 2005-2019 [1]

2.2.3 On a European Scale, the Heat Pump Market Is Big

When comparing the success of the heat pump market in European countries, the market must considered in proportion to the population or to the number of houses. In the EHPA, the European Heat Pump Association, statistics of 2018, Table. 1, the sales volumes have been presented in proportion to the number of households.

When looking at Fig. 3, two main observations can be made. Firstly, there are roughly three groups of countries. The first group comprises Northern European countries: Norway, Estonia, Finland, Sweden, and Denmark. All of these countries boast sales of more than 20 units per 1,000 households. After these countries, there is rather a large gap. The second group is led by France with sales of 9.5 heat pumps per 1,000 households, followed by Switzerland (9.3), Lithuania (9.0) and Italy (7.8). The last group, mainly Central European countries, is characterised by very low heat-pump market shares, or in other words, very high potential. [2]

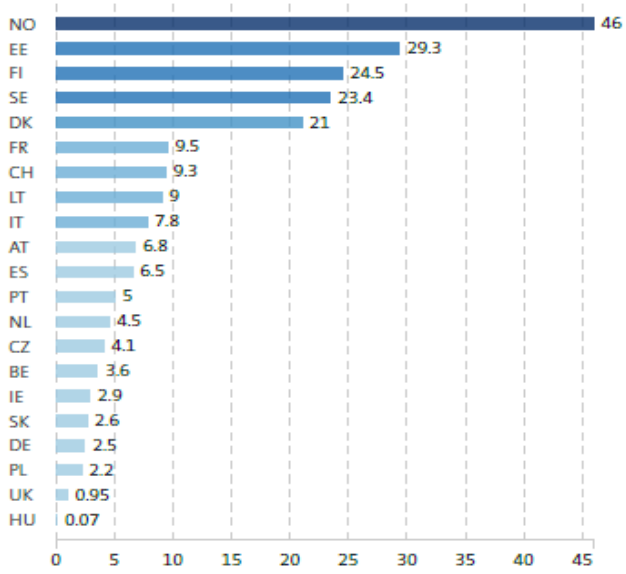

Fig. 3 Heat Pump Sales in Europe per 1000 Households, 2018 [2]

2. Market Drivers and How to Have an Impact on Them

The prerequisites for heat pumps in Finland are excellent. In a cold climate, a lot of energy is needed. In a typical single-family house, the usual annual consumption for heating and domestic hot water is 15,000-25,000 kWh of electricity or 2,000-3,000 litres of oil. Since Finland is a big country with a small population of 5.5 million, having e.g. a comprehensive gas network is unprofitable. The lack of this competitor favours heat pumps.

When considering the recent general developments in the construction business, the heat pump business has clearly strengthened its position in the heating and cooling of houses. However, it is only in the early stages of its success. The direction of the heat pump market development is clear, but the right type of advocacy, lobbying, will have an enormous impact on the degree of this development. The real market drivers have to be identified the means as well with which to influence them. The areas of this lobbying are multifaceted and, therefore, here are a few examples of current, genuine sectors in which lobbying is conducted in practice.

The heat pump market has increased a thousand-fold in Finland for 20 years. It is necessary to investigate the true market drivers and to consider whether they can be influenced and how.

3.1 Profitability

The most important of them is certainly profitability. The investor is a consumer, the user of energy, a house owner, most often a private individual. They must, at least, get the feeling that they are getting a sufficient return on their investment.

This they very often get in Finland. Fig. 3 shows the investments and the savings in both energy as well as in Euros for different types of heat pumps, indicating the price levels of 2019, in single-family houses as compared to electricity and oil heating. Approximately the same investment and savings ratios are reached with larger facilities where the comparison is usually with district heating.

Table. 1 Savings and Investments of Various Heat Pump Types in Single Family Houses [1]

Heat-pump type	Savings per year, kWh	Savings per year, €	Investment, €
Ground-source heat pump	14 000…17 000	1 800…2 200	14 000…20 000
Air-to-water heat pump	8 000…13 000	1 000...1 700	8 000…12 000
Exhaust-air heat pump	3 000…7 000	400…800	6 000…10.000
Air-source heat pump	2 000…7 000	250…800	1 500…2 500

Is it possible to have an impact on profitability? Yes, it is, at least on a long-term basis. As the market grows, market mechanisms bring system investments to the right level. Various subsidies are, in practice, always temporary and may boost the market for a short while but should not be allowed to disturb market-based development in the long run.

The profitability of heat pumps is very dependent on the price of fuels, electricity and district heating. In any case, they include a lot of taxes. Having an impact on these taxation structures is possible in the long run. Indeed, this is one of the foremost objectives of lobbying for the Finnish heat pump industry. For instance, by taking away the tax subsidy for fuel oil and by putting it in the same tax class as diesel transport fuel, heat pumps would receive a 20-30% leap in profitability. This is, after all, what our neighbour Sweden already did in the 1990s. The flourishing of the heat pump business that this, in part, created is something that we as a neighbouring country have been left to envy for a couple of decades now already.

Furthermore, the increase of electricity-price taxation would suit the heat pump business, since the competitiveness of heat pumps would improve in 700,000 electrically heated houses and almost 500,000 holiday homes.

3.2 Information, Communication and Visibility

Consumers, decision-makers and politicians must all have the most accurate information as possible and as much of it as possible. If they do not know that the profitability of heat pumps is excellent, business will not flourish, nor will heat pumps feature in discussion agendas, nor will they be acknowledged in regulations, law, rules or instructions.

Here, if anywhere, is the place for advocacy, for lobbying. The Finnish heat pump interest organisation, the Finnish Heat Pump Association SULPU, has extensively focused on providing this information, both qualitatively as well as quantitatively, in various media, such as the press, TV, radio, social media, with presentations, panel discussions, statements, and expressions of opinion. Regarding the development of the heat pump market, it is also very important to participate in the preparatory work of regulations, laws and instructions in ministries.

The principal messages when relaying this information must be carefully chosen and repeated systematically in the media, regardless of the channel of communication. A heat pump is profitable, the return on capital invested is excellent, it improves Finland's current external balance, it offers employment, and is a major and profitable environmental act. These arguments must be expressed repeatedly in all communication.

There is never enough of this type of lobbying, influencing. Nevertheless, it has been rewarding in Finland and can be seen in the development of the heat pump market.

3.3 Surveys Are the Best Fuel for Lobbying, Increasing Information, and for Quality

The heat pump business has carried out and participated in surveys that shed light on the possibilities of heat pumps and prospects. Here are three survey examples in which the heat pump industry has been involved and has used in its lobbying.

According to a survey conducted by the independent consultants Gaia Ltd, a total of EUR 12 billion will be invested in heat pumps by 2030, creating approximately 3,000 new jobs in the field. By then, heat pumps will be producing 22 TWh/a, 15 TWh of which is renewable energy that is extracted from around the building. These investments will also have a billion-class effect on Finland's current external balance and the value of

its building stock. [3] The breath-taking result of this survey has brought heat pumps a lot of credibility and weight now when, e.g., the Finnish Climate and Energy Strategy is being prepared.

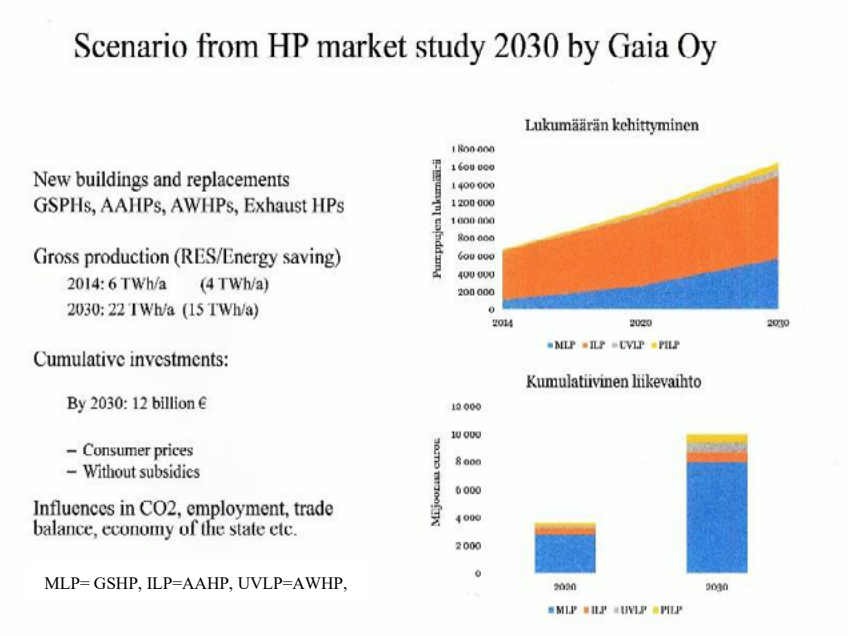

Fig. 4 The Role of Heat Pumps in 2030 [3]

Also, a study of how much exhaust air heat pumps can save of district heating in an apartment building. More than 30,000 apartment buildings release exhaust air that is warmer than 20 degrees Celsius. The entire air volume of the building is changed once every two hours, and that air vanishes up into thin air. Therefore, exhaust-air heat pumps have gradually become more common also in apartment buildings. About 2,000 apartment buildings have already been fitted with a heat pump that retains the heat of the exhaust air. This reduces even as much as 50% of the district-heating or other energy consumption of the building. After the fitting of this heat pump, it is also often decided that the remaining energy need will be covered with a ground-source heat pump, and district heating becomes redundant. Finnish Energy Industry, with the support of the heat-pump industry, commissioned VTT Technical Research Centre of Finland Ltd to study the effects of exhaust-air heat pumps on the district-heating network as well their market potential (3-5 TWh /a) [4].

There are 600,000 air-source heat pumps in Finland, and approximately 50,000 more are installed every year. It is common knowledge that in a Finnish house they save money, they cool the building, they work, and people buy them. There was no reliable information available as to how much energy they extract from around a building. That's why a study on the Energy Saving Potential of Exhaust Air Heat Pumps in Single Family Houses was performed a couple of years ago. Commissioned by the Ministry of the Environment and the heat-pump industry, VTT Technical Research Centre of Finland Ltd modelled an air-source heat pump for the heating system of a few houses and studied their energy-consumption effects in old, new and in the upcoming nearly zero-energy single-family houses. For the first time now, it has been possible to reliably define, in figures, the energy-saving potential of an air-source heat pump in Finnish conditions. The study took into consideration, in detail, the characteristics of the heat pumps and the buildings [5]. The result of this complicated and challenging modelling was that air-source heat pumps can provide 40-60% of the heating of a single-family house. The authorities, constructors and single-family house inhabitants will benefit from these results. These results have been used, e.g., in the nearly zero-energy buildings (NZEB) regulations that will be finalised shortly. Naturally, these results have been used to acquire lots of positive visibility in the Finnish media.

4. Summary

The heat-pump industry has become a significant renewable-energy business in Finland. 1,000,000 heat pumps produce over 10 TWh/a of energy, over 7 TWh of which is energy that is extracted from around the building. This already represents as much as 15% of the heating energy of all Finnish buildings. The prospects for heat pumps are good. The market will certainly develop in the future. The heat pump business can be described as an integrator that operates amidst and between renewable energy, electricity, and heating and cooling production. Heat pump technology and its applications can also be seen as an interface to a carbon-free age.

This paper looked at the Finnish heat pump market, at market drivers and whether they can be influenced. The heat pump industry market drivers must, indeed, be identified in order to be able to influence them. Finnish heat pump industry market drivers include profitability, the quality and quantity of information and communication, visibility, study results, and the quality of operations. It is certain that the significance of the heat pump industry will become greater. However, the degree of that significance can be influenced by influencing these drivers.

Profitability is affected by not only investments but also by the price of energy. The state taxes both fuels as well as electricity heavily. The structure and the scale of taxation are not, however, carved in stone. Taxing of CO2 releases must be accelerated.

The quality and quantity of information and communication as well as visibility have an immediate impact on the market. Increasing these is challenging in terms of resources, know-how and shaping the media environment. It has, however, proved to be possible and rewarding. Research that supports the development of the heat pump industry, research that is preferably conducted close to the market interface, plays a significant role in the management of this information. Developing quality and training schemes alongside the development of the heat pump market is important, and it is also a means for lobbying.

All too often, the importance of lobbying is forgotten, even though it is a very essential aspect in creating the preconditions for a new industry. The material required for lobbying, and the vision and goal for the heat pump industry, can be acquired from, e.g., surveys that are conducted by independent consultants. But also, close co-operation and communication on an international (IEA HPT TCP) and European scale (EHPA) and, of course, at a wider national level provide the basis for lobbying.

According to one of those above-mentioned independent surveys in 2030, there will be 2 million heat pumps in Finland producing 15 TWh worth of renewable energy. By then, a total of EUR 12 billion will have been invested in heat pumps, and 3,000 new jobs will have been generated. The savings that will have been made will by then be in the region of one billion euros per year.

More pressure or possibilities for heat pumps have been created by the political promise to make Finland carbon neutral by 2035. For this purpose, the Smart Energy Transition consortium has published a study estimating that heat production by heat pumps should be increased to 38 TWh/a by 2040 [6]. In the Finnish heating system district heating plays a very big role, about 50% of the heating market. Decarbonisation of the heat market by heat pumps means a lot of heat pumps in the production of district heating but also saving district heating by heat pumps installed locally in individual houses.

After fulfilling one million heat pump vision in 2020, the next target of two million heat pumps can be set for 2030.

Abstract

The reduction of operational heating costs by deploying the building flexibility is investigated using a predictive rule-based control and building simulations. This paper focuses on the applicability of a proposed price-based control strategy in different buildings and climate zones where also electricity spot prices differ. More specifically, the operational costs of a heat pump system in a Norwegian and Swiss residential single-family house are compared. The aim of the price-based control is to shift the operation of an air-to-water heat pump to times when electricity spot prices are low. The results show, that the success of the control strategy with regard to operational cost savings is highly dependent on the hourly fluctuations of the electricity spot price. Furthermore, it is shown that also the design of the heating system as well as the chosen temperature set-points of the control influence the outcome substantially. Results show, that a 5% cost reduction can be achieved even though the electricity use increases.

Keywords: heat pump system; price-based control; capacity-controlled heat pump

1. Introduction

With the growing share of renewable energies in the electricity mix, demand side flexibility gets more important to enable the full potential of the renewables [1][2]. Heat pumps are more often applied to heat buildings and their share among other building heating systems is growing, especially in highly energy-efficient buildings [3]. The application of capacity-controlled heat pumps has become more common during the last decade as the increased efficiency during part-load operation leads to distinct benefits compared to on-off heat pumps. Detailed studies on heat pump systems are usually performed for one specific country, whereas there is a lack of studies that evaluate similar control approaches for heat pump systems for different countries.

Clauß et al. [4] tested different price-based control strategies for heating a residential building located in Norway. In their study, they evaluated price-based heating control strategies for different building insulation levels. The implemented price-based control aims at reducing operational costs by deploying the energy flexibility potential of the building. To evaluate how the heating strategies proposed by Clauß et al. work for the Swiss climate and Swiss national boundary conditions, the control strategies are applied to a Swiss building. The Swiss building is described in detailed in Rominger et al. [5], where different building insulation levels and thermal masses have been applied to the Swiss building.

2. Methodology

Two different residential buildings have been simulated. In a previous study, Clauß et al [4] studied a Norwegian residential single-family house using the dynamic building performance simulation tool IDA ICE

* Corresponding author. Tel.: +41 55 222 43 25
E-mail address: carsten.wemhoener@hsr.ch

Version 4.8 The Swiss residential building is simulated using Matlab Simulink and the CARNOT-toolbox [6]. A brief comparison of both buildings in presented in Table 1.

It is mentioned here that there are distinct differences for the building and heating, ventilation and air-conditioning (HVAC) system models for the original Norwegian study and the study performed in this paper. The main differences are the building location, the building size and thus the load profiles and the layout of the HVAC system. The original work of Clauß et al. [4] considers a water tank for space heating (SH). In this study, the heat pump is in many cases connected directly to the floor heating (FH) system.

However, the same heat pump, HOVAL Belaria SRM 4, is chosen for both studies. To be able to provide a meaningful comparison of the results from this work and the previous work by Clauß et al. [4], the U-values of the building envelopes are aligned, as also shown in Table 2. The same price-based control strategies are implemented in both studies to research the effect of the spot price signals on the operational costs. Furthermore, the temperature set-points (TSP) for SH and domestic hot water (DHW) heating are varied (1) within the same range (+10 K; -5 K for DHW) to compare both case studies and (2) within a lower range (+3 K; -3 K for DHW) to also show the influence of TSP choices on the energy system performance and operational costs. The TSP for SH depends on the fact whether a SH storage tank is used or not.

Table 1. Comparison of the case study buildings.

Parameter	Unit	Norwegian (Clauß et al. [4])	Swiss

2.1. Building envelope

The characteristics of the building envelope are according to the Norwegian passive house (PH) standard for residential buildings, NS 3700 [7]. This building standard also requires a balanced mechanical ventilation with a heat recovery effectiveness of the air handling unit of 85% at nominal conditions. The constant air volume ventilation has a nominal air flow rate of 120 m^3/h and a supply temperature set-point of 19 °C. The Norwegian PH building is a wooden lightweight building. For the Swiss PH, the same building structures are used as for the Norwegian PH, but the geometry of the building remains the same. However, the basement of the Swiss PH is a concreate construction. The Swiss heavyweight construction (HC) building is designed to meet the new building requirements of Switzerland MuKEn 2014 [8]. Except for the roof, everything is in heavyweight construction. Table 2 summarizes the building envelope and HVAC characteristics.

Table 2. Insulation level and HVAC characteristic

Component	Parameter	Unit	Building insulation type		
			Norwegian	Swiss	
			PH	PH	HC
Building envelope	$U_{exterior\ Wall}$	W/(m²K)	0.10	0.10	0.16
	$U_{inner\ Wall}$	W/(m²K)	0.34	0.34	0.70
	$U_{Basement\ Wall}$	W/(m²K)	-	0.17	0.17
	U_{Roof}	W/(m²K)	0.09	0.09	0.15
	U_{Floor}	W/(m²K)	0.09	0.09	0.71
	$U_{Floor\ Basement}$	W/(m²K)	-	0.17	0.17
Infiltration	$V_{dot,i}$	ACH	0.6	0	0

	$Q_{dot,Aux,DHW}$	kW	3	0	0
	$Q_{dot,Aux,SH}$	kW	9	0	0
SH needs	Q_{SH}	kWh/(m²yr)	34	19	27

2.2. HVAC system

The HVAC systems of the previous work by Clauß et al. [4] and this case study are slightly different. The main difference is the use of a SH tank. In this case study, two system layouts have been considered: (1) the heat pump is directly connected to the heat distribution system and (2) the heat pump is connected to a SH tank, like in the Norwegian study.

The HVAC system simulated in this study consists of an air-source heat pump that is connected to a DHW storage tank, while the heat pump is directly connected to a FH system to provide SH. The heat pump runs at full load in DHW mode, whereas it modulates between 30 % and 100 % of the nominal compressor capacity in SH mode. Regarding DHW mode for the Norwegian case study, at the beginning of a heat pump cycle the heat pump is operated at full load and the mass flow through the circulation pump is adjusted by a P-controller to meet the temperature set-point at the condenser outlet. As soon as the mass flow is at its maximum, the speed of the heat pump compressor is adjusted to stay close to the required DHW temperature set-point. In the Swiss building the DHW storage is charged by step-charging with a constant mass flow. For the SH, the mass flow is kept constant for both building cases while the heat pump modulates to achieve the required floor heating supply temperature. For the Swiss case study, the FH supply temperature is kept constant throughout the whole year and is not dependent on the outdoor air temperature. A simplified sketch of the heating system configuration is presented in Figure 2.

For the case where a SH tank is used, the volume of the SH storage tank is aligned to the volume of the previous Norwegian case study, being 243 liters (l). However, the DHW storage tank of the Swiss buildings has a chosen capacity of 500 l, compared to 215 l for the Norwegian case study. To ensure a minimal tapping temperature of 45 °C, the heat pump switches on as soon as the temperature at a relative tank height of 0.8 drops below 50 °C. The heat pump is switched off again as soon as the temperature of 50 °C is reached at a relative tank height of 0.4. For the Swiss building, the internal heat exchanger is placed at the bottom of the DHW storage tank. The same strategy as for the DHW storage tank is used for the SH storage tank with a temperature set-point of 30 °C and relative heights of 0.8 and 0.2. For the cases without a SH storage, the heat

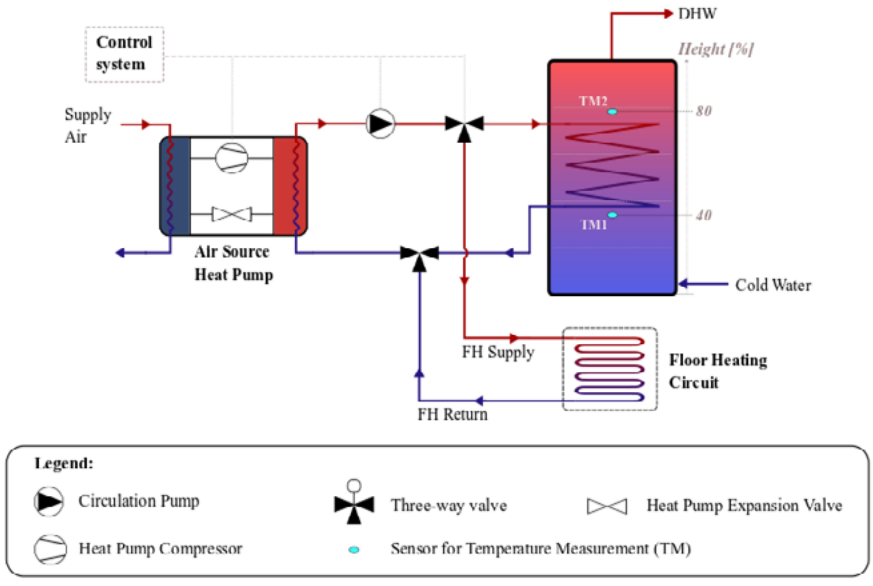

Figure 2. Configuration of the heating system

pump is switched on based on the room temperature. The temperature set-point (TSP) of the room is 21 °C with a hysteresis of 2 K.

2.3. Power sizing

The performance map of the selected air-source heat pump HOVAL Belaria SRM 4 is shown in Figure 3.

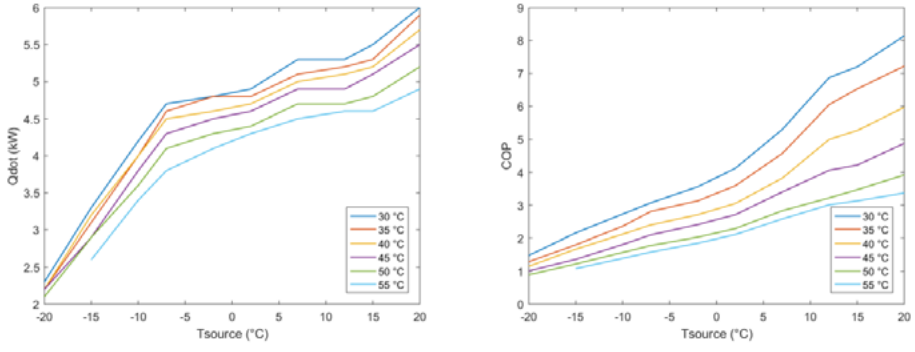

Figure 3. Performance map of HOVAL Belaria SRM 4 at 100 % compressor speed

The heat pump is designed for a monovalent operation, but it can be used as a bivalent/mono-energetic system where an auxiliary heater would cover peak loads. In Switzerland, a heat pump is designed for monovalent operation according to the building regulation, which does not allow bivalent heat pump systems with a direct electric heater. In Norway, a heat pump system can also be sized as a bivalent system. This difference will be important when comparing the price-based controls of both studies in Section 5.

For all cases, the same heat pump is used, although the heat pump is generally oversized for the PH cases. However, since there are no heat pumps on the market, which are significantly smaller than the chosen one, it seems to be a realistic assumption that this heat pump can also be applied to PH cases.

To simulate the inverter-controlled behavior, the heating capacity of the heat pump can be controlled from 30 % to 100 % of its maximal capacity, while the mass flow of the floor heating circuit is kept constant. The detailed control strategies are described by Clauß et al. [4] and Rominger et al. [5]. For the sake of simplicity, the COP increase during part-load operation is not modeled. The COP is held constant over the whole part-load range.

2.4. Boundary conditions

Weather data as well as electricity spot prices were taken for one year. In the previous study by Clauß et al. [4], simulations were performed for the year 2015, whereas this Swiss case considers the data for 2018. By using spot prices and weather data from the same year, it can be ensured that possible weather dependencies of the electricity price are taken into account.

For the Swiss cases the internal user profiles for occupancy and electric appliances (including lighting) are taken from the Reference Framework for System Simulations [9]. However, these profiles are scaled according to the pre standard SIA 2024 [10] for single-family houses.

Based on Fanger`s Predicted Mean Vote (PMV) / Predicted Percentage Dissatisfied (PPD) method, it is assumed that indoor operative temperatures can be varied between 20 °C and 24 °C while still keeping a similar comfort level. According to EN15251:2007 [11], this temperature range corresponds to $-0.5 < PMV < 0.5$ and a $PPD < 10\%$ for a clothing level of 1.0 and an activity level of 1.2 MET.

3. Simulation scenarios

3.1. Reference strategy

In the reference case, called business as usual (BAU), temperature set-points for DHW heating and SH are kept constant at all time at 50 °C and 21 °C, respectively. Constant temperature set-points are chosen for the reference scenario, because heating systems in residential buildings are usually controlled in this way.

3.2. Control Strategy Price, CSP

This work investigates demand response scenarios, where the DHW and SH set-points are modulated depending on the hourly spot price. Electricity spot prices vary throughout the day, which means that operational costs could be reduced, if a heating system is operated during low-price periods and/or if the operation during high-price periods is avoided. The TSPs for SH are either increased by 3 K or decreased by 1 K depending on the current spot price and the spot price trend for the next 24 hours. In the case without a SH storage, the switch-off hysteresis is decreased by 1 K during high-price periods. Therefore, the heat pump switches off earlier. On the contrary, the temperature set-point is increased by 1 K during low-price periods. Two temperature ranges for TSP variation are investigated for DHW: (1) the TSPs for DHW heating are increased by 10 K or decreased by 5 K, or (2) the TSPs are increased or decreased by 3 K respectively. The capacity control of the heat pump is not affected by the price signal.

To generate the price-based control signal, two principles are applied and compared, control strategy price principle (a), CSP-a and principle (b), CSP-b. Both principles are illustrated in Figure 4 [4]. The spot price of the prospective 24 hours can be divided into three price segments (i.e. low, medium and high price segments) using two price thresholds. The heating set-points can then be adjusted based on the spot price of the current hour relative to the price segment. A 24 hours sliding horizon is considered to determine a low-price threshold (LPT) and a high-price threshold (HPT). The determination of the thresholds follows the approach presented in [4]: describing the maximum and minimum spot prices for the next 24 hours as SP_{max} and SP_{min}, the HPT can be determined by $SP_{min} + 0.75\ (SP_{max} - SP_{min})$ and the LPT by $SP_{min} + 0.30\ (SP_{max} - SP_{min})$. The choice of thresholds is important for the operation of the heating system, as different thresholds will lead to a different number of hours per price segment and thus the respective heating set-points.

CSP-a aims at charging the thermal storage during periods with the lowest prices and simply increases TSPs when the current price is below the LPT and decreases TSPs as soon as the current spot price is above the HPT.

CSP-b aims at charging the thermal storages just before high-price periods. For this case, the control signal is also based on the three price segments and additionally considers whether the spot price will be increasing or decreasing in the next two hours. The TSPs are increased, if the current spot price is between the two thresholds and if the spot price is increasing the next two hours. On the contrary, the temperature set-points

are decreased, if the current spot price is between the HPT and LPT and is decreasing the next two hours. The TSPs remain at the reference set-point if the current spot price is below the LPT.

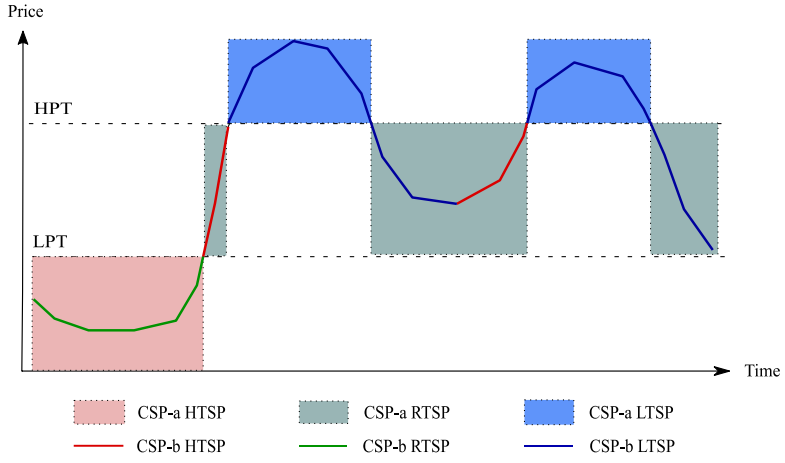

Figure 4. Determination of price-based control signals for control strategies CSP-a and CSP-b (HTSP – High temperature set-point, RTSP – Reference temperature set-point, LTSP – Low temperature set-point) [4]

4. Key performance indicators

The results are evaluated with the help of the following key performance indicators (KPI):

- Annual energy use for heating in kWh, consisting of the delivered electricity ($El_{del,i}$) to the heat pump compressor
- Annual heating costs for the operation of the heat pump system, calculated by

$$E_{Costs}\left[\frac{€}{year}\right] = \sum_{i=1}^{n} El_{del,i}[kW] \cdot 1h \cdot Spot\ Price_{el,i}\left[\frac{€}{kWh}\right] \quad (1)$$

Other performance indicators such as primary energy or CO_2-emissions are not considered in this study.

5. Results

It is shown in Table 3 that CSP-a performs better than CSP-b for the Swiss case study, whereas in Norway CSP-b shows a better performance than CSP-a. For all cases, the used electrical energy increases with the CSP compare to the BAU. That is obvious, since TSP are increased to charge the thermal storages when electricity prices are low. Higher storage temperatures also lead to higher storage losses and lower COP for the heat pump (as a result of higher temperature lift).

It is possible to reduce the energy costs with CSP-a using the Swiss spot prices. Applying the Norwegian electricity spot prices to the Swiss building and energy system, the annual operational costs increase. It can therefore be concluded that CSP-a works well, if the spot price varies strongly enough. The Swiss spot price in 2018 has a difference from the average to the 0.75 quantile and the 0.25 quantile of 10.8 €/MWh respectively 11.0 €/MWh. Whereas the Norwegian spot price only varies 5.9 €/MWh respectively 6.0 €/MWh from the average spot price to the 0.75 quantile and the 0.25 quantile. However, also with the Swiss electricity prices, the measure of increase and decrease of the TSP is decisive for a decrease of the costs.

With the comparison between the Swiss PH with and without a SH storage it can be determined that the cost reduction is bigger without a SH storage tank. This is due to the fact that the thermal heat storage capacity to which the heat pump is connected to, is bigger for the building thermal mass compared to the SH storage tank, although the building thermal mass is also for the case with the SH storage tank indirectly connected to the heat pump. The higher thermal mass of the Swiss HC compare to the Swiss PH does not lead to an increase in cost savings. Furthermore, the Swiss electricity spot prices in combination with CSP-b do not cause cost savings.

In the Norwegian case study by Clauß et al [4], a bivalent heat pump system was used. They found that the

electric auxiliary heater operated more often, if price-based control strategies were applied for both, SH and DHW heating, which was due to the fact, that the heat pump prioritized DHW heating over SH. If there was a demand for DHW and SH at the same time, the heat pump was heating DHW and the electric auxiliary heater provided SH.

Table 3. General Results (PH – Passive house, BAU – Business as usual, CSP – Control strategy price, SH – space heating, SPF – Seasonal performance factor, NSP – Norwegian spot price, SSP – Swiss spot price, Swiss HC – Swiss solid construction)

Set points	Building	Spot price	Control strategy	Electrical energy		Cost	
				kWh	%	NOK*/€	%
Variant 1	Norwegian PH	NSP	BAU	2199	-	484*	-
(TSPs for DHW +10 K or –5 K)			CSP-a	3057	+39	605*	+25

6. Conclusions

The results of this paper show that a sufficient hourly fluctuation of the spot prices is necessary to achieve cost savings for the proposed demand response strategies. The additional energy use due to charging the thermal energy storages are only outweighed, if the difference in the electricity spot prices are sufficient. However, a stable electricity price indicates, that there is no incentive for a price-based control.

Since the total electrical power of all the electrical heat pumps in Switzerland is about 1.5 GW [12] and the maximal electricity power of the hydro storage power plants are 11 GW [12] it is hard to say how much the spot price would be influenced, if all heat pumps would use the CSP-a controller. In addition, the Swiss electrical grid is well connected with its neighbours, which makes it even more difficult to predict the influence of the CSP-a control on the spot price.

This study confirms the conclusions found by Fischer et. al. [13]. The success of a demand response strategy is highly dependent on the sensor position and the control strategy to run the heat pump. In the Norwegian

case, with the lower sensor being positioned relatively high in the SH storage, the potential of shifting the load is limited. However, for the Swiss building and HVAC layout, the best results were achieved for a system without a SH storage tank. Due to the fact that the thermal mass of the building is bigger than the thermal mass of the water storage tank and the building thermal mass is directly accessible, more energy can be shifted for the case without a SH storage tank. For the Swiss PH with its lightweight structure there is no need of a SH storage tank regarding the run time of a capacity-controlled heat pump. Therefore, in this case an HVAC system layout without a SH storage tank is preferable.

Furthermore, the procedure/regulations for sizing a heat pump are an important factor that influences the success of a control strategy. For the Norwegian case study by Clauß et al. [4], the system was designed as a bivalent system with a direct electric heater as an auxiliary heater. On the contrary, building regulations in Switzerland do not allow bivalent sizing of the heat pump with a direct electric heater. Therefore, the efficiency loss due to higher TSPs is smaller in Switzerland than in Norway, where it is possible to run the heat pump and the direct electric heater at the same time to provide DHW heating and SH. Thus, for a bivalent heat pump system, the price-based control strategy should be improved to prevent the electric heater from switching on too frequently. Regarding the choice of the TSPs and their influence on the operational costs, it can be concluded that a too large TSP variation lowers the efficiency too much so that it impairs the operational cost savings. This also shows that the potential cost savings with a sensible heat storage is limited, due to the efficiency decrease with temperature increase. Therefore, a latent heat storage might be suitable to increase the flexibility and the operational cost savings, if the charging and discharging power of it is sufficient.

Acknowledgements

The authors would like to acknowledge the international research collaboration "IEA HPT Annex 49 - Design and Integration of Heat Pumps for nZEB" which provided the framework for this work. The support and funding of the IEA HPT Annex 49 by the Swiss Federal Office of energy SFOE is highly acknowledged.

Cost optimized design of ground probe fields with solar regeneration

Simon Buesser[a], Carsten Wemhoener[a*], Lukas Rominger[a]

[a]IET Institute of Energy Technology, HSR University of Applied Sciences Rapperswil, Oberseestrasse10, 8640 Rapperswil, Switzerland

Abstract

Solar regeneration is often used to raise the temperature of the ground above the natural level in order to enable a more efficient operation of heat pumps. The aim of this simulation study was to find the most cost-effective configuration of ground probes in combination with solar regeneration. The results show that with the help of regeneration not only the costs, but also the efficiency of the heat supply can be improved in comparison to the case without regeneration. Besides that, good conditions are achieved for freecooling with the ground probes despite the regeneration, as well.

Keywords: Ground source heat pump, regeneration, ground probe field design, cost-optimal design

1. Introduction

Heat pump systems enable low-carbon heating of buildings. The ground is often used as a heat source. The advantage of ground-source heat pump systems compared to air-to-water systems, which are also widely used, is the low noise emission, even in large systems, and the lower electrical power requirement in colder weather conditions. However, higher initial investment cost is required for ground-coupled systems. Another problem can occur with large construction projects or refurbishments. For space reasons, the probes may have to be arranged in compact fields, which can lead to a strong temperature decrease in the ground.

One way to prevent this problem is to regenerate the ground using a second heat source. This can limit the long-term temperature degradation during the use of the ground probes over several decades. In addition, the lowering of temperatures during a single winter can be reduced. Furthermore, it was also assumed that the use of solar collectors would result in cost advantages. On the one hand, since the number of probes could be reduced, on the other hand since a part of the domestic hot water can be heated directly and thus less electrical energy and less source energy is needed for the operation of the heat pump.

In practice, the aim of a solar regeneration is usually to raise the temperature of the ground above the natural level in order to enable a more efficient operation of the heat pump. This requires a heat input to the ground that exceeds the heat extraction in the annual balance. The focus thereby is on energy efficiency rather than on cost efficiency.

To determine the potential of a strictly cost-optimized design, a simulation study has been carried out. A residential complex consisting of six buildings with a totally heated area of 16,800 m^2 is used as a case study. Active cooling operation with the heat pump used as chiller was not analyzed for this application, as active space cooling is not common in residential buildings in Switzerland, yet. However, the free cooling potential by the ground are addressed based on the evaluated ground temperatures. Nevertheless, the system configuration has also cooling potential and indeed, in the luxury residential segment also active cooling is more often asked on the market. Thus, further investigations shall also include the space cooling operation as further operation mode of the system.

2. Method

The aim of the simulation study was to determine the minimum number of probes required as a function of the collector area. In addition, the power consumption of the heat pumps and the pumps for the source circuit were determined. In this way, the level of investment and operating costs as well as the consumption of electrical energy could be determined. The same model has been used for all simulation variants.

The only parameters varied were the number of probes, the distance between the individual probes and the area of the collectors.

The simulation model was created with Matlab/Simlink and the Carnot Toolbox [1]. The model contains very well insulated buildings. The heat demand for DHW (19.8 kWh/(m^2yr)) is slightly lower than the heat demand for space heating (21.2 kWh/(m^2yr)), but in the same range. The location of the buildings is Zurich. The heating period lasts from the beginning of October to the middle of May. Each building has two storage tanks for the hot water system and collectors on the roof. The collectors are oriented to the south with an inclination of 30°. One storage tank serves to preheat the water through the collectors, the second tank is supplied by the heat pump. In order to shorten the calculation time, the buildings were not modelled in detail. Instead, load profiles created in advance were used. In this profiles, space cooling is not taken into account.

An unglazed, selective collector was used. In the first priority, the collectors preheat the domestic hot water, in the second priority they deliver heat to the ground probes. The collectors were distributed evenly on the roofs of the six buildings.

The heat source is a central ground probe field with a bidirectional low-temperature network with a cold and a warm distribution pipe to which all heat pumps and collectors are connected. Each building has its own heat pump. The temperature difference between the warm and cold conductor is 5 K.

A self-developed model is used for the ground probes, which is based on the EWS model developed by Huber [2] for the probe tube and the close range (3 m around the ground probe). For the boundary conditions, the method for the analytical calculation of the g-functions according to Lamarche and Beauchamp [3] was used. In addition, the probe loads are superposed for half a year at an interval of seven days. The probes are installed to 200 m depth, the mean ground surface temperature is 9 °C and the geothermal gradient is 0.03 K/m. Further parameters of backfill and ground are listed in Table 1. The probes are always arranged in squares.

Table 1. Material properties of the backfill and the ground

Component	Backfill	Ground
Thermal conductivity (W/m/K)	0.81	2.4
Specific heat capacity (J/kg/K)	3040	1000
Density (kg/m^3)	1180	2600

The collector area required for differently sized ground probe fields was determined so that the ground does not cool down too much. The design criterion was that the temperature of the cold distribution pipe must not fall below -3 °C during the first 50 years of operation, according to the Swiss standard SIA 384/6:2010 [4].

In order to evaluate the configurations from an energetic point of view, the electrical consumption of the heat pumps and the pumps in the source circuit is evaluated. The characteristic diagram of a commercially available speed-controlled heat pump was used. When calculating the electrical consumption of the frequency controlled circulating pumps, only the pressure drop by the ground probes was taken into account according to the pressure drop calculation tool of Huber et al. [5]. The pressure loss of the horizontal connecting pipes was neglected. The pipes of the ground probes have a diameter of 32 mm. The efficiency of the circulating pumps is 0.5.

Configurations of the following combinations of ground probe fields and probe distances were investigated:

- ground probe fields: 3×3 / 4×4 / 5×5 / 6×6 / 7×7 / 8×8
- ground probe distances: 6 m / 8 m / 10 m / 20 m

An attempt was made in each case to select the collector area in such a way that the minimum temperature in the cold distribution pipe is as close as possible to -3 °C. The exact values for the collector area, the power consumption, the system efficiency and the regeneration share were finally interpolated. The following definitions were used:

- Power consumption: Average electricity consumption of heat pumps and source pumps over 50 years
- System efficiency: Quotient of heat demand for space heating and domestic hot water and power consumption

- Regeneration share: Total collector yield divided by the total source heat demand for space heating and domestic hot water. The source heat demand includes the heat that was directly used for preheating the domestic hot water and heat for the heat pump extracted of the ground probes.

As a comparison, the number of probes necessary to achieve the design criterion without regeneration was also determined for the various probe distances. The results were also interpolated. For this reason, a number of probes can result for the required probes that cannot be arranged in a square.
The system costs are calculated from the interpolated values for the collector surfaces and the number of probes. The following values which are common in Switzerland, were assumed:

- Electricity: 0.15 €/kWh
- Investment costs ground probes: 80 €/m
- Investment costs for collectors: 400 €/m² (includes planning, mounting system, piping and installation work)

3. Results

Fig. 1 shows the values for the minimum temperature of the cold distribution pipe in the first 50 years of operation of all simulation variants. The range of the marked square on the left is enlarged in the right figure.

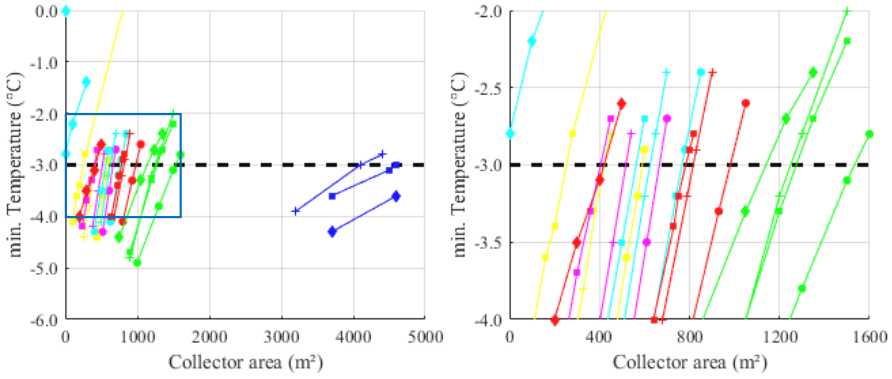

Fig. 1. Minimum temperature of the cold conductor in the first 50 years of operation. (Fields: blue: 3×3, green: 4×4, red: 5×5, cyan: 6×6, violet: 7×7, yellow: 8×8 / Distances between ground probes: dots: 6 m, crosses: 8 m, squares: 10 m, diamonds: 20 m)

Fig. 2 shows the temperature curves of the cold and the warm distribution pipe of a case with and without regeneration as a comparison. It can be seen, that by the reduction of the ground probe length, the system reaches negative temperatures already after a few years of operation, but the temperatures remains more or less constant from then on. The non-regenerated system does not come close to a stationary state even after 50 years. The difference between the maximal and minimal temperature is significantly higher in the regenerated case, because of the smaller usable heat capacity of the ground compared to the larger, non-regenerated field.

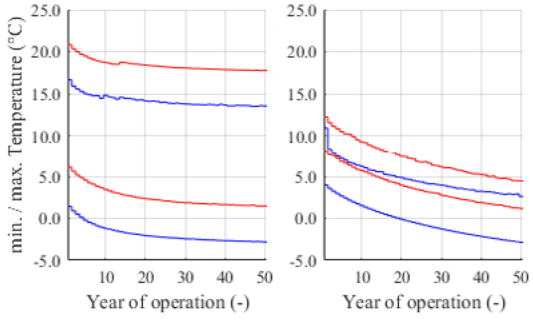

Fig. 2. Plot of the maximum and minimum temperature of the cold (blue) and the warm (red) conductor per year.(left: 5×5 ground probes in a distance of 10 m with 820 m² collector area, right: 10×10 ground probes in a distance of 10 m without regeneration)

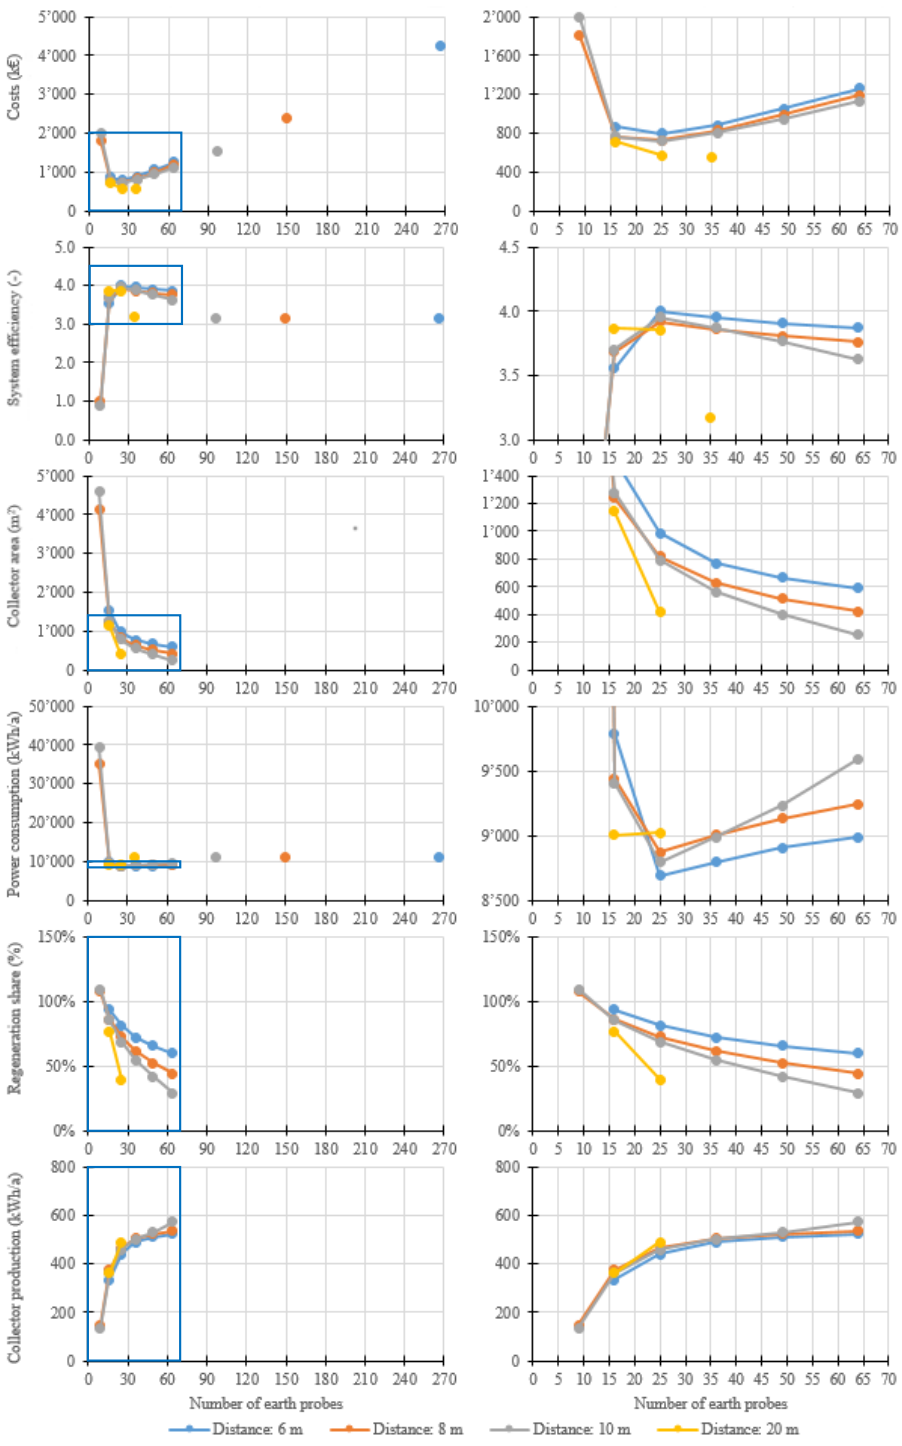

Fig. 3. Costs, System efficiency, collector area, power consumption and regeneration share as a function of the ground probe field

Fig. 3 shows the interpolated values for the required calculated costs, the system efficiency, the collector area, the power consumption and the regeneration share for the various system configurations. The single points represent the cases without regeneration. The marked area in the left figure is depicted enlarged in the right figure.

The results demonstrate that by means of regeneration not only the total cost can be reduced, but also the efficiency of the heat supply can be improved. Besides that, there are still good conditions for free cooling with the ground probes, since the regenerated field is operated colder than with higher shares of regeneration.

The distance between the probes has a large influence on the reduction potential of the cost. The smaller the distance between the probes, the higher the saving potential, which can be evaluated by a comparison of the cost curve with regeneration and the single points without regeneration. In the case with a distance of 10 m, the cost optimum is achieved with approximately 16-25 probes. Compared to the case without regeneration with 97 probes, this is a 74-84% reduction in probe length and about 42% in costs. This can be advantageous for refurbishments when space is limited. But, it can also be beneficial for new buildings. By reducing the need for ground probes with the help of regeneration, the distance between the ground probes can possibly be increased. That could allow a further reduction of the number of ground probes. The lowest overall cost is reached, however, for the largest distance of 20 m.

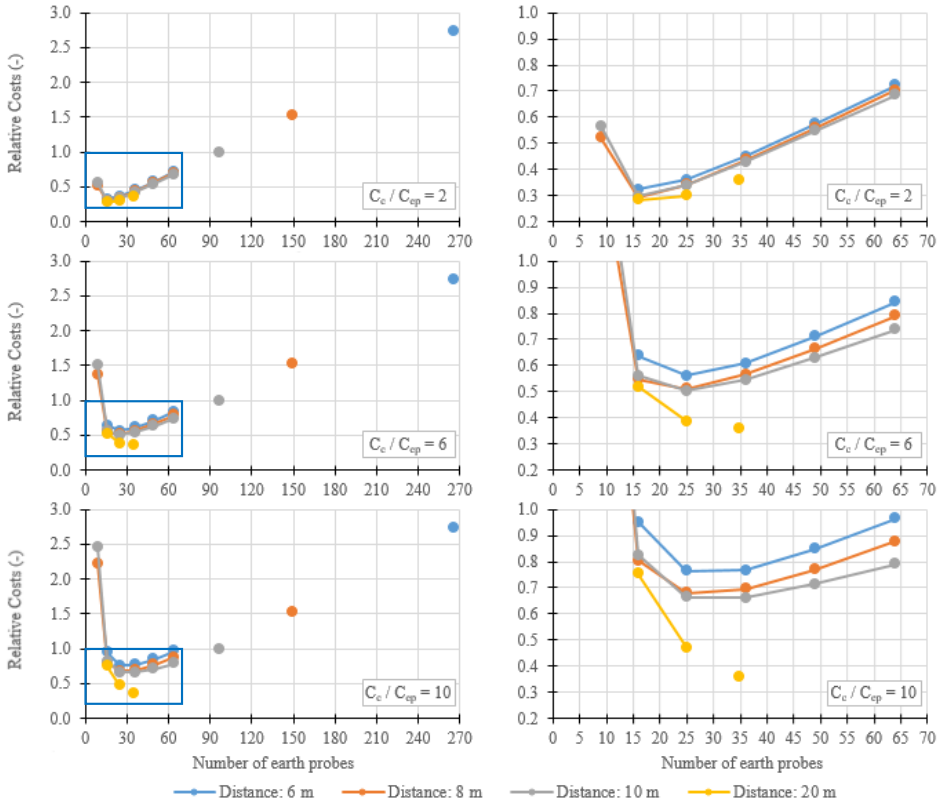

Fig. 4. Relative costs for different ratios of the cost per square meter of collector area (C_c) to the cost per meter of ground probe with the cost of a 5×5 field with a 10 m borehole distance as a basis.

The system efficiency is increased, although the temperatures in the cold distribution pipe in winter already reach negative values after a few years. One reason for this is the partly direct supply of hot water by the collectors, the other reason is the temporarily high source temperatures for the heat pumps. Fig. 2 on the left shows the case with the ground probe field 5×5 and a ground probe distance of 10 m and a collector surface of 820 m^2, which is close to the cost optimum. Fig. 2 right shows the case without regeneration with 100 probes arranged in a square of 10 m distance, corresponding to the minimum number of probes without regeneration.

Due to the lower number of probes the temperatures are lower only during the heating period. During the other seasons, the domestic hot water can be produced very efficiently at higher source temperatures. In the described case, the DHW share produced by the collectors is 49%. Thus, a performance increase can be expected in particular in larger new buildings, where the DHW share reaches the same energy amount or is even higher than the space heating needs.

The energy consumption of the pumps has a significant influence on the total power consumption only for small fields. With the 3×3 fields it can reach up to 80%. With the 4×4 fields it is 6-25% and with the 5×5 fields it is reduced to less than 5%. The higher power consumption with the small fields is due to the higher pipe resistance, since the mass flow is kept the same as in larger fields. Additionally, due to the larger collector area, a higher collector yield has to be transferred to the ground. This is also the reason, why for the small fields the system performance is notably reduced, since the fraction of auxiliary energy expenditure for the pumping of the fluid rapidly increase up to low overall system performance. Due to the large regeneration shares, also the system cost increases disproportionally. These system designs are thus not reasonable neither from the energy performance nor from the cost viewpoint and are henceforth not considered for the evaluation of the results.

The cost of ground probes and collectors can vary significantly depending on the region and system size. Therefore, in Figure 4 the relative costs were calculated as a function of the ratio of the price per square meter of collector area (C_c) to the price per meter of ground probe (C_{ep}). The electricity price was set to 0.00 €/kWh in all cases. The influence of the electricity price in the range of 0.00 €/kWh - 0.20 €/kWh on the total costs is in all cases less than 0.5% and is therefore negligible. The costs for the case with a 5×5 probe array with 10 m probe spacing were taken as a basis. In graph 3 the ratio is $C_c / C_{ep} = 5$.

It can be seen that the results do not fundamentally change even for large and small ratios C_c/C_{ep}. But, the cheaper the geothermal probes are, the less advantageous is a substitution by collectors.

4. Conclusion and Perspective

Results of the investigations show that a design of the ground source to shorter length by regeneration can yield cost and performance increase, which is also due to a direct production of used energy by the regeneration system, in this case the direct solar DHW operation of the collectors. Since for this investigation, selectively coating unglazed solar collectors have been considered, DHW use temperatures can be reached by the collector in summer operation. However, current investigations only reflect one particular weather data set, load situation and system configuration. Therefore, further investigations are necessary, also e.g. regarding longer cold periods. Due to the smaller number of ground probes compared to a conventional configuration without regeneration, the system is more vulnerable to cold periods. During cold periods lasting several days, the area around the probes can cool down considerably. Due to the lower number of probes, the available heat around the probes is smaller, which leads to a stronger cooling.

For the considered buildings the system performance is increasing with the regeneration, in particular in case of limited space for the ground probes. However, for the considered case, the annual DHW demand is in the same range as the energy demand for space heating, and thus the summer operation is more pronounced. Therefore, for different buildings loads, the effect on the system performance should also be considered. Since the minimal temperature level in winter is lower for the considered regenerated cases than in the reference case without regeneration, see comparison in Fig. 2, the system efficiency could decrease for certain times compared to the reference case.

Moreover, for the regeneration with unglazed solar collectors, a large collector area is needed. The influence of alternative heat sources for regeneration, such as outside air, waste water or free cooling of the connected buildings should also be examined in more detail.

In this context also the low system performance in case of only a few ground probes is to be analyzed in more detail, which, however, is according to the present evaluation not cost-effective due to a very large regeneration need.

Abstract

With increasing heat pump use, heat sources gain importance. For high performance, the heat source should deliver high temperature levels. Compared to outdoor air solar installations like unglazed collector or photovoltaic/thermal installations can extract energy from the ambient air, but also yield higher temperatures at solar irradiation.
To overcome cost barriers compared to cheaper outside air heat pumps, a multi-functional operation for direct solar space heating/domestic hot water (DHW) generation at high solar irradiation has advantages. During nighttime, also space cooling by heat rejection to the colder ambient temperatures/night sky can be provided which increases performance of the overall system by multi-functional integration.
Test rig measurement of solar components as heat sink are evaluated and seasonal performance calculations are performed by simulation. Results indicate that in particular in buildings with higher space cooling and DHW shares, solar components can yield higher overall seasonal performance factors than outdoor-air heat pumps. Night cooling capacities can be enhanced by an evaporation on the collector, which also enables to vary surface properties to adapt to DHW production during daytime and space cooling during nighttime.

1. Introduction

Currently, residential buildings are seldom cooled actively in central European countries like Switzerland, while in office buildings, there is already a cooling demand due to higher internal gains. However, recent studies indicate, that due to increasing outdoor air temperatures, rising number of electric devices and higher comfort requirements, also residential cooling demands will increase notably until the mid of the 21st century.

In [1] an increase of the cooling demand in residential buildings in Switzerland of 300% to 700% for the reference year of 2060 has been evaluated by simulations, see Fig. 1. Since buildings have a long life cycle, it is thus important to consider changing boundary conditions already in the planning phase. In addition to purely passive measures regarding the design of the building envelope, efficient cooling processes must also be developed in order to maintain comfort conditions, but limit the electrical expenditure for the cooling function.

Free cooling methods have already been introduced, but mainly in non-residential buildings. In residential buildings free cooling methods are often limited to nighttime ventilation or ground-coupled free cooling when a ground-coupled heat pump is used as heat generator. A possibility of free cooling in residential buildings, which is not much applied so far, is the heat dissipation by activated outer surfaces of the building envelope, e.g. those installed with solar thermal components. These components, which are designed to generate heat, can also reject heat to the ambiance during nighttime operation, under the condition that there is a good thermal connection to the ambiance.

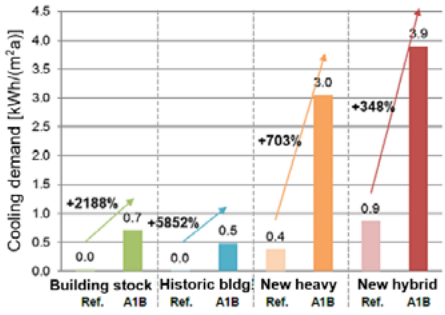

Fig. 1. Longterm development of residential cooling demands in Switzerland to the reference year 2060 [1]

In addition to pure heat dissipation to the outside air by convection, heat dissipation by infrared radiosity to the ambiance and particularly to the sky is used, since a cloudless night sky has a significant lower equivalent sky temperature that is up to 20 K colder than the outdoor air temperature.

Fig. 2 shows the cooling mechanisms that can be used for nighttime cooling on the outer surfaces of buildings. The heat emission is especially favourable for uncovered solar components, which are in direct contact to the ambiance. An increase in the cooling capacity of these components can be achieved by an additional evaporative cooling, if the surface of the components is wetted with water. In order to have a sustainable water source, reuse of decentralized treated grey- and wastewater is investigated as water for wetting the absorber.

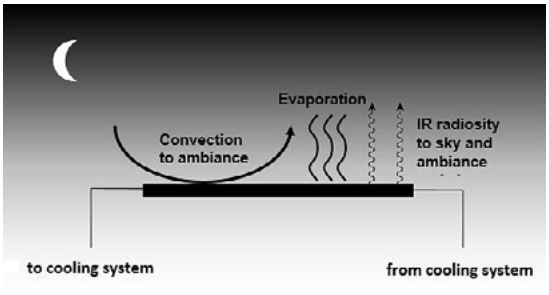

Fig. 2. Different cooling mechanisms on building outer surfaces

2. Simulation case study

In order to evaluate the feasibility of free cooling by the outer building surfaces, simulation studies were carried out for residential and office buildings. The simulations for residential buildings were carried out for a single- and multi-family house. For both types of buildings, energy-efficient new buildings have been considered that meet the requirements of the Swiss building directive MuKEn 2014 [5]. Summarizing, the following building cases were considered in the simulation study:

- Single family building as low energy (according to Swiss label MINERGIE) and passive house level (according to the Swiss label MINERGIE-P)
- Multi family building as low energy (according to Swiss label MINERGIE) and passive house level (according to the Swiss label MINERGIE-P)
- Office building according to the future Swiss building directive MuKEn 2014

The varied building parameters are given in chap. 2.1. In this publication, the investigations of the residential buildings, in particular in single-family buildings, are presented. Results for the office buildings examined show that high free cooling fractions of 80% to almost 100% can be achieved for Zurich Meteoschweiz weather station according to the Swiss guideline SIA 2028 [2] and boundary conditions of use according to SIA 2024 [3], depending on comfort requirements and properties of the outer building surface. This means, that active cooling by a chiller can be significantly reduced to back-up operation for the cases of adverse weather conditions with high nighttime temperatures.

Since typical nighttime air temperatures in Zurich Meteoschweiz weather are in the range of 15 °C, there is a good potential for cooling by outer surfaces, and the mentioned high fractions of 80 – 100% can be reached.

2.1 Building parameters

The single-family house has an energy reference area of 200 m^2. The U-value of the outer walls with U_{AW} of 0.17 W/(m^2K) corresponds to the requirements of the Swiss building directive MuKEn 2014. The window fraction of 40% is evenly distributed across all façade orientations. The windows are triple glazed with an U_w-value of 1.0 W/(m^2K) and a low fraction of the frame of only 10%. The g-value of 0.5 is in the typical range for triple glazing. For shading, variants are calculated that reflect the user behavior.

With optimal shading, from 200 W/m^2 irradiance and a room temperature of 23.5 °C, the total energy transmission is reduced to a g-value of 0.1. Irradiance of 400 W/m^2 and 600 W/m^2 are considered as variants for non-optimal shading and 1000 W/m^2 as unshaded case. For the hot water consumption, 150 l or 37.5 l/person with a used temperature of 55 °C were kept constantly throughout the year, which corresponds to an energy consumption of 2900 kWh or 14.5 kWh/(m^2yr) used energy for the hot water demand.

The multi-family building has five stories with a total of 10 flats. The total energy reference area is 1500 m^2. The U-value of the outer walls is with a U-value of 0.185 W/(m^2K) just above the limit value according to MuKEn 2014 and the U-value of the triple-glazed window with a frame proportion of 10% with U_w of 1.2 W/(m^2K) is also slightly higher than the requirement for single building components. The g-value is 0.5, which is reduced to 0.14 when shading is activated. Shading is controlled dependent on the façade orientation. The activation of the shading of 200/400/600 W/m^2 irradiance on the façade is also varied in order to model different user behavior. The occupancy of the flats with 5 persons or one person area of 30 m^2/person is higher than in a single-family house with a person specific area of 50 m^2/person. Hot water consumption is assumed to be a slightly lower consumption of 30 l/person inline with the standards for multi-family buildings at a hot water temperature of 55 °C.

The residential buildings are equipped with mechanical ventilation and heat recovery, which has a thermal efficiency of 80%. In summer mode, heat recovery is reduced to 10% for modelling a summer bypass. The residential buildings are also both equipped with floor heating, which corresponds with 0.1 m pipe spacing to a rather large dimensioned floor heating, which enables low flow temperatures and thus creates favourable conditions for renewable energy use. The floor heating serves as emission system for both heating and free cooling operation.

2.2 System configuration

The building technology consists of a solar absorber, which is connected to a water-glycol source storage tank and serves as the only heat source for the heat pump. The heat pump operates in both heating and hot water mode. If the temperature level of the solar absorber is high enough, the hot water generation can also be switched-over to the absorber and be carried out directly with the solar absorber. In this study a selective absorber is considered, which can reach the hot water temperatures in summer operation due to the reduced radiative losses at higher temperatures. Furthermore, both a buffer tank for heating operation and the hot water tank are integrated. In cooling mode, the source storage is used as a cold storage. Then the absorber circuit is operated during the night for heat losses to the ambiance in order to cool down the storage tank. When charging the storage tank with the heat extracted from the building by the floor heating, the comfort limit of a floor surface temperature of at least 19 °C must be considered. Table 1 summarizes the parameters of the single-family and multi-family house.

Table 1. Building and system parameters for the single-and multi-family building

Building and system parameters	Single-family house	Multi-family house
Residents/People	4	50
Window fraction	40%	40%
Energy reference area (ERA) [m^2]	200	1500
Annual heating demand [kWh/(m^2_{ERA}yr)]	25	15
Annual hot water demand [kWh/(m^2_{ERA}yr)]	14.5	19.5
Annual cooling demand [kWh/(m^2_{ERA}yr)]	4-6	4-6
Absorber area [m^2_{ABS}]	11-18	71-178

The hot water demand of the multi-family building exceeds the heating energy demand due to a low space heating demand of 15 kWh/(m²yr) on average among the flat, ranging from 9.3 kWh/(m²yr) of a flat on the third floor in south orientation to 27.4 kWh/(m²yr) of a flat in north orientation on the top floor. The low space heating demand is due to the lower area-to-volume ratio of the multi-family house.

In addition, the multi-family house has a higher occupancy with 30 m²/person, which increases the hot water requirements and also lowers the space heating needs due to about two-thirds higher internal gains compared to the single-family house. However, the loads for equipment and lighting remain the same. The cooling requirement is with an average of 4 kWh/(m²yr) still moderate and ranges from 2.6 to 4.8 kWh/(m²yr) among the flats. It is slightly lower than for a single-family house, partly for similar reasons as for heating, e.g. due to the smaller outer surface area compared to the energy reference area and also due to slightly lower window area per energy reference area. In Switzerland, the energy reference area comprises all treated areas for heating or cooling of the building storeys as gross area, i.e. including the insulation layer thickness.

3. Results of the feasibility study

In the following results for the single family house are presented in more detail. Results on the multi-family house are discussed in more detail in [7] and are shortly summarised in chapter 3.3.

3.1 Energies and seasonal performance factors single-family house

For the single family house, the following variants are considered:

- Variation of collector area 10.7 m² (6 absorbers) and 17.8 m² (10 absorbers)
- Variation of activation of the shading of 200/400/600 W/m². Moreover, an unshaded case (activation at 1000 W/m²) is considered.
- Variation building envelope according to the Swiss low energy and ultra-low energy house labels MINERGIE®- and MINERGIE-P® [4]
- Variation of weather boundary conditions Zurich Meteoschweiz normal and warm data set

The MINERGIE®-single family house has shading of 200 W/m² and an effective space heating demand including the ventilation heat recovery of 26.1 kWh/(m²yr). The DHW demand is 14.6 kWh/(m²yr) and the space cooling demand is by the good shading moderate with a 4 kWh/(m²yr). With a MINERGIE-P®-building envelope the space heating demand decreases to 17.1 kWh/(m²yr) and the space cooling demand increases to 4.8 kWh/(m²yr). Thereby, the space heating demand approaches the DHW demand. Despite the moderate space cooling demands at optimal shading the cooling demand surpasses on single days the DHW demand in the summer months of June - August, where peaks in the cooling demand are observed.

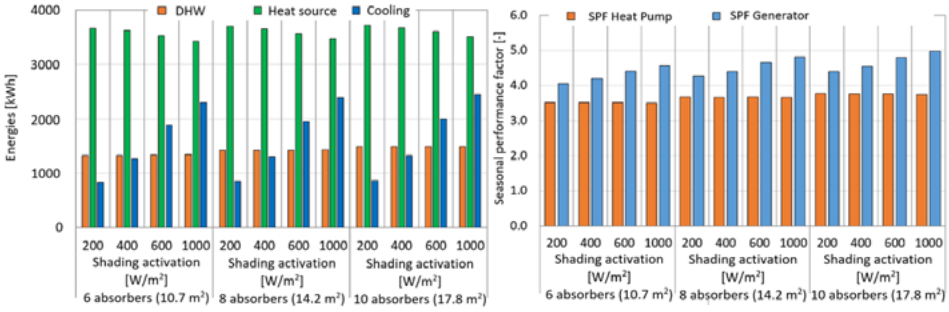

Fig. 3. Collector yield of different operation modes (left) and seasonal performance factor of the heat pump and overall (right)

Even without solar thermal DHW production, which reduces the heat pump operation in summer time, to cover the cooling demand only in simultaneous operation with the heat pump in DHW operation would be difficult. Fig. 3 left shows the collector yield for the different collector areas at variation of the shading activation of 200 W/m² to 1000 W/m² (unshaded). The space heating operation is not affected by the higher solar gains in the case of lower shading. The DHW yield is only dependent on the absorber area, and is independent of the shading. At lower absorber area the solar DHW fraction is about ca. 40%, at higher absorber areas it increases to ca. 46%. In the summer months, it is about 75-90%.

The yield of the absorber in the space cooling operation, though, is directly correlated to the shading of the building, since the space cooling loads increase with reduced shading of the building. In the unshaded case, the absorber yield in cooling is about 3 times of the space cooling energy with optimal shading. In Fig. 3 right, the performance factors of the heat pump and the overall performance factor of all generators is contrasted. As expected the shading affects the performance factors of the heat pump only slightly. The performance factor in space heating operation is almost 4, in DHW operation almost 3, which corresponds to an overall performance of 3.5-3.8.

At higher absorber area, the performance factor increases due to higher source temperatures in space heating and DHW operation by about 0.1-0.2, leading to an overall performance of 3.8.

For the ultra low energy building (MINERGIE-P building), which is not depicted, the required yield in space heating is reduced by 25%. The solar fraction corresponds to the low energy single family house (MINERGIE building). The absorber yield in cooling operation corresponds at optimal shading to the low energy house, in the unshaded case, it increases by 15%.

With smaller absorber areas and lower outside temperature with little solar irradiation, problems with the lower operation limit of the heat pump may occur, which may require an emergency heating or a second heat source, which, however, has not been modelled. At larger absorber areas, the source temperature level in the source storage increases, and thereby also the performance factor of the heat pump, which mitigates problems with the lower temperature limit of the heat pump.

For the consideration of the overall seasonal performance factor of the heat pump and the direct solar and free cooling operation, the seasonal performance of the generator (SPF_{gen}), which is depicted in Fig. 3 right. The SPF_{gen} describes the overall efficiency with the application of multiple generators and relates the thermal energy to the electricity input. In this case the condenser heat and the direct solar thermal yield of the collector is related to the electricity for the heat pump and the collector pump. Pumping energy for the source energy of the heat pump, the DHW production and free cooling is taken into account. For all operation modes, values up to around 5 can be optained for the SPF_{gen}, which is by 0.6-0.8 higher than the SPF_{HP}, as shown in Fig. 3 left.

3.2 Thermal comfort single family house

The comfort evaluation is depicted uniformly for an absorber area of 17.8 m^2. The comfort is evaluated by the operative temperature according to the requirement of the SIA 180 [6] for air-conditioned buildings, even though the building is not actively conditioned, but just free cooling is applied. The impact of the humidity is not evaluated, since with free cooling operation, the relative humidity cannot be affected. As the winter room temperatures are well in the comfort range of SIA 180 (temperature band 20.5 °C to 24.5 °C), the summer comfort only is depicted in the following. Here, the operation of the shading as well as the free cooling operation is decisive.

Fig. 4 shows the room temperatures in the summer season of mid of April until the end of September without (Fig. 4 left) and with optimal shading (Fig.4 right), with and without free cooling operation in both figures. Without shading, a maximum temperature in the range of 33 °C is reached. By a free cooling operation without shading, the temperature can be limited to a maximum of 28 °C. However, thereby, single comfort violation also occur with free cooling, as the comfort limit is set to 26.5 °C in the standard SIA 180., see also Fig. 5. By an optimal shading without free cooling, maximum temperatures are limited to 29 °C.

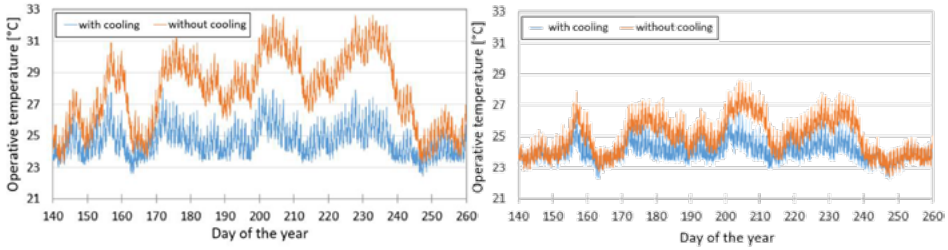

Fig. 4. Room temperatures in the summer without shading (left) and with optimal shading (right) with and without free cooling

With optimal shading starting with irradiation values of 200 W/m^2 and free cooling operation the temperatures stay in the comfort range. In Fig. 5 the hourly averaged room temperatures are depicted in the comfort range of SIA 180 for the annual period based on the moving average of the last 48 h of the ambient temperature.

In winter operation the temperature are well in the comfort range with temperatures of 22-23 °C, which are often measured in monitoring projects.

In Fig. 5 left the room temperatures with optimal shading and no free cooling operation are depicted. The 340 overheating hours outside the comfort range mainly occur in summer operation. In Fig. 5 middle the room temperatures without shading, but with free cooling are depicted. The overheating hours are reduced to 260 with about 150 hours occurring in the mid-season and about 110 hours in the summer. The overheating hours in the mid-season indicate optimisation potentials in the control, as the capacity of the collector at colder outdoor condition should be sufficient. Free cooling allows to reduce significantly the number of overheating hours that occur during summer time. Fig. 5 right shows the comfort range at optimal shading and free cooling operation.

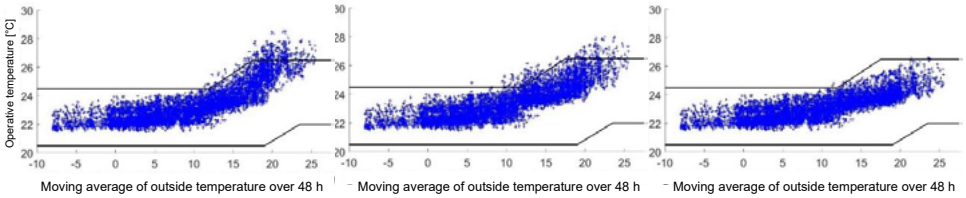

Fig. 5. Room temperature with shading and without free cooling (left) and without shading but with free cooling (middle) as well as with optimal shading and free cooling (right)

No overheating occurs anymore and there is even a reserve until the comfort boundary is reached. Thus, the free cooling operation can compensate a non-optimal shading within limits. But a shading cannot be entirely replace with the considered design of the free cooling system, in particular at high outdoor temperatures.

3.3 Summary of results of the multi-family house

For the multi-family building similar indicators are evaluated as for the single family building. The main results are summarised below. However, the energy demands and system efficiencies are affected by the specific building parameters and load. For instance, the multi-family building has a more compact building envelope with a lower surface-to-volume ratio paired with a higher occupancy of 30 m^2/person and thereby higher internal gains. This lowers the space heating demand to an average of 15 kWh/(m^2yr). Nevertheless, depending on the location in north or south orientation, the space heating demand varies among the flats. But, due to the higher occupancy, the specific DHW demand increases to 19.7 kWh/(m^2yr) and has a higher impact on the overall performance. Cooling demand is thereby considered the same as in the single family house. The same variations as for the single family house are considered.

The seasonal performance factor of the heat pump in the multi-family house is in the range of 4.5–4.9 depending on the collector area. For larger collector area the source temperature for the space heating operation increases. In the DHW operation the average SPF is 2.8, with a moderate increase of 0.1 with larger collector areas, as due to the direct solar fraction, the heat pump is producing the water at higher temperature levels. Meanwhile, the higher impact of the DHW operation the performance factor increases by 0.2-0.3 with larger collector area leading to performance factor of the heat pump SPF_{HP} in the range of 3.5–3.8.

The solar fraction increases with doubled collector area only moderately from 33% to 40%. The moderate increase is due to the limited DHW storage volume. With an extension of the storage size, the solar fraction could be increased up to 50%. The overall performance factor including heat pump, direct solar fraction and the free cooling operation SPF_{gen} yields higher performance values in the range of 4.5–5.0. Thereby, also the shading has an impact, since with reduced shading the cooling demand and the free cooling fraction increases.

Also the thermal comfort shows the same tendencies as in the single family building, but the difference between shading-only and free cooling operation becomes more distinct. The thermal comfort in winter can be maintained quite well. For a collector area of 107 m^2, optimal shading and no free cooling, about 1000 overheating hours are observed, so shading-only is not sufficient. With free cooling operation overheating hours can be limited to 100, and violations of the comfort range are mainly in the mid-season and may be further reduced with optimised control. With a combination of optimal shading and free cooling operation the comfort range can be maintained the whole summer with temperatures up to 26 °C, and still holding a little reserve regarding the comfort limit. For warmer boundary conditions of a warm summer some overheating hours result even with optimised shading and free cooling. An additional active cooling by the heat pump would have to be applied to entirely stay in the comfort range.

4. Test rig results for the space cooling operation

In order to further characterise the space cooling operation with test rig results, measurement have been performed on a selectively coated unglazed solar collector on the accredited test rig of the HSR Institute SPF, which is the national test centre of Switzerland for solar thermal collector. Fig. 6 left shows the unglazed solar collector on the test rig and Fig. 6 right depicts a sketch of the measurement system including a legend of the measurement points. In order to determine the capacity of the absorber in free cooling mode, the inlet and outlet temperatures of the absorber fluid are measured. With the measured volume flow the enthalpy change on the fluid side and thereby the cooling capacity can be evaluated. The fluid is a water-glycol mixture.

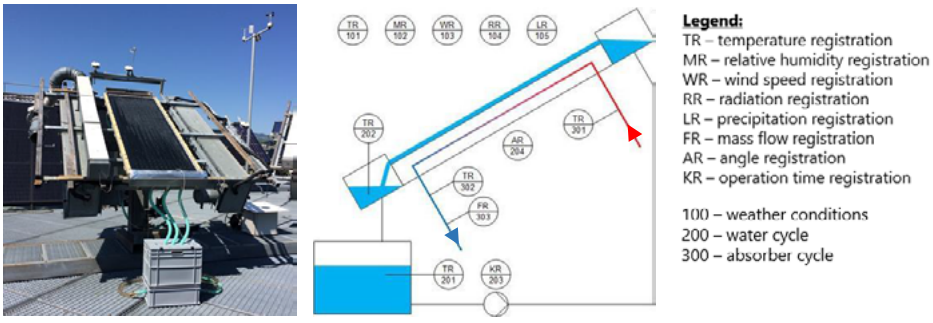

Fig. 6. Unglazed solar collector on the test rig (left) and sketch of the test rig with measurement points including the legend of the measurement points (right)

Additionally, the weather boundary conditions of the short wave solar irradiation, the downward long wave radiation, the ambient temperature and relative humidity as well as the wind speed and precipitation are measured in order to characterize the impact on the cooling capacity. As expenditure for the free cooling operations the electricity input to the pump is measured. For the operation of the system, continuous and cyclic operation can be run. During continuous operation, the absorber surface is continuously wetted by a water film running down on the absorber surface. In cyclic operation, the film is only continued for 10 seconds every 2 minutes, which saves pump electricity.

In the following figures, the cooling capacity for different weather boundary conditions is depicted. Fig. 7 left shows the temperatures linked to the nighttime absorber operation in cooling mode. The inlet and outlet temperature are decisive for the evaluation of the cooling capacity. The inlet temperature is kept constant at about 20 °C. By the high volume flow rate of 200 l/h, the temperature difference between inlet and outlet is limited to 2 K. With a lower mass flow rate, the temperature difference can be increased, but the capacity is reduced, since the average temperature difference to the ambient is decreased. Thus, as in space heating, a lower mass flow decreases the outlet temperature, but also the cooling capacity. The temperature of the tank characterizes the temperature of the water film on the absorber. In this case, a night with a moderate ambient temperature and a clear sky is depicted. This can be seen at the temperature difference to the (fictive) sky temperature that characterizes the long wave radiation exchange between the absorber and the sky.

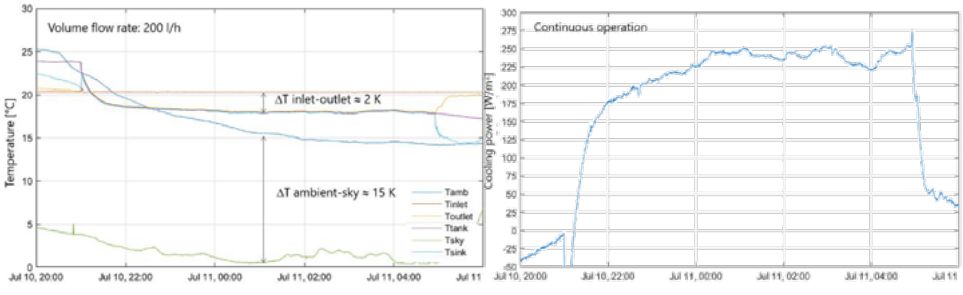

Fig. 7. Temperatures (left) and cooling capacity (right) of the unglazed solar collector on the test rig at favourable nighttime ambient conditions with clear sky and moderate ambient temperature

Since the water vapour in the atmosphere absorbs long wave radiation and reemits it as long wave downward radiation, a clear sky is a more favourable weather condition than a cloudy sky and the sky temperature reaches values up to 20 K lower than the ambient air temperature.

Fig. 7 right depicts the cooling capacity of the absorber. At favourable conditions a cooling capacity in the range of 250 W/m^2 is reached. Until about 10 p.m., the ambient temperature is still higher than the average absorber temperature, which limits the cooling capacity. Nevertheless, even at warmer ambient temperatures, a cooling capacity by radiation and evaporation surpasses the convective gains by the ambient temperature. During the night, the cooling capacity is increased with the decrease of the ambient temperature, which is in line with the decrease of temperatures from the building as well as the inlet temperature to the collector in real operation.

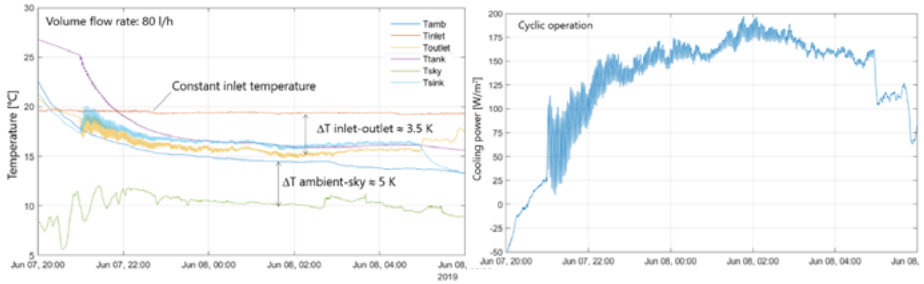

Fig. 8. Temperatures (left) and cooling capacity (right) of the unglazed solar collector on the test rig at moderate nighttime ambient conditions with cloudy sky and moderate ambient temperature

Fig. 8 depicts a cyclic operation with cloudy sky conditions and a lower mass flow rate of 80 l/h, which is the nominal mass flow of the collector at heating conditions. In this case, the temperature difference between the ambient and the sky temperature decreases to only 5 K, which is due to a higher long wave downward radiation from the sky. Despite the lower cooling capacity, which is depicted in Fig. 8 right, a temperature difference for 3.5 K over the absorber is reached due to the lower mass flow rate.

The cooling capacity is not constant due to the cyclic operation. The water on the collector surface is partly evaporating, which has also influence on the radiation properties, since the collector has a selective coating. If water is on the collector, the long-wave emissivity in the infrared spectrum ε_{IR} is defined by the water to values around ε_{IR}=0.95. However, if the water is evaporated, the emissivity changes to the one of the selective coating, which has an emissivity around ε_{IR}=0.15. Thus, the evaporative and radiative cooling capacity is reduce at dry parts of the collector surface, which leads to a decrease of the cooling capacity in cyclic operation. In the beginning of the night, the water for the wetting of the absorber is still warm, which leads to the higher swing in the temperatures. The swing is successively reduced down to differences of about 20 W/m^2. This effect of the selective coating is depicted in Fig. 9. In this case, the inlet temperature to the collector is adapted to the ambient temperature. Until about 1:30 am the collector is wetted. Then, the water film is stopped for two hours until 3:30 am, and the collector is drying completely. In the drying process cooling capacity successively decreases, and for the dry collector, the cooling capacity is strongly decreased from initially 125 W/m^2 before the drying process down to values around 10 W/m^2 after complete drying of the collector surface.

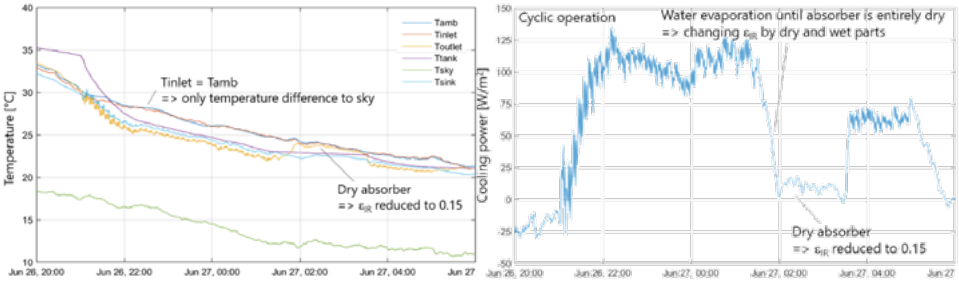

Fig. 9. Temperature difference for wet and dry absorber (left) and respective cooling capacity (right)

At the test rig, there is also the option to switch-on artificial wind in the range of wind speed of 1-3 m/s. The ventilator is located directly along the long side or the absorber and shown as a white box in Fig. 6. As the wind changes both the convective and evaporation heat transfer coefficients, a significant increase of the cooling capacity is measured with artificial wind. Fig. 10 left depicts the temperatures and Fig. 10 right the cooling capacity at clear sky conditions and artificial wind of 3 m/s. A cooling capacity up to 450 W/m^2 is measured at ambient temperature of 13 °C and a temperature difference to the sky of 15 K.

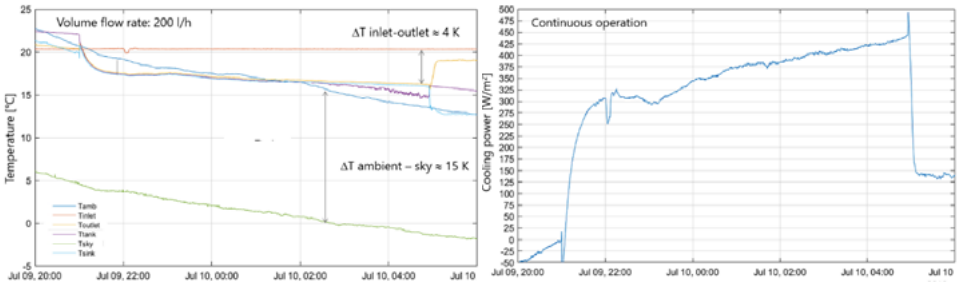

Fig. 10. Temperatures (left) and cooling capacity (right) with 3 m/s artificial wind on the absorber surface at clear sky conditions

5. Conclusion and Outlook

Result of a feasibility study for different building types and heat pump systems with solar heat source confirm a good performance of the heat pump in space heating and DHW operation with an overall SPF in the range of 3.5 – 3.8. By direct solar operation in DHW mode during the summer with higher solar irradiation values, the DHW performance can be increased above the pure heat pump operation to values above 4. Moreover, the unglazed solar collector can also be used for the integration of the free cooling operation during nighttime, where the collector rejects heat by convection, radiation and evaporation, if the collector surface is wetted. Besides the evaporative cooling effect by wetting the collector surface, also radiative properties can be changed in case of a selective coating of the collector. Thereby, a selective coating helps to reach higher temperature in the DHW operation during daytime due to a reduction of the radiative losses, while it enhances radiation losses due to the high emissivity of water up to 95% in nighttime of the free cooling operation. The overall performance including the free cooling operation can reach overall SPF values above 5 in low energy buildings depending on the space cooling and DHW loads.

For the feasibility study, however, only limited test data including the evaporative cooling were available. Therefore, test rig measurements have been carried out at the accredited test rig of the national Swiss solar test center for solar thermal systems at the HSR Rapperswil, which confirm good specific cooling capacities in the range of 100 – 300 W/m^2 depending on the ambient conditions, which are even higher than the values used in the feasibility study. Wind on the collector surface enhances the convective and evaporative heat transfer to the ambiance and values up to 450 W/m^2 have been measured at a wind speed of 3 m/s at the collector surface. However, in summer, low wind speeds at night are predominant, thus the potential for higher cooling capacities by wind is limited.

In the frame of the project, also the application of treated greywater as water source for the space cooling operation is investigated in collaboration with the Institute of Ecopreneurship of the University of Applied Sciences Northwestern Switzerland FHNW in the frame of the Swiss Competence Centre for Energy Research, Efficiency of Industrial Processes (SCCER-EIP). First results indicate that fouling and scaling on the collector surface can be effectively avoided by the water treatment in a decentral membrane bioreactor (MBR) water treatment process, and cooling capacities are not affected. Also, bacteria growth meets the requirements for evaporative cooling, so treated wastewater can be a sustainable water source for the evaporative free cooling. Experiments and respective simulation studies will be carried on in order to further characterize the process and free cooling potentials.

Abstract

Large-scale ammonia refrigeration and heating systems have been widely used in industry due to their high efficiency, broad temperature ranges of operation and innocuous environmental effects. However, implementation of this technology in small to medium systems has not yet been very successful. Factors like the toxicity of the refrigerant and prices of ammonia equipment are some of the obstacles that this technology must overcome before being able to enter a market dominated by systems running on HFC refrigerants. This paper presents a concise review of the research and development of ammonia systems designed to supply small to medium capacity applications. Based on this review, a low charge ammonia chiller and heat pump unit intended to supply both needs providing 180 kW of cooling and 200 kW of heating was proposed. A market overview was performed to find the available equipment that can guarantee proper operation with the lowest possible refrigerant charge. Furthermore, a numerical study of three concepts for this system was performed to study the performance, as well as refrigerant charge estimation and distribution within the equipment. The analysis laid the foundation to propose a suitable configuration to embrace the intended market segment not only considering the high coefficient of performance but also specific refrigerant charge.

Keywords: Low charge, Ammonia, Chiller, Heat Pump;

1. Introduction

The latest regulations promoting the phase-out of HFC refrigerants e.g. The Kigali Amendment [1], are forcing the refrigeration and heating industry to develop new systems that make use of refrigerants with low or preferably zero GWP. Thus, systems with natural refrigerants like ammonia are a suitable option to keep supplying cooling and heating demands. Ammonia has proven to be an efficient and environmentally harmless refrigerant. That is why industrial-sized refrigeration systems have used ammonia since the beginning of the refrigeration industry. Besides, district energy applications have increased the use of ammonia systems in the last decades. Thus, in large-scale systems, shifting from HFC towards ammonia can prove to be a viable solution for manufacturers and industrial consumers. However, toxicity is an issue that has excluded this refrigerant from smaller scale refrigeration and heating applications for many years. Consequently, the re-introduction of small (≈10 kW) to medium-sized (≈200 kW) ammonia systems as a replacement for HFC systems, would require the development of new methods to prevent hazards from leakages. Hence, as presented by Ciconkov [2], researchers and companies have recognised that one main improvement to keep embracing the use of ammonia systems is the reduction of refrigerant charge.

Regardless of the system's application, most of the studies and developments to minimize charge or improve performance and security during operation are for large ammonia systems and, to a low extent, studies for small-scale ammonia systems. However, the optimization of medium capacity ammonia systems has not received much attention. Moreover, there are few reference cases about the construction or performance of this kind of equipment on the market. The present paper will present a concise review of the current research to minimize charge in ammonia systems. This acquired knowledge allows the introduction of a medium-capacity chiller-heat pump unit concept. A numerical model of the system will show not only the performance but also the specific charge of the system when using the equipment available in the market.

1.1. Review of Ammonia Chiller and Heat Pump Research

The application of ammonia cooling and heat pump systems has been a topic of interest in the last decades. Stoecker [3] introduced expanded applications for ammonia within the refrigeration industry. The author presented water chiller and ice thermal storage applications that, at the time, were considered as prototypes of what is now recognised as conventional systems. Furthermore, the effects of ammonia leakages from the systems was also a topic of concern in the study. Thus, the author presented methods and numerical models to analyse the consequences of releasing ammonia into the atmosphere. Similarly, Korfitsen [4] showed the suitability of applying ammonia heat pumps in several food refrigeration applications. Not only they presented case studies to assess the advantages of ammonia over other refrigerant systems but also, they are the ones who introduced the high-pressure/temperature (40 bar) ammonia heat pump concept, which nowadays is a standard operation mode in high-temperature heat pump applications. The market and technology development have increased the acceptance of large scale ammonia systems in the last decades, as a matter of fact, Skačanová et al. [5] showed that by 2017, more than 90% of the large refrigeration installations in Europe use ammonia as working fluid. Besides, Skačanová et al. discussed the substantial increment of low charge ammonia systems in industrial applications and regions. Low charge systems have also received attention from researchers mainly related to industrial applications. Chapp [6] and Poggi [7] describe the possibilities of charge reduction with emphasis on industrial refrigeration systems and the effect of charge minimization in each component. Likewise, Pearson [8] explained the advantages and disadvantages of charge reduction in industrial ammonia systems. These three studies [6]–[8] concluded that industrial systems tend to accumulate substantial amounts of refrigerant within the liquid lines. Furthermore, inappropriate charge reduction could have a counterproductive effect on the operation and performance of the system. From a component-oriented perspective, Hrnjak [9] demonstrated that ammonia has the best potential for being used in low charge systems if a rational approach to minimize charge within the components is applied. Similarly, Ayub [10] showed the reduction of charge and price of an industrial heat pump through optimizing the selection of the evaporator.

On the other hand, low charge small ammonia systems have also received attention from researchers. Palm [11] proposed a 9 kW ammonia heat pump with a specific charge of 11 g/kW. The author also performed a market analysis to spot different components that can be embedded in this kind of systems concluding that there is a lack of proper components for small ammonia systems. Similarly, Hrnjak [12] proposed an air to water ammonia chiller concept with a 13 kW capacity and specific charge of 18 g/kW. Hrnjak also compared the specific refrigerant charge of the prototype with different chillers available in the market to show how commercial systems are still not optimized in terms of refrigerant charge. These works have proven that there is plenty of opportunities to reduce refrigerant charge in ammonia systems, thus improving the competitiveness of this refrigerant in the market. Nevertheless, approximately a decade has passed since these last two studies were published and it is still not possible to embrace small ammonia systems and their entrance in the market. For instance, Zajacs [13] introduced a small-scale ammonia heat pump concept for space and water heating. They also recognized that the lack of components for small-scale ammonia systems still is a drawback on introducing them to the market. In the same way, Wu [14] presented a study of the progress in the development of ground source heat pumps with natural refrigerants. In this comprehensive survey, Wu showed that large-scale systems are still embracing the market. However, they were not able to recognise further improvements in small ammonia systems. Among the literature related to medium capacity ammonia chillers or heat pumps, Nielsen [15] modelled the performance of a 150 kW heat pump with different refrigerants. Aside from proving that the heat pump performance is higher when using ammonia as a refrigerant, the author also performed a charge estimation concluding that the ammonia system with a specific charge of 23 g/kW was the one with the lowest refrigerant charge needed to operate. Furthermore, Nelson [16] examined the long-term suitability of medium-sized ammonia chillers. Using a 280 kW unit as a case study, Nelson showed the economic benefits of replacing HFC units with ammonia ones. The two afore-mentioned papers are recent and do not refer to prior studies of suitability or optimization of systems working with these capacities.

Few companies produce medium-capacity ammonia systems. Most of these companies do not have a complete description of the operating conditions or sizes. On top of that, few companies can provide systems with the so-called "very low" refrigerant charge, ranging 100 g/kW to 200 g/kW. However, the approach used to assure low charge seems to be the same, a compact designed system with plate heat exchangers as evaporator and condenser. Moreover, manufacturers agree that the proper implementation of the receiver helps to minimize the amount of ammonia within the system. Based on the performed review related to ammonia chiller and heat pumps, the current work presents a concept that could be a suitable option to supply medium-capacity cooling and heating applications. The inspiration for the current concept comes from a real case study in which there is a need to provide cooling for different industrial processes of a mineral wool manufacturer plant. On

the other hand, the heat pump mode will serve a district heating network of a municipality located in the vicinities of the plant. The concept proposes a combined ammonia chiller and heat pump with a nominal cooling capacity of 180 kW and a heating capacity of 200 kW.

2. Methods

2.1. Medium Capacity chiller-heat pump concept

The rating test conditions for process chillers of the European standard EN 14511:2018 [17] was used as an inspiration to define the operating conditions of the evaporator and condenser when the system is working in chiller mode. However, the current standards developed for heat pumps are focused on space heating applications, which are not the same as district heating applications. Thus, the specifications of heat pumps available in the market that have been used in district heating applications were used as an inspiration to define the operating conditions of the condenser when the system is working in heat pump mode. Moreover, in the design of the evaporator, the temperature difference is maintained in both chiller and heat pump modes. Thus, when the system is working in heat pump mode, the temperature difference in the evaporator is maintained as the one from the chiller mode operation. Finally, the chosen evaporator and condensation temperatures entail the same design pressure ratio in both chiller and heat pump mode. Table 1 compiles the design operating conditions of the proposed concept.

Table 1. Operating conditions of the Chiller-heat pump concept

	Chiller		Heat Pump	
Data	Value	Units	Value	Units
Capacity	180	kW	200	kW
Evaporation Temperature	0	°C	30	°C
Temperature of inlet/outlet water in evaporator	12/7	°C	42/37	°C
Condensing Temperature	40	°C	80	°C
Temperature of inlet/outlet water in condenser	30/35	°C	65/75	°C

With the operating conditions defined, the three configurations presented in figure 1 were analysed to quantify the difference in performance and refrigerant charge. First, a direct expansion (DX) configuration (figure 1a) was studied to define the minimum charge needed by the system to operate. However, there will be a difference in the amount of refrigerant needed by the cooling and heating modes. Consequently, a receiver is required to store the excess refrigerant [18]. That is why the second configuration analysed was the DX system with the addition of a high-pressure receiver (figure 1b). Finally, Pearson [8] proposed a suitable configuration to minimize refrigerant charge in industrial ammonia systems. Thus, using this concept as inspiration, a flooded evaporation system with a low-pressure receiver was analysed (figure 1c). The analysis of these three systems required additional operating conditions to be defined. For the DX systems, superheating of 10K at the outlet of the evaporator was assumed to guarantee stable operation whereas, subcooling is not considered.

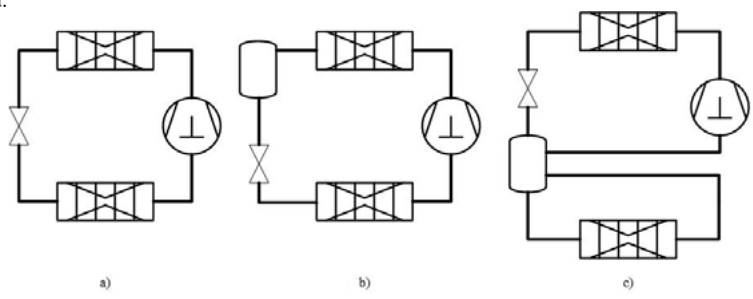

Fig. 1. Proposed configurations to study charge distribution. a) Direct Expansion, b) Direct expansion with high-pressure receiver, c) Flooded evaporator with low-pressure receiver.

The main components in the system were selected based on the market availability of equipment for ammonia systems. In the case of the compressor, it is necessary to find a compressor that fulfils the operating conditions of both chiller and heat pump modes. The considered reciprocating compressors available in the market and developed for ammonia chiller applications were not able to operate with the current cooling capacity proposed for the system. Thus, an open screw compressor seemed to be the only option for the current application. However, according to the manufacturers, these compressors can only operate under the chiller operating conditions, not the heat pump conditions.

On the other hand, suppliers of ammonia heat pump compressors also offer open screw compressors that can be used in the current heat pump application. Nevertheless, they do not assure that the compressors could operate within the chiller mode operating conditions. In the current concept, the pressure ratio of both chiller and heat pump operation modes are similar. Thus, it is assumed that if a screw compressor can operate in chiller mode, it would also be possible for it to operate in heat pump mode. Finally, at the current condensation temperatures, the discharge temperature is high. Consequently, manufacturers restrict the discharge temperatures to a lower value with the addition of oil cooling systems to the compressor. In this case, the suggested temperatures by the manufacturers of the compressors were used as a reference. The important dimensioning specifications of the compressor are summarized in Table 3.

Table 2. Compressor specifications

Type	Displacement [m^3/h]	RPM	Isentropic Efficiency	Discharge Temperature Chiller mode [°C]	Discharge Temperature Heat pump mode [°C]
Screw Compressor	250	2900 (50Hz)	0.6	80	110

Regarding the evaporator and condenser, plate heat exchangers were analysed. The supplier used as a reference for the plate heat exchangers was SWEP, which recommends the use of stainless steel plate heat exchanger for the proposed application. The specifications of the chosen heat exchangers are summarized in Table 2. In the case of the evaporator, the same heat exchanger was used in all the configurations, with the difference that the pressure drop will be lower for the flooded evaporator with low-pressure receiver configuration. Moreover, for the flooded evaporator, SWEP also stated that the circulation number for the brazed plate heat exchanger should be around 1.1 (outlet quality of 0.9) which is the value used for the current concept. The condenser is smaller in dimensions when compared with the evaporator. Since ammonia has a high heat transfer coefficient during condensation, the condenser needs smaller heat transfer areas than the evaporator.

Table 3. Plate heat exchangers specifications

Heat Exchanger	Heat Load [kW]	Heat Transfer Area [m^2]	# Plates	# Channels	Volume [dm^3]
Evaporator	180	11.9	94	93	7.9
Condenser	200	3.9	100	99	4

2.2. Numerical Model

The analysis was based on a numerical model of the chiller-heat pump unit to study the thermodynamic cycle for the operating conditions presented in Table 1. This calculation yielded an estimation of the expected coefficient of performance for both chiller and heat pump modes. The model was implemented in Matlab R2018b making use of ammonia properties from REFPROP 10. The compressor used in this concept is a generic proposal based on different specifications from manufacturers. That is why it was not possible to obtain performance curves given as polynomials. A simple model was used for the compressor in which the assumed isentropic efficiency is used to estimate the difference between an ideal compression and a real compression process. Moreover, the heat loss from the compressor was also calculated based on the assumed discharge temperatures and the theoretical discharge temperature. Finally, the amount of refrigerant in the compressor was calculated based on the method proposed by Poggi [7] making use of the volumetric displacement.

For the evaporator and condenser, detailed models were implemented for analysing component performance and refrigerant inventory. The detailed models accounted for the specifications provided by the manufacturers of each component. The models utilized a 1D-discretization approach with a Newton-Raphson solver in which the heat exchanger was divided into 100 control volumes of equidistant enthalpy steps during the phase change of ammonia through the plate heat exchangers. Mass and energy balances as well as heat transfer equations were formulated for each control volume. Calculation of the heat transfer coefficient for two-phase flow was based on the correlations from Amalfi [19] for the evaporator and Yan [20] for the condenser. In case of single phase heat transfer coefficient, the correlation of Longo [21] was used for ammonia and Kim [22] for water. The models also computed the pressure drop along the plates based on the correlations for the fanning friction factor of Amalfi [19] in case of the evaporator and Arman [23] for the condenser. For the single phase friction factor, Martin [24] was used for ammonia and Kim [22] for the water. The calculation of refrigerant mass inside the evaporator and condenser needs the implementation of a void fraction model. However, there is no model developed for ammonia within plate heat exchangers. In this case, aside from the homogeneous model, the void fraction models of Zivi, Smith, Rouhani-Axelsson, Premoli, Hughmark, Yashar and Boher, presented by Godbole [25] and Poggi [7], were selected as suitable models for the current application. The component models for compressor, condenser and evaporator were coupled to simulate the operating conditions of the units when working in the chiller and heat pump mode as well as to simulate the dependency of the refrigerant charge between these components.

The dimensioning of the receiver is based on its capacity to store the excess of refrigerant during a change of operation mode. However, in the current study, we were mainly interested in the amount of refrigerant needed to act as a seal between the incoming and outgoing refrigerant streams at design conditions. Following a conservative approach, Rajapaksha [18] recommends that the amount of refrigerant in the receiver has to be one-sixth of the charge needed by the system in design conditions. Finally, the piping between the different components was also considered as part of the charge estimation. In this case, a fixed pipe length of 1 m was assumed for suction and discharge pipes of the compressor and 0.5 m for the liquid lines. However, the pipes that connect the low-pressure receiver with the flooded evaporator were dimensioned to have a suitable driving force to run the evaporator with thermosiphon effect. Moreover, standard pipe diameters for ammonia systems were used considering that the flow velocities of the refrigerant would not exceed the values recommended for ammonia systems by Granryd [26].

3. Results

The coefficient of performance (COP) of the vapour compression cycle with ideal compression for chiller mode using the temperatures specified in table 1 is 5.6 and likewise 5.6 for the heat pump mode using the temperatures specified for the heat pump mode. However, the use of real components specifications and the different configurations will affect this ideal COP. For instance, as can be seen in figure 2, the operating cycle for the DX systems (dashed red line) for both chiller and heat pump, varies considerably from the ideal compression cycle (blue line).

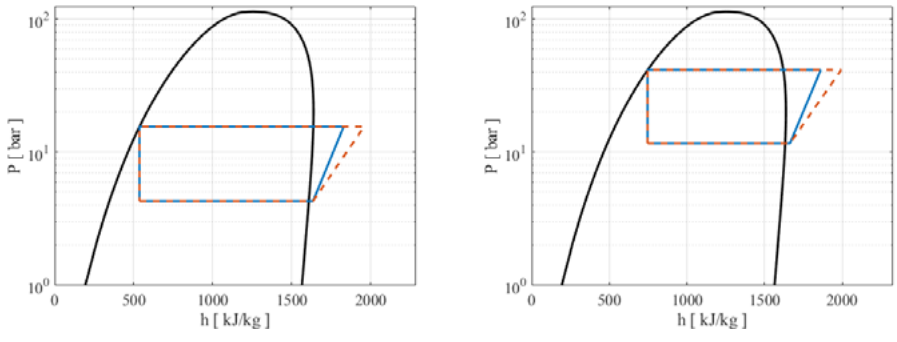

Fig. 2. Log-ph diagram of the Ideal compression cycle and the DX cycle configuration for: a) Chiller operating mode, b) Heat pump operating mode.

For each system configuration presented in figure 1, the mass calculation with the eight void fraction models was applied. Table 4 shows the COP and the average total charge for chiller and heat pump modes and, for the different configurations.

Table 4: COP and refrigerant charge of the systems

	Chiller			Heat Pump		
	DX	DX-HPR	Flooded-LPR	DX	DX-HPR	Flooded-LPR
COP	3.4	3.4	3.5	3.0	3.0	3.2
Average Total Charge [kg]	1.0	1.2	2.2	1.2	1.5	2.7

A quantitative comparison of refrigerant charge presented in Figure 3 for the chiller and Figure 4 for the heat pump, shows the estimation in each component as well as the total refrigerant charge for the three proposed configurations. As can be seen, the refrigerant charge in the compressor is negligible when compared to the total charge of the systems. On the other hand, there is a significant amount of refrigerant that the system accumulates inside the pipes that connect the condenser, expansion valve and evaporator, where the refrigerant is mainly in the liquid phase. Thus, the distance, as well as diameters of these pipes, should be optimized to accumulate the least possible amount of liquid. In the case of evaporator and condenser, the mass distribution shows that most of the refrigerant charge is located inside the evaporator. On the contrary, the charge inside the condenser remains steady despite the type of system. The results for the DX system with high-pressure receiver showed that the addition of the receiver imposes and increment of refrigerant charge due to the liquid level needed at the bottom of it. Besides, more pipe is needed to connect the receiver with the condenser and evaporator. Hence, the share of liquid refrigerant accumulated inside the pipes increases. The flooded configuration presents a different tendency in the charge distribution compared with the previous configurations. In this case, the largest share of refrigerant is still inside the evaporator. However, the share of the pipes slightly increased mainly due to the addition of more pipe circuits to connect the low-pressure receiver.

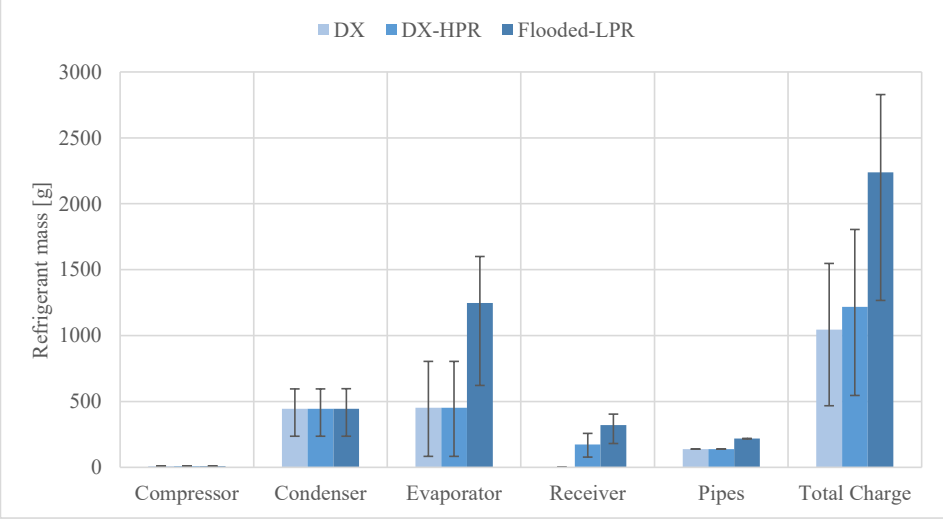

Fig. 3. Refrigerant inventory of the proposed configurations working as a Chiller

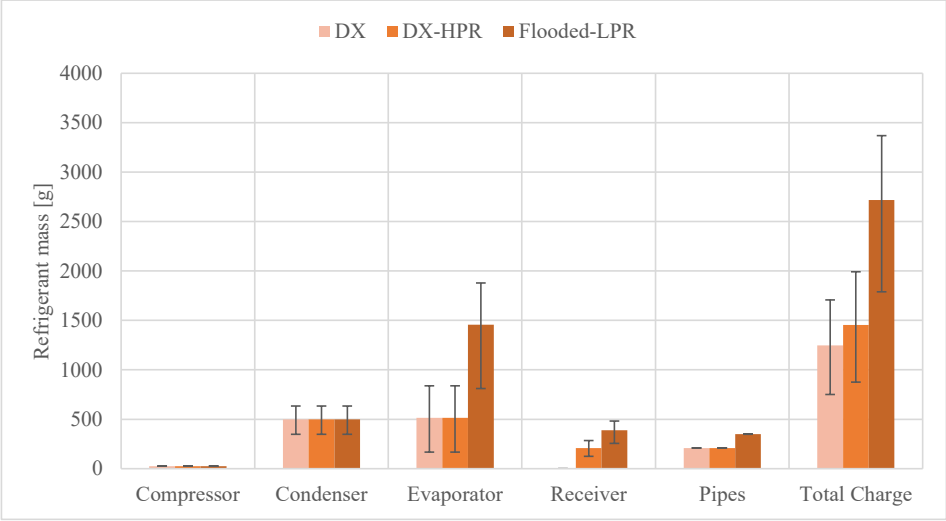

Fig. 4. Refrigerant inventory of the proposed configurations working as a Heat Pump

The error bars shown in Figure 3 and Figure 4, represent the variation that can be expected in the refrigerant charge estimation based on the different void fraction models. To properly depict this dependency on the calculations, Figure 5 shows the eight void fraction models used for a saturation temperature of 0 °C and a saturation temperature of 80 °C. When increasing operating saturation temperature of ammonia, the void fraction models tend to estimate a lower fraction of the heat exchanger being occupied by the vapour phase. Thus, a higher share of the liquid phase is present inside the heat exchangers. Even though between the saturation temperature of 0 °C and saturation temperature of 80 °C, there is a reduction of 20% in liquid density, there is more than 800% increment in vapour density. Therefore, a larger refrigerant charge estimation would be obtained when the concept is operating as a heat pump.

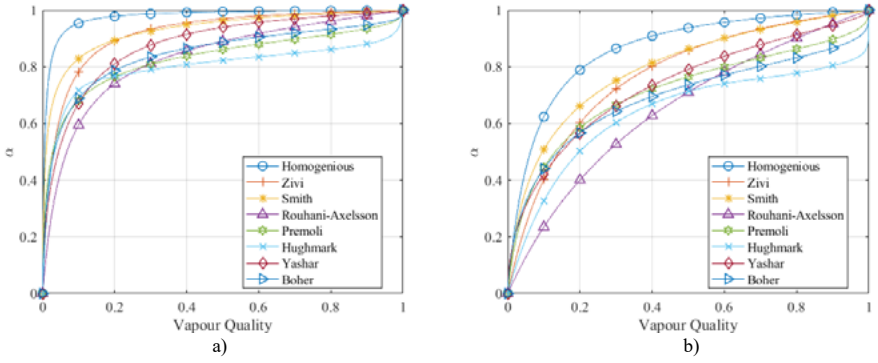

Fig. 5. Void fraction models for Ammonia at: a) Evaporation temperature of 0 °C, b) Condensation temperature of 80 °C.

For each system configuration presented in figure 1, the minimum, average and maximum specific refrigerant charge is presented in table 5. Moreover, the table shows the values of specific charge presented in the introduction to verify the current results.

Table 5: Specific refrigerant charge comparison

	Chiller			Heat Pump			Literature			
	DX	DX-HPR	Flooded-LPR	DX	DX-HPR	Flooded-LPR	Palm [11]	Hrnjak [12]	Nielsen [15]	Industry
Minimum Specific Charge [g/kW]	2.6	3.0	7.0	4.2	5.0	10.0				
Average Specific Charge [g/kW]	5.8	6.8	12.4	7.0	8.0	15.0	11.0	18.0	23.0	100-200
Maximum Specific Charge [g/kW]	8.6	10.0	15.7	9.5	11.0	19.0				

4. Discussion

The COP of the three systems is considerably lower when compared with the Carnot COP. The explanation for this is because of the current selection of equipment for the three configurations. The isentropic efficiency of the compressor plays an important role for the performance of the system. Regarding the calculated refrigerant charge of the three configurations, the average values of specific charge presented in Table 5 are remarkably low when compared with the refrigerant charge of the systems designed by Palm [11], Hrnjak [12], Nielsen [15] or the available systems in the market. The amount of refrigerant charge calculated in this study has a direct dependency on the void fraction model used to estimate the refrigerant charge inside the plate heat exchangers. The results of the simulations showed that the homogeneous model yields the lower estimation for both evaporator and condenser in either chiller or heat pump mode. The higher estimation for evaporator and condenser of the DX systems, in either chiller or heat pump mode, was obtained with the Hughmark model. However, for the flooded evaporator, the highest charge estimation was obtained with Rouhani-Axelsson. Moreover, among the three proposed configurations, the major variation in the refrigerant charge estimation is on the evaporator. Nonetheless, if the values of maximum specific charge are considered as valid, the specific charge will be within the same range as the results presented by Palm [11] or Hrnjak [12].

The selection of larger evaporator and condensers will substantially increase the charge accumulated inside of them. Besides, the pressure drop through these components will decrease and the COP of the system will increase. Hence, a further study to analyse the trade off between the increment in COP and the increment in refrigerant mass will define the optimum size of the system. The amount of refrigerant accumulated in the receiver is also an assumption that affects the charge estimation of the proposed systems. If a higher value for the excess refrigerant in the receiver was assumed, a higher refrigerant inventory would have been estimated. However, the receiver needs further analysis to account for its influence on the performance of the system. In a more detailed study, simulations of the system at different operating conditions are essential to estimate the difference in refrigerant mass needed for the components. Thus, a more accurate value of refrigerant mass within the receiver can be determined. Finally, the consideration of more components that are normally part of these type of systems like liquid or oil separators will improve the estimation of the refrigerant charge. Furthermore, the analysis of more configurations would help to improve the knowledge of the charge distribution of medium capacity ammonia chiller and heat pumps.

5. Conclusion

Medium capacity ammonia systems still need to be developed and optimized to keep improving components as well as the portfolio of ammonia systems within the market. Furthermore, it will facilitate the inclusion and development of small ammonia systems. Three concepts of a medium-capacity low charge ammonia chiller and heat pump able to provide 180 kW of cooling capacity and 200 kW of heating capacity were analysed. The calculation showed that the average amount of refrigerant needed for the system to operate either in cooling or heating mode is 1.2 kg for a DX system, 1.5 kg for a DX with a high-pressure receiver and 2.7 kg for a flooded system with a low-pressure receiver. Even though the flooded system will tend to accumulate a higher amount of liquid refrigerant than the DX system, it is still possible to conceive a flooded system with a low refrigerant charge. The main conclusion from the refrigerant inventory calculation is that industrial or commercial ammonia systems can still be optimized to reduce the amount of refrigerant. Nonetheless, the study of more complex configurations will extend the knowledge and development of low charge ammonia systems.

High-temperature vapor compression heat pump using butane (R600) – development of a prototype and first measurements

Manuel Verdnik[a,*], René Rieberer[a]

[a]Graz University of Technology, Institute of Thermal Engineering, Inffeldgasse 25B, 8010 Graz, Austria

Abstract

The application of industrial heat pumps for waste heat recovery can reduce the usage of fossil fuels and increase the energy efficiency of industrial processes. Utilizing a trans-critical vapor compression cycle extends the operating range of refrigerants beyond their critical temperature, enabling high heat sink temperatures with natural refrigerants, which are characterized by zero ozone depletion potential and a negligible global warming potential.
To prove the concept of a trans-critical vapor compression cycle using butane as refrigerant, a prototype to achieve a nominal heating capacity of 30 kW at heat sink outlet temperatures of up to 160 °C for utilizing waste heat (at 60 °C) was developed. The one-stage cycle with a suction gas cooled reciprocating compressor is equipped with a low-pressure accumulator and an internal heat exchanger (IHX) for suction gas superheating. First measurements of sub-critical and trans-critical operation show remarkable coefficients of performance (COPs) and confirm that optimum high-side pressures yielding the maximum COP exist. In trans-critical operation the optimum pressure can be shifted towards lower pressures by increasing the suction gas superheat in the IHX.

Keywords: industrial heat pump; high-temperature application; hydrocarbons; optimum high-side pressure; trans-critical cycle;

Nomenclature

1…9	state point	p_{hp}	high-side pressure (bar)
accu	low-pressure accumulator	$\pi = p_{ref,1}/p_{ref,2}$	pressure ratio of the compressor (-)
COP	Coefficient of Performance	$\dot{Q}_{SI}$	heating capacity on water side (kW)
$\eta_{is,ov}$	overall isentropic efficiency (-)	ref	refrigerant
$\eta_{is,i}$	internal isentropic efficiency (-)	ρ	density (kg·m³)
η_{FI}	frequency inverter efficiency (-)	s	isentropic change of state
EXV	electric expansion valve	sat	saturated state
h	specific enthalpy (kJ/kg)	SI	heat sink
IHX	internal heat exchanger	sim	simulated
in	inlet	SO	heat source
λ_{vol}	volumetric efficiency	ΔT_{sup}	suction gas superheat (K)
meas	measured	t	temperature (°C)
$\dot{m}_{ref}$	refrigerant mass flow (kg/h)	t_{cond}	condensation temperature (°C)
out	outlet	$\dot{V}$	volume flow
p	absolute pressure (bar)	VIHX	3-way-valve internal heat exchanger
P_{el}	electric power of compressor and inverter (kW)	$\dot{V}_{swept}$	compressor swept volume flow (m³/h)

1. Introduction

Improving the efficiency of energy systems is a key to decrease energy consumption. Implementing all available energy efficiency measures between now and 2040 would allow to double the global gross domestic product by 2040 while limiting the increase in primary energy demand to levels only slightly higher than those today [1]. Through the application of high-temperature heat pumps, the utilization of waste heat to cover industrial process heat demands can be accomplished. A trans-critical vapor compression cycle as proposed by Lorentzen [2] offers the possibility to extend the operating range of refrigerants beyond their critical temperature. While this process is state-of-the art for CO_2, the application of other refrigerants is very limited. Besbes et al. [3] developed a high temperature trans-critical heat pump utilizing R32, capable of producing hot air at 120 °C. Abi Chahla et al. [4] extended the supply temperature to 150 °C by using the HFO 1234ze(E). Regarding natural refrigerants Kimura et al. [5] developed a test apparatus of a trans-critical cycle for R600 using oil-free turbocompressors enabling heat supply temperatures of 180 °C according to simulations.

This work is based on the development of a prototype of a vapor compression heat pump utilizing a natural refrigerant in a trans-critical cycle enabling heat supply temperatures higher than 150 °C. In a trans-critical cycle, the refrigerant is compressed to a supercritical state and the heat rejection occurs at high-side pressure levels exceeding the critical pressure of the refrigerant at gliding temperature. Considering the available components with respect to the necessary pressure, R600 was chosen as refrigerant. The influence of the operating parameters on the efficiency of the prototype were investigated by means of simulation. Measurement data of the prototype is compared to results from the simulation model. The prototype, simulation model and results from experiment and simulation as presented by Verdnik et al. [6] are analyzed in more detail and used to derive an improved simulation model.

2. Prototype of the trans-critical vapor compression heat pump

The development of the prototype was based on a study by Verdnik et al. [7] on the application of R600 in a trans-critical vapor compression cycle. The application specific challenges such as the required suction gas superheat due to the overhanging two phase region of the refrigerant and safety measures due to the flammability of the refrigerant were addressed during the design of the prototype.

2.1. Hydraulic layout

Fig. 1. shows the realized hydraulic layout and a picture of the prototype.

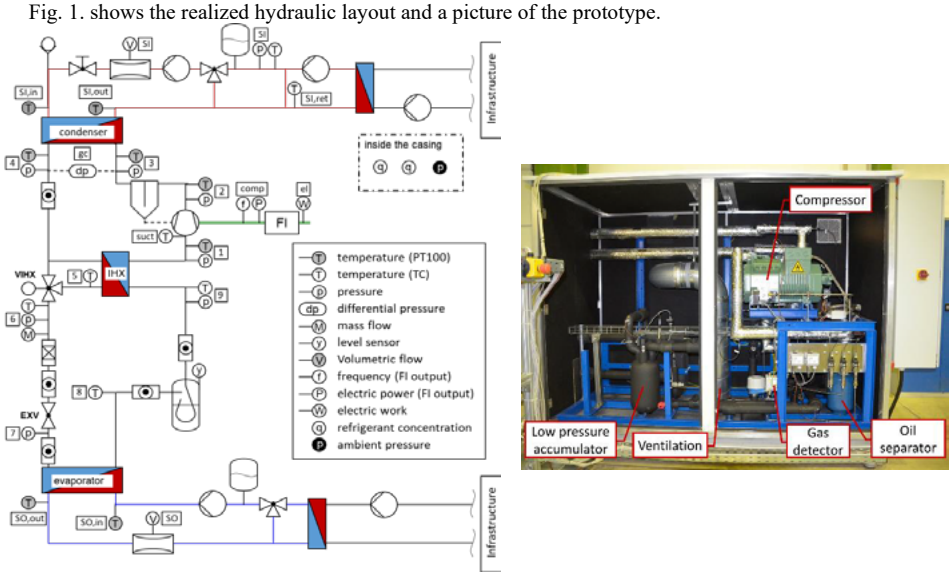

Fig. 1. Hydraulic layout including sensor positions of the high-temperature heat pump (left) and the prototype with opened casing (right)

The single stage cycle utilizes an inverter driven suction gas cooled reciprocating compressor. In order to maximize the evaporation temperature and to accomplish the necessary suction gas superheating in the internal heat exchanger (IHX) saturated refrigerant at the evaporator outlet is targeted. This is accomplished by using a low-pressure accumulator (accu) and the corresponding refrigerant charge to allow for a liquid level in the accumulator.

Experimental data from the prototype is shown in t/h-diagrams with operating points in sub-critical (Fig. 2 left) and trans-critical operation Fig. 2 (right). The state points are corresponding to Fig. 1.

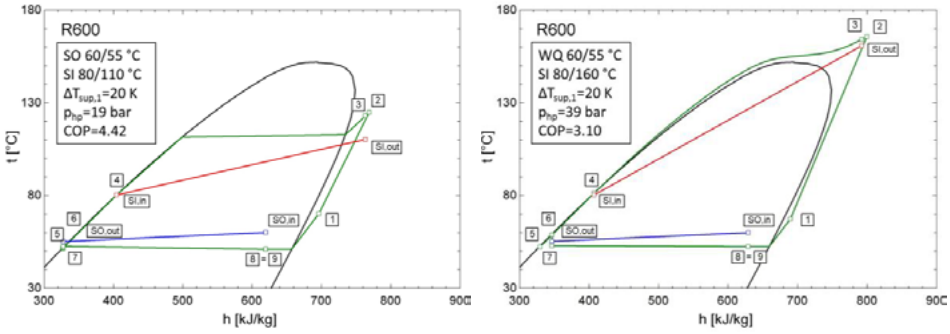

Fig. 2. t/h-diagrams of a measured sub-critical operating point (left) and trans-critical cycle operating point (right)

Refrigerants with an “overhanging” two phase region require a certain degree of suction gas superheat in order to avoid a compression into the two-phase region. According to Moisi and Rieberer [8], the required suction gas superheat for R600 is 18 K assuming a positive evaporation temperature and isentropic compression. At the prototype, the suction gas superheat is evaluated at the compressor suction port as well as before the refrigerant flows into the cylinder after cooling the electric motor according to equation (1) and (2), respectively. While the superheat before the cylinder acts as a threshold for the minimum superheat, the value at the control inlet is used as the control variable for the VIHX.

$$\Delta T_{sup,1} = t_{ref,1} - t_{sat}(p_{ref,1}) \tag{1}$$

$$\Delta T_{sup,suct} = t_{ref,suct} - t_{sat}(p_{ref,1}) \tag{2}$$

The three-way-valve (VIHX) controls the degree of suction gas superheat at state point 1. The electronic expansion valve (EXV) is used to control the high-side pressure. Assuring saturated vapor at the outlet of the evaporator and inlet of the IHX by using an accumulator also decouples the control loops for high-side pressure and suction gas superheat. In order to keep the pressure throughout the condenser above the set pressure and to dampen pressure oscillations from the compressor the condenser outlet pressure is used as the control variable for the high-side pressure control loop.

The auxiliary hydraulic cycles representing the heat source and heat sink use pressurized water at 10 bars which is corresponding to a boiling point of 180 °C. A hydraulic separator with a bypass pump is used in the sink cycle to avoid high return temperatures ($t_{SI,ret}$) at the heat exchanger connecting the test rig with the infrastructure.

Due to the flammability of the refrigerant, two gas detectors are installed in the machine casing. If the concentration of R600 reaches 20% of the lower flame level, an explosion proof ventilation system is activated and the power supply to the rest of the prototype is cut.

With exemption of the prototype compressor, off-the-shelf parts as listed in Table 1 are used in the trans-critical heat pump.

Table 1. Main components used in the refrigerant cycle

Component	Manufacturer	Specifications
Compressor	Bitzer	$\dot{V}_{swept}$ @50Hz 34.7 m³/h
Oil separator	ESK Schultze	V=7.5 l
VIHX	Siemens	p_{max}=43 bar
EXV	Carel	t_{max}=70 °C
Accumulator	Frigomec	V=7.8 l
Heat exchangers	Alfa Laval	Brazed plate with asymmetric channels
		Brazed plate
		Brazed plate

2.2. Measurement equipment and evaluation

The used measurement equipment is listed in Table 2 including the expected uncertainties of reading at the measured operating points of the prototype. The accuracy of the temperature sensors was determined through calibration. For the other measured quantities manufacturers' specifications regarding the accuracy of the sensor as well as the acquisition system were taken into consideration. The uncertainty of measurement of evaluated quantities have been estimated using the Gaussian Error Propagation implemented in the Engineering Equation Solver (EES) [9]. Properties of R600 and water are evaluated with EES.

Table 2. Measurement equipment used for evaluating the capacities and evaporation temperature

Measured quantity	Location	Sensor	Uncertainty of reading
Temperature	SI,in; SI,out	Pt100	± 0.1 K
Volumetric flow rate	SI	Electromagnetic flow meter	± 0.0015 l/s
Electric power consumption	el	Wattmeter	± 1% of reading
Pressure	4	Strain-Gauge	± 0.25 bar
Pressure	7	Strain-Gauge	± 0.09 bar

The systems COP is evaluated according to equation (3) by averaging 10 minute long measurements of steady operating points at a measurement interval of 1 second.

$$COP = \frac{\dot{Q}_{SI}}{P_{el}} = \frac{\dot{V}_{SI,in} \cdot \rho_{SI,in} \cdot (h_{SI,out} - h_{SI,in})}{P_{el}} \quad (3)$$

The power consumption of the heat pump is measured at the terminal of the frequency inverter with a wattmeter.

2.3. Experimental investigation of optimum high side pressure

In order to determine the influence of the high-side pressure on the COP the high-side pressure was varied while the heat sink and source temperatures, the suction gas superheat and the compressor speed were set constant. It was found that an optimum value for the high-side pressure exists. Fig. 3 shows t/h-diagrams of measured sub-critical operating points at a pressure lower than the optimum pressure, close to the optimum pressure and at a too high pressure from left to right. During sub-critical operation the location of the pinch point in the condenser is determined by the sink temperature levels and the condensing temperature. Through controlling the high-side pressure, the EXV determines the condensation temperature. At too low high-side pressures, as shown in Fig. 3 (left), the pinch point occurs at the refrigerants dew line, i.e. within the condenser. This limits the heat transfer leading to an increased refrigerant temperature at the condenser exit (state point 4) which reduces the heating capacity. Increasing the high-side pressure increases the compressor outlet temperature to the cost of increased compression work. Too high pressure levels as seen in Fig. 3 (right) decrease the COP since the pinch point at the condenser outlet limits the heat transfer and the increase in

heating capacity is outmatched by the increase in compression work. In between these two cases an optimum high-side pressure, as depicted in Fig. 3 (middle), yielding the maximum COP can be found.

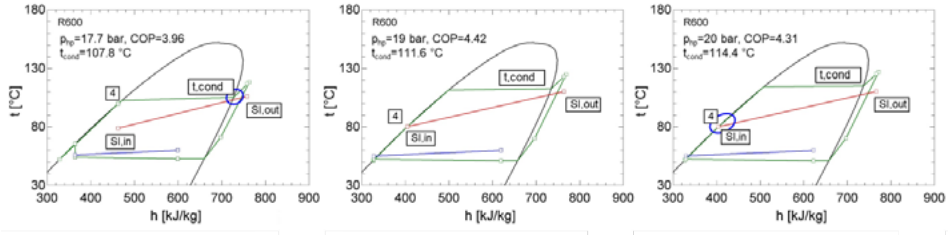

Fig. 3. t/h-diagrams of measured sub-critical operating points at different high-side pressures at source inlet/outlet temperatures of 60/55 °C, sink inlet/outlet temperatures of 80/110 °C and a suction gas superheat of $\Delta T_{sup,1}$=20 K

Similar observations can be made during trans-critical operation. At a constant compressor inlet state, the compressor outlet temperature and subsequently the condenser inlet temperature (state point 3) depend on the high-side pressure. The location of the pinch point in the condenser depends on the condenser inlet state, thus the heat transfer in the condenser is affected by the high-side pressure.

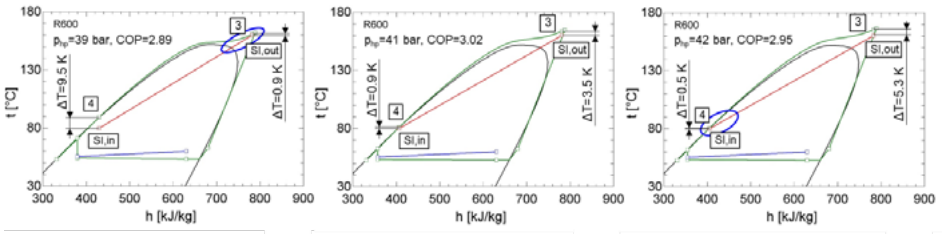

Fig. 4. t/h-diagrams of measured trans-critical operating points at different high-side pressures at source inlet/outlet temperatures of 60/55 °C, sink inlet/outlet temperature of 80/160 °C and a suction gas superheat of $\Delta T_{sup,1}$=10 K

The second operating parameter studied experimentally is the suction gas superheat. Fig. 5 shows the dependency of the COP on the high-side pressure for 10 K, 15 K and 20 K of suction gas superheat at the compressor inlet.

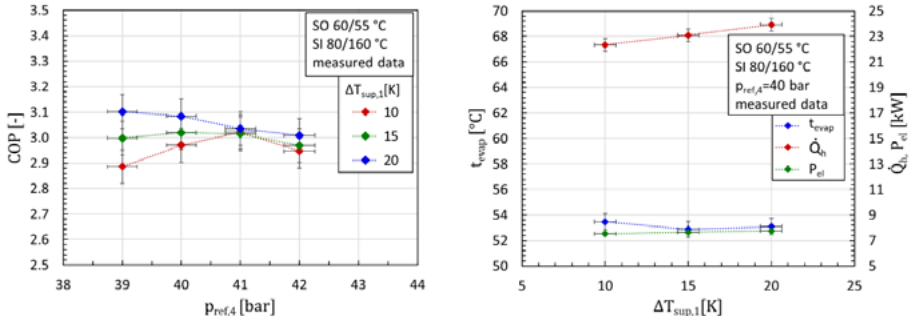

Fig. 5. Measured COP at source inlet/outlet temperatures 60/55 °C and sink inlet/outlet temperatures 80/160 °C for different values of suction gas superheat (left) and the influence of the superheat on evaporation temperature and capacities (right)

It can be seen that by increasing the suction gas superheat in the IHX the levels for optimum high-side pressure can be shifted to lower values while an increase of the COP is possible, which is in agreement with

the simulation study conducted by Verdnik et al [7]. This is possible because the increase in suction gas superheat established in the IHX does not lead to a drop in the evaporating temperature as can be seen in Fig. 5 (right). The increased condenser inlet temperature lead to an increase in the heating capacity which is larger than the increase in compressor power, which subsequently leads to the observed increase in the COP.

3. Simulation model

The TIL Suite package [10] was used to develop a simulation model of the trans-critical heat pump. This Dymola library contains models for components and media properties in the object-based Modelica language, Predefined models of the package have been modified or extended with user specific geometries or correlations for heat transfer and pressure drop.

3.1. Compressor model

The compressor is modeled using the overall isentropic efficiency, inner isentropic efficiency and volumetric efficiency according to equation (4), (5) and (6) respectively. The efficiencies are based on data extracted from the manufacturers' software [11]. As first experiments showed a stronger decline in the volumetric efficiency, the slope of the gained approximation was increased by 30 %. In order to calculate the power consumption at the terminal of the frequency inverter, an inverter efficiency of 95% is assumed according to equation (7), yet all simulations and measurements in this work have been conducted at an inverter frequency of 50 Hz.

$$\eta_{is,ov} = \frac{\dot{m}_{ref} \cdot (h_{ref,2s} - h_{ref,1})}{P_{comp}} = 0.684 - 0.002 \cdot \pi - 0.0004 \cdot \pi^2 \quad (4)$$

$$\eta_{is,i} = \frac{h_{ref,2s} - h_{ref,1}}{h_{ref,2} - h_{ref,1}} = 0.76 - 0.002 \cdot \pi - 0.0004 \cdot \pi^2 \quad (5)$$

$$\lambda_{vol} = \frac{\dot{m}_{ref}}{\rho_{ref,1} \cdot \dot{V}_{swept}} = 1.04 - 0.05 \cdot (1 + 30\%) \cdot \pi = 1.04 - 0.065 \cdot \pi \quad (6)$$

$$P_{el} = \frac{P_{comp}}{\eta_{FI}} = \frac{P_{comp}}{0.95} \quad (7)$$

3.2. Modelling of the heat exchangers

The TIL-Suite includes models for plate heat exchangers based on a finite volume approach. For the IHX and evaporator these models were used with a discretization of 10 cells. The model for the condenser was adopted to account for the asymmetric channel widths of the refrigerant and the water side and a discretization of 80 cells was used. A sinusoidal chevron pattern with an inclination angle of 60° was assumed for all heat exchangers. Table 3 shows the used geometry for the heat exchanger models as well as the correlations for the heat transfer coefficients (HTC) and pressure drops (Δp).

Table 3. Correlations used in the heat exchanger models

		Condenser		Evaporator	IHX		
		Refrigerant	Water				
Refrigerant	HTC	Forooghi and Hooman [12]		Longo [13]	Refrigerant	HTC	Forooghi and Hooman [12]
	Δp	Martin [14]		Longo [15]	high-pressure side	Δp	Martin [14]
Water	HTC	Martin [14]		Martin [14]	Refrigerant	HTC	Longo [13]
	Δp	Martin [14]		Martin [14]	low-pressure side	Δp	Martin [14]

3.3. Simulation study on variation of the operating parameters

The influence of suction gas superheat, heat source temperature level and heat sink inlet and outlet temperatures on the COP have been studied over a range of high-side pressures.

An increase of the suction gas superheat lowers the optimum high-side pressure and increases the COP as can be seen in Fig. 6. Since the heat sink inlet/outlet temperatures of 80/160 °C, as depicted in Fig. 6 (left), can be reached with pressures slightly above the critical pressure (37.96 bar), this effect can be seen clearer at sink inlet/outlet temperatures of 80/170 °C, as depicted in Fig. 6 (right).

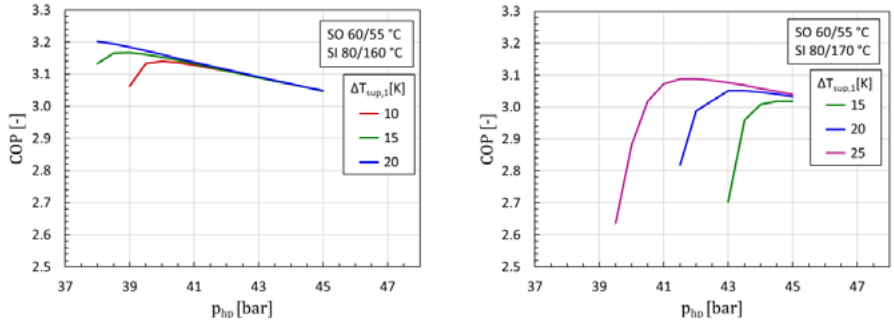

Fig. 6. Simulated COP for different high-side pressures at varying suction gas superheat for source inlet/outlet temperatures 60/55 °C, sink inlet/outlet temperatures 80/160 °C (left) and heat sink inlet/outlet temperatures 80/170 °C (right)

A variation of the sink inlet temperature, as depicted in Fig. 7 (left), shows that an increase of the sink inlet temperature leads to a decrease of the COP, but the value of the optimum high-side pressure is not influenced. Varying the sink outlet temperature, as illustrated in Fig. 7 (right), shows that higher high-side pressures are necessary to achieve higher sink outlet temperatures, which leads to a decrease of the maximum COP. By comparing the two graphs it can be seen, that the system COP is more sensitive in a change of sink inlet temperature than sink outlet temperature.

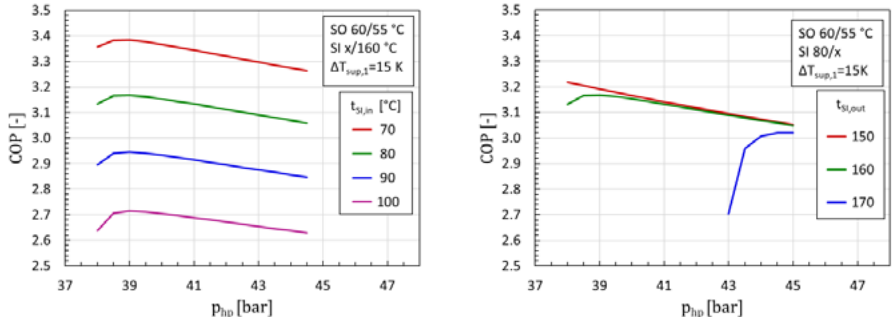

Fig. 7. Simulated COP for different high-side pressures at varying suction gas superheat for varying sink inlet temperature (left) and varying sink outlet temperature (right)

The last operating parameter to investigate is the heat source temperature. Fig. 8 shows a variation of the heat source temperature with a constant difference between inlet and outlet temperature of 5 K. As can be seen in Fig. 8 (left), an increase of the heat source temperature leads to an increase of the COP because of the reduced pressure ratio the compressor has to overcome. The level of the optimum high-side pressure is slightly shifted towards higher pressures but is very close to the minimum pressure needed to reach the set heat sink outlet temperature. As the heat source temperature determines the evaporation temperature, an increase of the heat source temperature leads to a strong increase in compressor power and heating capacity, as can be seen in Fig. 8 (right.)

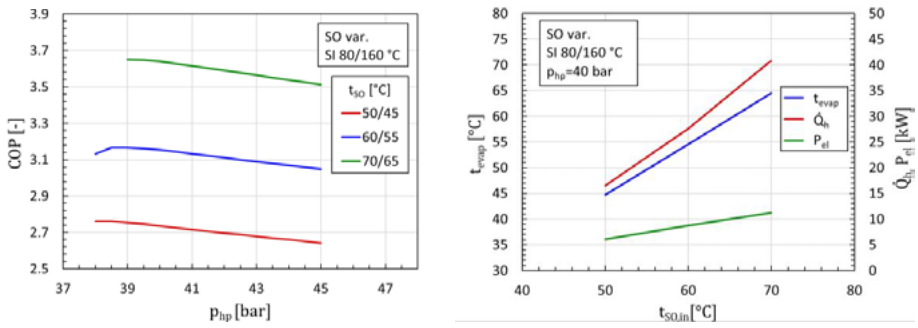

Fig. 8. COP for different high-side pressures at varying suction gas superheat at varying source temperatures (left) and the influence of the source temperature on evaporation temperature and capacities (right)

4. Simulation vs. measured data

Fig. 9 compares the results of the simulation model with the experimental data gathered with the prototype for the same operating point and different values of suction gas superheat. The simulation reflects the characteristic relation of the COP on the high-side pressure, although the value of the optimum high-side pressure is not exactly reproduced.

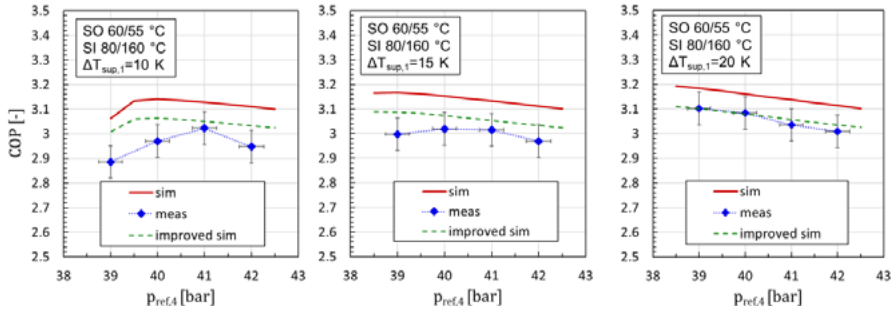

Fig. 9. Measured and simulated COP for heat source inlet/outlet temperatures 60/55 °C, heat sink inlet/outlet temperatures 80/160 °C and suction gas superheat of $\Delta T_{sup,1}$=10 K (left), 15 K (middle) and 20 K (right)

A direct comparison of the simulated and measured values for the COP, the heating capacity and the electric power consumption in Fig. 10 shows a deviation between simulation and experiment of +7%, +20% and +15% respectively which is caused by a slight overestimation of the evaporation temperature and compressor volumetric efficiency in the simulation. As first steps to improve the simulation model, the vapor quality at the accumulator outlet, the compressors volumetric efficiency, the pressure drop and assumptions regarding the plate pattern geometry in the evaporator were investigated. In the improved simulation model, the vapor quality at the outlet of the low-pressure accumulator was modelled with values less than unity depending on the filling level instead of the ideal behavior of saturated vapor. In the evaporator, momentum, manifold and port, and gravity pressure drop according to Longo et al. [13] were considered on the refrigerant side. The assumption regarding corrugation angle and pitch were altered to 10° and 10 times the corrugation height, respectively. The compressors volumetric efficiency was modelled with equation (8).

$$\lambda_{vol} = 0.945 - 0.056 \cdot \pi \tag{8}$$

The results of the improved simulation model yield a deviation to experimental data of less than 5% in COP, less than 7% for the heating capacity and less than 5% for the electric power consumption as can be seen in Fig. 10.

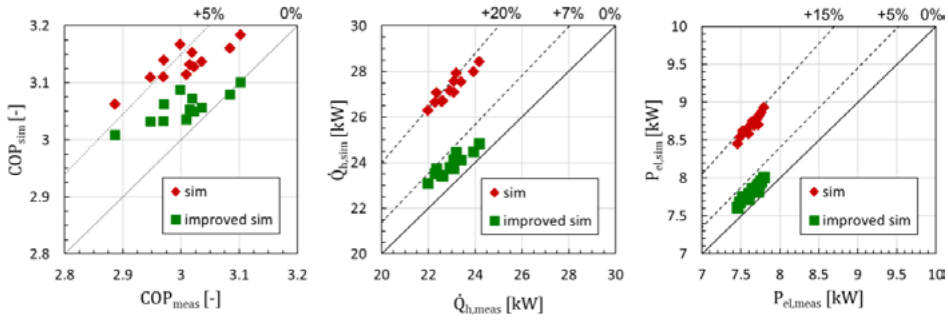

Fig. 10. Comparison of simulated and measured COP (left) heating capacity (middle) and electric power consumption (right)

5. Conclusions and Outlook

A prototype of a high-temperature vapor compression heat pump utilizing R600 in a one-stage cycle using a reciprocating compressor, low-pressure accumulator and IHX for suction gas superheating has been developed. First measurements prove the concept of using R600 in a trans-critical cycle. Tests conducted at heat source inlet/outlet temperatures of 60/55 °C showed a COP of 4.42 for heat sink inlet/outlet temperatures of 80/110 °C in sub-critical operation. Increasing the high-side pressure to values exceeding the critical pressure of the refrigerant enabled heat sink inlet/outlet temperatures of 80/160 °C, yielding a COP of up to 3.10 depending on the suction gas superheat and high-side pressure. Energy balances over the IHX showed that the refrigerant vapor quality at the outlet of the low-pressure accumulator is in the range of 0.9 depending on the operating point, which reduces the possible suction gas superheating in the IHX.

The originally introduced simulation model reproduced the system COP with a deviation of less than 7%, while the heating capacity and electric power consumption were overestimated by 20% and 15%, respectively. After further considerations regarding refrigerant vapor quality at the accumulator outlet, volumetric efficiency of the compressor and evaporator geometry and pressure drop, the deviation was reduced to less than 5%, 7% and 5% in COP, heating capacity and electric power consumption, respectively.

The next steps will be to conduct further measurements to evaluate the compressor and system efficiency as well as more detailed investigations regarding the refrigerant charge and pressure drop in the condenser. The simulation model will be refined and validated using experimental data. The operational envelope in terms of heat source temperatures, suction gas superheat and inverter frequency will be experimentally determined with respect to the compressor power and sufficient cooling of the electric motor. These insights should serve to develop a control strategy for the optimal high-side pressure and suction gas superheat depending on the operating conditions of the high-temperature heat pump.

Analysis of the impact of different HVAC configurations andcontrol strategies on primary energy and cost savings for an office building

Mara Magni[a], Fabian Ochs[a]

[a]University of Innsbruck, Technikerstraße 13, Innsbruck 6020, Austria

Abstract

In order to mitigate climate change, sustainable and responsible use of resources is required. In the present study, different technologies applicable for the renovation of an office building are evaluated considering, both economic feasibility and environmental impact for the climates of Rome Stuttgart and Stockholm. Decentralized heating and cooling systems represented by different types of heat pumps (i.e. air-to-air On/Off and modulating) are considered in combination with photovoltaic panels (PV), battery and efficient lighting (LED) in order to investigate the achievable energy savings and the additional cost. The environmental impact is evaluated in terms of electricity and total primary energy (PE) savings calculated with constant and monthly conversion factors representing different scenarios with different share of renewables in the electricity mix.
It was observed that the energy savings calculation method influences the ranking of renovation packages. High-energy savings with low additional cost are achievable with HP in combination or not with LED and PV, in Stockholm and Stuttgart, and with LED and PV in combination with electric heating in Rome. Battery brings additional energy savings with high additional cost.

1. Introduction

In spite of higher efficiency, the energy consumption of buildings has increased over the past decades and the European Union has set restrictive targets. To reach these goals, buildings have to be transformed from energy consumer to energy provider. In non-residential buildings, the available façade area for the installation of a renewables based system is limited and an optimization of the building system is required in order to reduce the primary energy demand.

The recast of the Energy Performance of Buildings Directive [1] states that member state (MS) must ensure that minimum energy performance requirements for buildings are set “with a view to achieve cost-optimal levels” in terms of global cost and primary energy need. The cost-optimal level must be calculated in accordance with a comparative methodology.

In the literature, some studies dealing with both economic feasibility and environmental impact for office buildings are present but they do not consider different scenarios for the evaluation of the influence of the electricity mix. Pikas E. et al. [2] is focused on the building envelope considering different fenestration design solutions. Gustafsson M. et al. [3] investigated energy renovation packages involving centralized heating and cooling system, windows, envelope insulation and solar photovoltaics (PV), for European office buildings. Sanja Stevanović presented a cost optimality study [4] for an office building located in Serbia where the cooling demands is predominant.

Ochs F, et al. [5] introduces a PE evaluation method considering different future development of the load (i.e. building stock) and electricity mix (share of REs) with seasonal variations. This works highlight the need of an appropriate evaluation method for comparing and ranking different passive and active technologies on micro- and macro- economic scale. Different EU MS adopts different national conversion factors for PE/CO_2, which are subject to change [5]. Seasonal variations are not considered at all, although the share of renewables within the period of consideration (e.g. 20 years) should be included [5].

In this work different HVAC retrofit solutions (i.e. HP, PV, Batteries, LED etc..) are compared against a reference case involving an electric heating system with an On/Off split unit for cooling and fluorescent lamps combining both economic and environmental analysis. A sensitivity analysis is carried out in order to evaluate the influence of input parameter (i.e. interest rate, investment cost and electricity price) on the results of the economic analysis. The environmental analysis is performed using different share of renewables in the electricity mix showing the impact of the development of increasingly share of RE on the ranking of the different retrofit solutions.

2. Method

2.1. Building model and boundary conditions

The reference building is chosen in order to be representative of a typical European office cell located in middle floor of a high-rise building [6]. Three different European climates are considered in this study: Rome (Mediterranean), Stuttgart (cold moderate) and Stockholm (cold climate). Fig. 1 shows the considered office cell, which has a heated area of 27 m^2 and a volume of 81 m^3. All the surfaces are considered adiabatic, except for the façade oriented toward South (with window-to-wall ratio of 60%) where ambient boundary conditions are applied. Shading from adjacent obstacles is not considered, whereas an external movable shading, able to block 70% of the incoming radiation, is activated when direct solar radiation impinging the south façade is higher than 120 W/m^2.

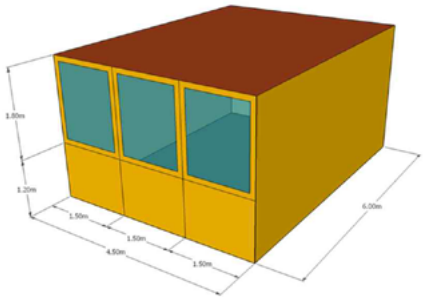

Fig. 1. View of the reference office zone [6]

Table 1 shows the yearly average ambient temperature ($T_{amb,av}$), yearly global irradiation over a horizontal surface ($I_{g,h}$) and yearly irradiation over a south oriented vertical surface (I_{south}) for each climate.

The thermal transmittance of the façade elements ($U_{ext,wall}$) and the characteristics of the windows such as the thermal transmittance (U_{win}), the solar heat gain coefficient (g-value) and the solar transmittance (τ_{sol}) depend on the three climates, as shown in Table 1. The internal walls are typical plasterboard walls, the exterior wall is a three layer structure with different insulation thicknesses depending on the climate.

User behavior (e.g. occupancy, appliances and lighting) is taken into account by means of hourly profiles, different for week and weekend days [7]. A contemporaneity index of 0.8 is used for occupancy and appliances. Three persons are present during the working time and a sensible and latent heat of 70 W/person and 0.08 kg/h/person are considered. The internal gain due to appliances is assumed to be 7 W/m^2 and the electric gain due to lighting is 10.9 W/m^2. The lighting schedule follows occupied hours and is defined considering a non-daylight responsive system

The natural infiltration rate is assumed to be constant and equal to 0.15 1/h. A fresh air supply of 40 m^3/h/person is covered by a mechanical ventilation system with heat recovery (70% sensible efficiency), which is active only during the working time (i.e. from Monday to Friday from 8:00 am until 08:00 pm).

Table 1. Main properties of the south oriented façade and climates [6]

	$T_{amb,av}$ [°C]	$I_{g,h}$ [kWh/m^2]	I_{south} [kWh/m^2]	$U_{ext,wall}$ [W/m^{2}K]	U_{win} [W/m^{2}K]	g-value [-]	τ_{sol} [-]
Rome	15.8	1632	1253	0.80	1.26	0.33	0.462
Stuttgart	9.9	1101	889	0.40	1.35	0.59	0.426
Stockholm	7.8	952	884	0.20	0.90	0.63	0.260

An anti-freezing resistance is heating up the ambient air when the external temperature falls below 0°C while a bypass of the heat recovery is activated when the temperature of the zone is higher than 23 °C and the ambient temperature is lower than the indoor temperature. The set point temperature for the indoor convective temperature during the wintertime and summertime are 21°C and 25°C. A detailed description of the boundary conditions is reported in D'Antoni, et al. [6]. The building model is developed in Matlab/Simulink and it has been validated against other dynamic simulation tools [8].

2.2. Renovation packages

The renovation packages discussed in this paper include the combination of different heating, cooling and lighting technologies optionally combined with PV and battery without modifying to the envelope. In addition, the effect of different control strategies is considered.

Table 2 reports all the technologies involved in this study highlighting in bold the reference system used for the comparison (i.e. electric heating and On/Off HP for cooling with a standby consumption running for the entire year, fluorescent lighting and the reference control system for the ventilation and free-cooling described in section 2.1). The electric heating system can be retrofitted with either a simple On/Off or improved modulating HP that might cover also the cooling load.

In the reference case the free cooling can be activated only during the working time therefore savings in terms of cooling demand can be achieved when the free cooling is activated every time the internal and external conditions makes it effective.

Switching off completely the cooling system during the winter season, enable savings by reducing the standby consumption. Switching off the heating and cooling systems during non-occupied periods (night set-back) might enable further savings. Moreover, using modern LED instead of fluorescent lamps can approximately halve the electricity consumption for lighting purpose.

Table 2. Characterization of the investigated renovation components

	Options	Description
Heating	**Direct electric**	Electric resistance, efficiency equal to 1.
	On/Off (Split type) HP	See Fig. 2. Two different On/Off HP sizes are considered.
	Modulating (Split type) HP	See Fig. 2.
Cooling	**On/Off** (Split type) Air-Con.	See Fig. 2. Two different On/Off HP sizes are considered.
	Modulating (Split type) Air-Con.	See Fig. 2.
PV	Mono-crystalline silicon	PV installed in the available wall area (5.4 m^2) in the south façade with an efficiency of 17.7% and a peak power of 877 Wp.
Battery	Ideal battery	Efficiency of 90% (4kWh capacity).
Control	HP and mechanical ventilation	**On/Off HP** and PI for the modulating HP, for the mechanical ventilation see the building description.
	Free cooling 7/7	Free cooling can be activated every time the internal and external conditions makes it effective.
	Improved standby consumption	Standby consumption of 10W accounted only during the working season of the considered technology (instead of the whole year).
	Night set back	The heating and cooling systems are switched off during non-occupied periods and restarted 4h before the working time.
Lighting	**Fluorescent**	10.9 W/m^2 (500 lux on the working desk, 8 luminaire).
	LED	5.45 W/m^2 (500 lux on the working desk, 8 luminaire).

As specified in Table 2, two On/Off HP with different sizes and one modulating HP are considered in this work. The main characteristics (i.e. COP, EER, heating and cooling power and air volume flows) are reported in Table 3 and the maps of performances in Fig. 2.

Table 3. Main characteristics of the modulating and On/Off heat pumps. The heating power and COP are specified for the external air temperature of 15°C and internal of 22°C while the cooling power and EER are specified for the external air temperature of 35°C and internal of 27°C. For the modulating HP the performances are specified for the maximum f_{max} and minimum f_{min} frequency.

	Internal air volume flow [m³/h]	External air volume flow [m³/h]	Heating power (15°C/22°C) [W]	Cooling power (35°C/27°C) [W]	COP (15°C/22°C) [-]	EER (35°C/27°C) [-]
Modulating HP	648	1872	f_{max}: 4006 f_{min}: 1006	f_{max}: 2510 f_{min}: 1248	f_{max}: 5.44 f_{min}: 5.86	f_{max}: 5.29 f_{min}: 5.05
On/Off HP low power	187	1872	523	1250	4.12	4.28
On/Off HP high power	648	1872	3923	2510	5.38	5.29

Fig. 2 shows the performances of the modulating, On/Off low (lp) and high (hp) power heat pumps in cooling and heating operation used in the simulations. The COP of the On/Off HP (Fig. 2.2b) considers a degradation of the performance due to deicing when the ambient temperature is between 7°C and 2°C. The modulating HP is modelled with a separated deicing model therefore the COP reported in Fig. 2.1b does not consider the losses due to deicing operation.

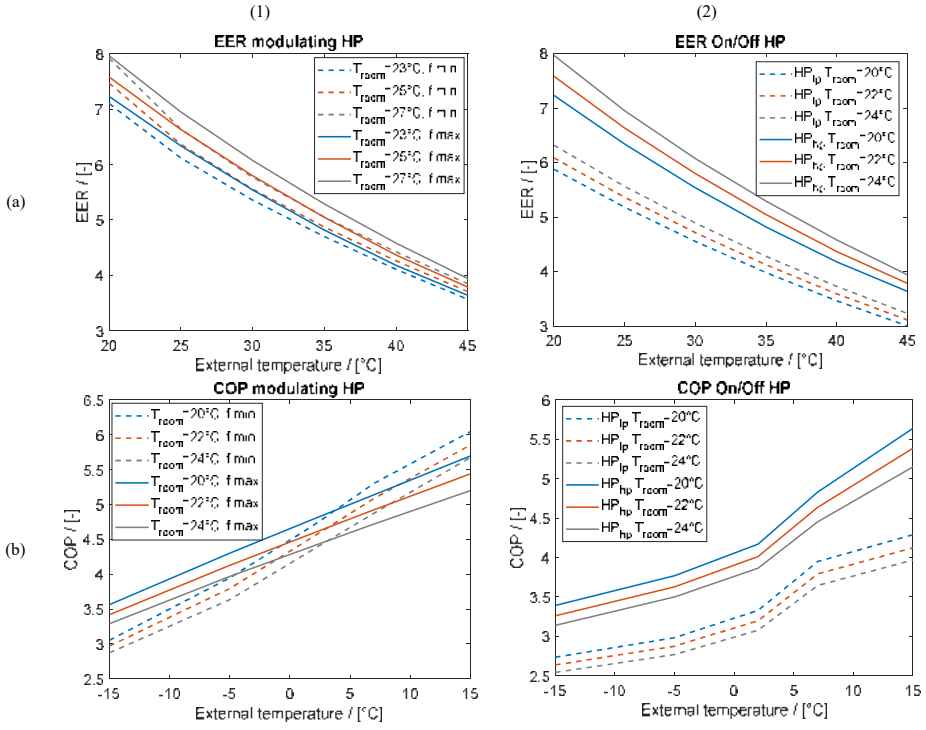

Fig. 2. Maps of performances of the modulating (1) and low power (lp) and high power (hp) On/Off (2) heat pump in cooling (a) and heating (b) mode

The schemes of the control system used for the On/Off and modulating HP are reported respectively in Fig. 3a and Fig. 3b. The On/Off HP is controlled with an hysteresis (±0.5 K) having as input the temperature difference between the heating set point and the air temperature ($T_{set,H}$-T_{air}) during the heating mode and the temperature difference between the air temperature and the cooling set point (T_{air} -$T_{set,C}$) during the cooling mode. The Look-up-Tables (LuT) deliver as output the COP/EER, the absorbed electric power (P_{el}) and the delivered thermal power ($\dot{Q}_{th}$). The transfer function (TF) with a time constant of 130 s is necessary to slow down the

system response and makes the heat pump behaviour more realistic. The LuT have as input the control signal, the air temperature (T_{air}) and the ambient temperature (T_{amb}).
The modulating HP is controlled with a proportional integral (PI) control having as input $T_{set,H}$-T_{air} during the heating mode and T_{air}-$T_{set,C}$ during the cooling mode. The equation (1) shows the PI control rule where the proportional parameter K_p is equal to 1 and the integral time constant T_n is equal to 418.7 s.

$$f(t) = K_p \cdot \left(err\ (t) + \frac{1}{T_n} \cdot \int err\ (t)\, dt \right) \quad (1)$$

The control system of the modulating HP includes also a minimum run (t_{ON}) and off (t_{OFF}) time and the deicing ($dt\ r_{deic}$). The deicing cycle, which last 600 s, starts only when the time counter reaches the defined waiting time that is a function of the ambient temperature (i.e. 11460 s for an ambient temperature of -7°C and 2406 s for an ambient temperature of 5°C). During the deicing cycle, the HP absorbs electric energy without delivering any thermal energy to the room. When the HP is switched on and is not performing the deicing cycle, it is forced to remain in operation with a frequency between the minimum and the maximum until the minimum run time counter reaches the threshold of 300 s. In the same way, when the HP is switched off, it is forced to remain in this status until when the minimum off time counter reaches the threshold of 600 s.

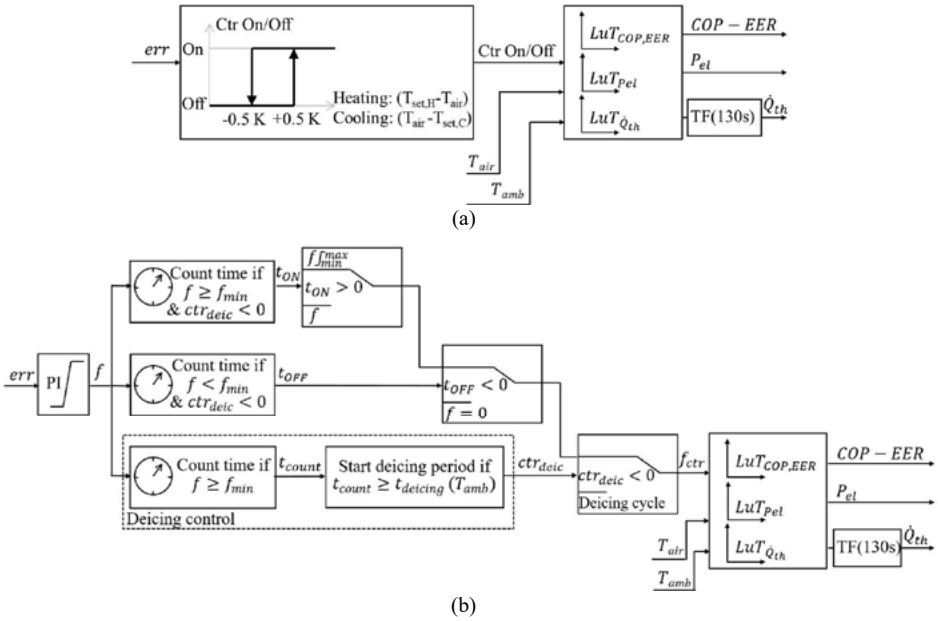

Fig. 3. Control of (a) On/Off and (b) modulating HP

The PV model from the Matlab/Simulink CARNOT library [9] is based on equation (2) and (3).

$$\text{Power}_{PV} = \left((25 - T_{\text{m odule}}) \cdot \Delta W_{p,T} + 1 \right) \cdot W_p \cdot f_{gen} \cdot \frac{Q_{solar}}{1000} \quad (2)$$

$$T_{\text{m odule}} = \frac{Q_{solar}}{1000\ \left(\frac{w}{m^2}\right)} \cdot 40 + T_{\text{am b}}\ [°C] \quad (3)$$

Where:

- $\Delta W_{p,T} = 0.00375$ is the temperature coefficient [1/K];
- $W_p = 877\ W$ is the peak power [W];
- $f_{gen} = 1 - 0.03$ is the efficiency of the PV considering losses in diodes, power mismatch and dirt;
- Q_{solar} is the solar irradiation impinging the PV panel corrected with the Incidence Angle Modifier (IAM).

The model of the inverter is provided by the CARNOT library [9]. It considers a standby consumption of 1 W and the efficiency is a function of the output power (i.e. when the output power is between 300 W and 3600 W the efficiency is above 0.95).

2.3. Economic analysis

The economic analysis adopted in this work is based on the Equivalent Annual Cost (EAC), considering investment and running costs over a reference lifetime (N). EAC is the annual cost of owning, operating, and maintaining an asset over its entire life, it allows comparing the cost-effectiveness of various assets that have unequal lifespans. Equation (4) shows the calculation of the EAC:

$$\mathrm{EAC} = \frac{\mathrm{C} \cdot \mathrm{r}}{1-(1+\mathrm{r})^{-\mathrm{N}}} \tag{4}$$

Where r is the real interest rate (3%). The total annual cost is calculated, for electrically driven systems, as:

$$Total\ \ annual\ \ cost\ \ = EAC + MC + FE \cdot el_{price} \tag{5}$$

Where MC is the yearly maintenance cost, FE is the final electric energy and el_{price} is the electricity price that is assumed to be 0.2 €/kWh. An escalation rate of the energy price of 2% is considered. A sensitivity analysis is carried out varying the interest rate, the investment cost and the electricity price in order to assess the sensitivity of the economic results to the input data. The annual interest rate is varied ±1% point from the default value (3%), the electricity price and the investment costs are varied ±20%. In Table 4 the investment, installation, maintenance costs, the technical lifetime and the resulting EAC for each technology are reported. The data for HP and PV are all taken from [3] except the investment cost of PV which is taken from [10] where mono-crystalline silicon PV are considered.

The reference technology for the cooling is the On/Off low power HP therefore when the modulating HP or the On/Off high power HP are considered, as a cooling technology, only the additional costs are accounted for (ΔEAC=143.5€).

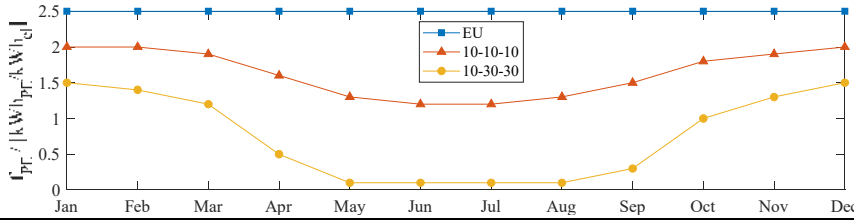
The data for battery and LED are assumed considering the current price of different sellers. The battery are usually guaranteed for 10 years while LED for 50000 hours that correspond to a lifetime of 15 years.

The PV self-consumption contributes to the reduction of the electricity demand of the building system. When the battery is considered, the PV surplus energy is stored and later used by the building, otherwise the benefit of selling the surplus to the main grid is disregarded.

Table 4. Investment costs, installation costs, maintenance costs and EAC of the studied renovation measures

Renovation measure	Investment costs [€]	Installation costs [€]	Maintenance costs [€/y]	Technical lifetime [y]	EAC [€]
On/Off HP low power	500 [3]	100 [3]	16 [3]	12 [3]	76.3
On/Off HP high power	1400 [3]	290 [3]	50 [3]	12 [3]	219.8
Modulating HP	1400 [3]	290 [3]	50 [3]	12 [3]	219.8
PV (877 Wp)	2322 [10]	380 [3]	34.2 [3]	20 [3]	215.8
Battery (4.8 kWh) with Inverter	4000	1400	0	10	663.1
LED light (8 luminaire)	640	300	0	15	78.7

2.4. Environmental analysis



In this case study all the analyzed solutions are using electricity as input, therefore they can be compared considering the savings in terms of electricity demand. In order to compare the savings in terms of primary energy there is the need to define the proper conversion factors.

The increasing share of renewables in the electricity mix affects the definition of the PE/CO_2 conversion factors especially because the energy production from renewables is not constant during the year but rather has a seasonal trend. Significantly increased share of RE electricity can be expected in the near future in particular in summer, while in winter only a moderate increase is likely, unless there is a significant further extension of wind power or seasonal storage capacities are strongly build up [5].

For this reasons, different scenarios for the PE conversion factor are taken into account.

Fig. 4 shows the monthly PE conversion factors considering a constant coefficient defined in [11], a simplified

scenario with an energy mix of 10% hydro, 10% wind and 10% PV and an energy mix of 10% hydro, 30% wind and 30% PV. The difference between the EU conversion factor and the 10-10-10 or 10-30-30 scenarios is higher during the summer than during winter. This means that using the EU conversion factor the same value is given to savings obtained in summer and winter while using the monthly conversion factors (i.e. 10-10-10 and 10-30-30) less importance is given to the energy savings occurring in summer.

	Jan	Feb	Mar	Apr	May	Jun	Jul	Aug	Sep	Oct	Nov	Dec
EU	2.5	2.5	2.5	2.5	2.5	2.5	2.5	2.5	2.5	2.5	2.5	2.5
10-10-10	2	2	1.9	1.6	1.3	1.2	1.2	1.3	1.5	1.8	1.9	2
10-30-30	1.5	1.4	1.2	0.5	0.1	0.1	0.1	0.1	0.3	1	1.3	1.5

Fig. 4. Monthly total PE conversion factor defined according to (EU) European definition, (10-10-10) scenario where a share of 10 % hydro, 10 % wind, 10 % PV and 70 % fossil is considered in the electricity mix, and (10-30-30) scenario where a share of 10 % hydro, 30 % wind, 30 % PV and 30 % fossil is considered in the electricity mix *[5]*

3. Results

3.1. Reference case and PV yield

The reference case is composed of a direct electric heating system and an On/Off HP_{lp} without PV. Fig. 5a shows, for each climate, the monthly electricity demand per square meter of floor area (27 m^2) for each component of the balance (i.e. heating, cooling, appliances, lighting, anti-freezing resistance of the heat exchanger and fans of the mechanical ventilation). The PV production in each climate is reported by the straight blue line. The cross (EU conversion factor), triangle (10-10-10 scenario) and square (10-30-30 scenario) markers refer to the right vertical axes reporting the primary energy consumption. As highlighted in section 2.4, increasing the renewables share in the grid leads to a reduction of the primary energy demand especially during the summer time.

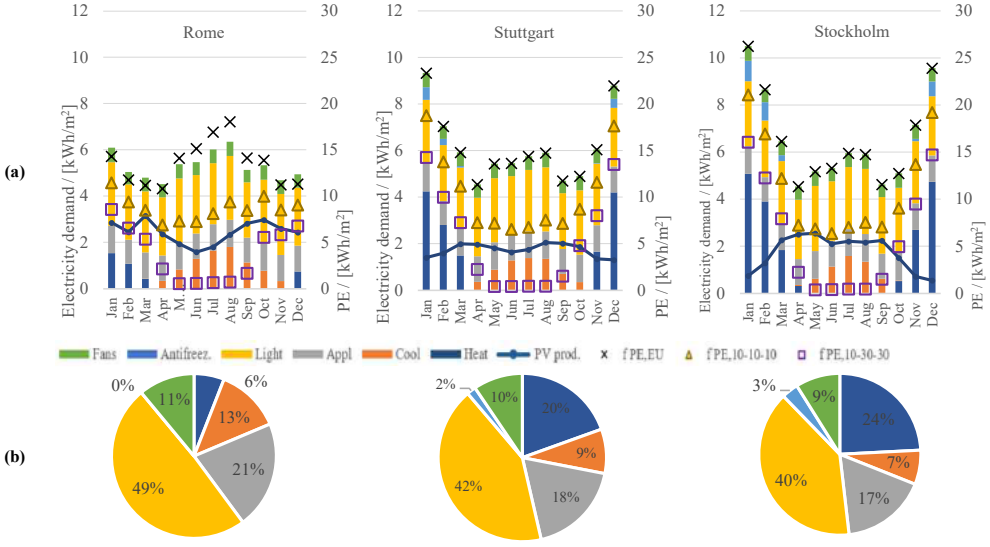


Fig. 5. Results for the reference case (direct electric heating and split HP) for the climates of Rome, Stuttgart and Stockholm. (a) Electricity demand for each end use and PV production; (b) share of electricity required by each end use.

Fig. 5b shows the share of electricity required by each end use, highlighting that the lighting is prevailing in each climate.

Table 5 reports the annual electricity consumption required by each end use and PV production for the climates of Rome, Stuttgart and Stockholm. The total electricity consumption of the reference case is 64 kWh/(m^2y) in Rome, 74 kWh/(m^2y) in Stuttgart, and 79 kWh/(m^2y) in Stockholm. The PV total production would cover the 46%, 28% and 26% of the total consumption in Rome Stuttgart and Stockholm respectively. From this analysis is already clear that the installation of PV in the façade (BIPV) in this case study would bring important energy savings.

Table 5. Annual electricity consumption required by each end use and PV production.

	Heating	Cooling	Appliances	Lighting [kWh/(m^2y)]	Antifreez.	Fans	PV
Rome	4	8	14	31	0	7	29
Stuttgart	14	6	14	31	1	7	21
Stockholm	19	5	14	31	3	7	21

3.2. Pareto solutions

The results of the dynamic simulations investigating different HVAC and lighting solutions (see section 2.2) are compared to the base case considering the additional capitalized cost and energy savings. The latter are expressed in terms of electric energy (E_{EL}) and of total PE calculated with the constant conversion factor (PE_{EU}), with the 10-10-10 scenario ($PE_{10\text{-}10\text{-}10}$) and with the 10-30-30 scenario ($PE_{10\text{-}30\text{-}30}$).

Fig. 6 shows the energy savings in terms of (A) E_{EL}, (B) PE_{EU}, (C) $PE_{10\text{-}10\text{-}10}$ and (D) $PE_{10\text{-}30\text{-}30}$ versus the additional total annual cost (see Equation (5)) of each technology for the climate of Stockholm. Fig. 7 shows the energy savings in terms of (E, F) E_{EL} and (G, H) $PE_{10\text{-}30\text{-}30}$ versus the additional cost for the climate of Rome and Stuttgart, respectively. In both Fig. 6 and Fig. 7, the square markers represent the results of the different technologies together with the PV panels, while the asterisk markers represent the solutions including battery and PV. The error bars shows the results of the economic sensitivity analysis, indicating the impact on the additional total annual cost by varying the investment cost, energy price and interest rate. The investment cost has the highest impact on the economic evaluation.

In this specific case, the analysis of the results does not change considering the PE_{EU} or E_{EL} since all the compared solutions are using electricity as energy source (see Fig. 6 A and B).

The two objects of this optimization are the minimization of the cost and the maximization of the energy savings under the constraint of maintaining thermal comfort. In such a case, typically a feasible solution that minimizes all objective functions simultaneously does not exist. The optimal cases lay on the Pareto front composed by solutions that cannot be improved in any of the objectives without degrading the second object. In Fig. 6 and Fig. 7, the Pareto front, for the set of solutions considered in this work, is highlighted with a light green underlay. The red underlay highlights solutions that are not optimal since enable lower savings and same cost of at least one solution of the Pareto front. The differences in terms of energy savings between the On/Off low or high power and modulating HP are not significant in all the considered climates but the modulating HP and high power On/Off HP are more expansive than the On/Off low power HP.

The night set back slightly reduces the heating demand, therefore it has a small effect in Stockholm and Stuttgart but no effect in Rome where the heating demand is almost zero.

Switching off the air conditioner, when not in operation, i.e. the during the winter season for the case when the electric heating is active), reduces the standby consumption and comes without any additional costs.

The free-cooling active seven days per week on the one hand reduces the cooling demand while on the other hand increases the energy consumption of the fans, increasing also the overall energy consumption. When the $PE_{10\text{-}30\text{-}30}$ instead of E_{EL} is considered, the results of the cases with free cooling (see violet and dark green markers) are overlapped to the respective cases without free cooling (see yellow and light blue markers).

Since in the reference case almost half of the electricity demand is required for lighting, changing the illumination system from fluorescent to LED has a great benefit at low cost. In fact, the solution with electric heating, HP and LED (see light gray circle marker) is close to the Pareto front in all the climates for both E_{EL} and PE savings plots. The same technology with PV (square light gray marker) is close to the Pareto front only for Rome. Since here, the heating demand is almost zero, the HP technology appears between the cost optimal solutions only when it is combined with PV and LED or PV, LED and battery. The reversible On/Off HP (for heating and cooling) either combined or not with LED, is always between the best solutions for the climate of Stockholm and Stuttgart. When the renovation package involving electric heating, On/Off cooling HP and

LED (see light gray circle marker) is compared with On/Off HP H/C (see yellow circle marker), in Stuttgart and Stockholm, it is noteworthy that the scenario for evaluation of the energy savings (i.e. E_{EL} or $PE_{10\text{-}30\text{-}30}$) might change the ranking of the solutions. In Fig. 6.A and Fig. 7.F, it can be seen that the renovation package with electric heating, On/Off cooling HP and LED (light gray marker) gives the same or even more E_{EL} savings than the On/Off HP H/C, but the situation is reversed when the savings are evaluated in terms of $PE_{10\text{-}30\text{-}30}$ (see Fig. 6.D and Fig. 7.H). The monthly conversion factors of the 10-30-30 scenario are almost zero during summer therefore the savings during the wintertime have higher impact on the calculated yearly energy savings. When the PV is considered together with the HP and LED with or without battery (see square and asterisk light blue markers) these solutions are cost optimal in all the climates.

The Pareto front highlights a set of cost optimal solutions from which one renovation package has to be selected based on economic restrictions and other parameters (e.g. thermal and visual comfort, quickness of the retrofitting, personal preferences, etc.). But there are some clear and remarkable trends that can be noted: in Stockholm and Stuttgart the solution with reversible On/Off HP_{lp} H/C + LED have the same cost but guarantee higher energy savings with respect to other solutions such as reversible On/Off HP_{lp} H/C and El. Heating + On/Off HP_{lp} + LED. Adding PV increases the energy savings but also the cost therefore the selection of this solution depend on the economic restriction. Adding battery only slightly increases the energy savings while the cost substantially increases. In Rome El. Heating + On/Off HP_{lp} + LED with or without PV allows to keep the additional cost near to zero enabling high-energy savings.

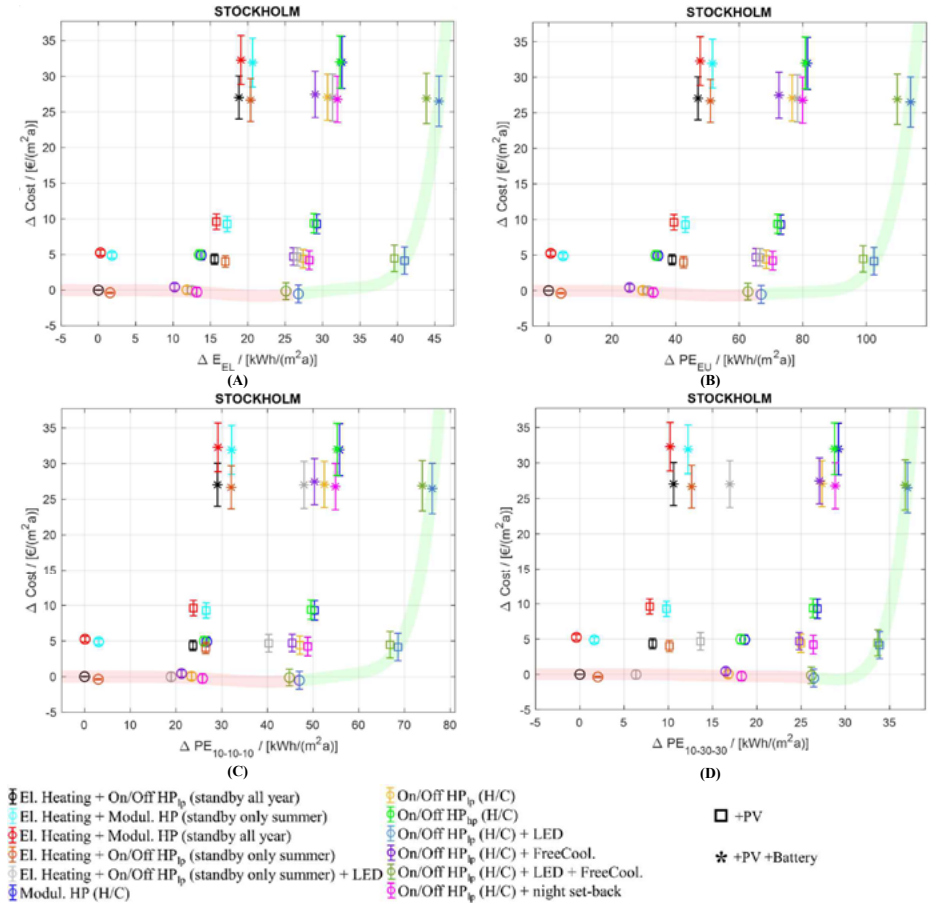

Fig. 6. Savings in terms of (A) Electric energy, (B) Primary energy according to EU conversion factor, (C) Primary energy according to 10-10-10 scenario conversion factors,(D) Primary energy according to 10-30-30 scenario conversion factors vs additional cost of the analysed technologies for the climate of Stockholm

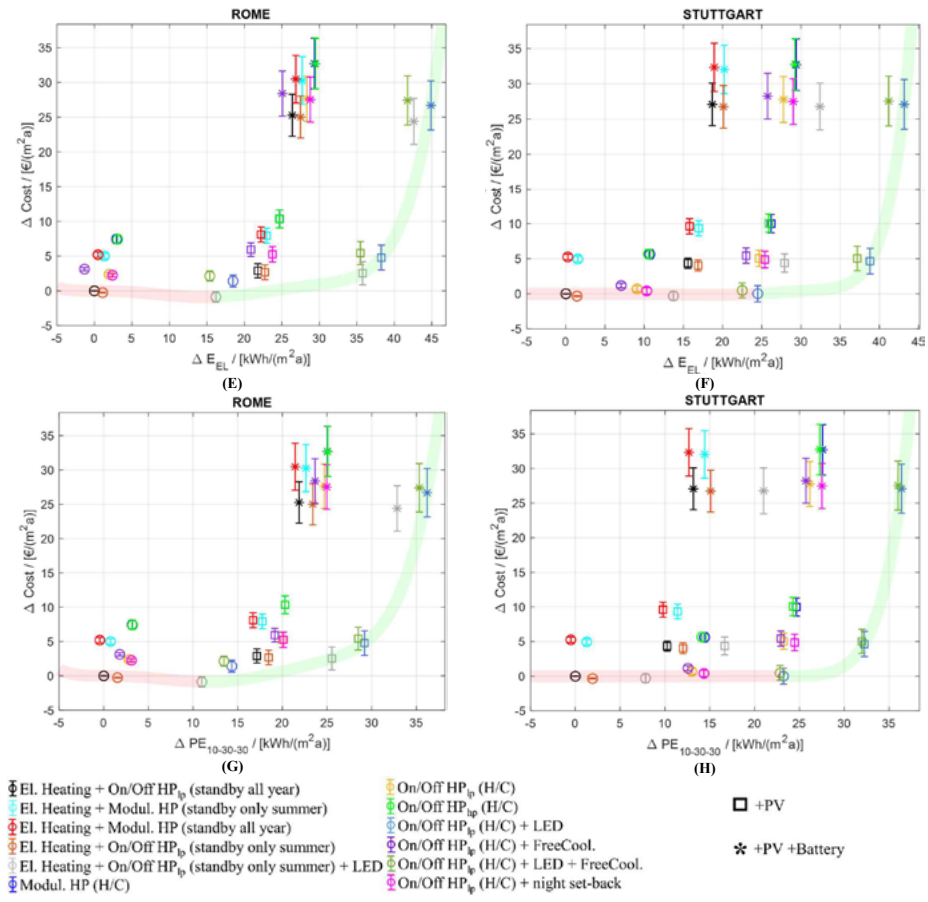

Fig. 7. Savings in terms of (E,F) Electric energy and (G,H) Primary energy according to 10-30-30 scenario conversion factors vs additional cost of the analysed technologies for the climate of Rome and Stuttgart respectively.

Table 6 shows the yearly heating and cooling demands and electricity consumptions for Rome, Stuttgart and Stockholm. Using the HP instead of the electric heating saves around 15% in terms of electricity demand in Stuttgart and Stockholm. The heating demand slightly increases and the cooling demand substantially decreases together with the electricity demand when LED technology is considered. Adding the free cooling to the On/Off HP (H/C) case, reduces the cooling demand while slightly increases the total electricity consumption, this effect is caused by the increased electricity demand of the fans. The night set-back, compared to the case with On/Off HP (H/C), slightly reduces the electricity demand only in Stuttgart and Stockholm.

Table 6. Annual heating, cooling demand and electricity consumption for the climates of Rome, Stuttgart and Stockholm.

	Heating demand [kWh$_{th}$/(m^{2}a)]			Cooling demand [kWh$_{th}$/(m^{2}a)]			Total Electricity demand [kWh$_{el}$/(m^{2}a)]		
	Rome	Stuttg.	Stock.	Rome	Stuttg.	Stock.	Rome	Stuttg.	Stock.
El. Heating+On/Off HP (standby all year)	2.7	13.1	17.2	32.7	26.0	24.5	63.8	73.8	79.0
Modul. HP (H/C)	3.1	13.5	17.6	33.4	26.7	25.0	60.8	63.1	65.2
On/Off HP$_{lp}$ (H/C)	2.7	13.1	17.2	32.7	26.0	24.5	61.8	64.7	67.1
On/Off HP$_{hp}$ (H/C)	2.8	13.1	17.2	32.9	26.2	24.7	60.7	43.3	65.4
On/Off HP$_{lp}$ (H/C) + LED	4.7	17.5	22.8	24.6	19.7	18.7	45.3	49.3	52.2
On/Off HP$_{lp}$ (H/C) + FreeCool	2.8	13.1	17.3	24.9	17.0	14.3	65.1	66.8	68.8
On/Off HP$_{lp}$ (H/C) + LED + FreeCool	4.7	17.5	22.9	17.8	12.0	9.8	48.4	51.3	53.9
On/Off HP$_{lp}$ (H/C) + night set-back	2.2	10.2	14.0	31.3	24.2	23.0	61.4	63.5	65.8

4. Conclusions

Different technologies applicable for the decentral renovation of a typical office building (cell) are evaluated considering, both economic feasibility and environmental impact for the climates of Rome, Stuttgart and Stockholm by means of dynamic building and HVAC simulations. The cost analysis is based on the equivalent annual cost (EAC) and a sensitivity analysis is performed in order to assess the influence of the used inputs on the results. The environmental impact is evaluated in terms of electricity demand and total primary energy (PE) savings calculated with a constant and monthly conversion factors representing different scenarios with different share of renewables in the electricity mix (i.e. 10-10-10: 10 % hydro, 10 % wind, 10 % PV and 70 % fossil and 10-30-30: 10 % hydro, 30 % wind,30 % PV and 30 % fossil). In this specific case study, since all the analyzed technologies require electricity as input, the same conclusion can be derived using the energy savings expressed in terms of electricity or total PE calculated with a constant conversion factor while the results might change if monthly conversion factors for different renewables scenarios are used. In fact, the renovation package with electric heating and LED has the same (in Stockholm) or higher (in Stuttgart) electricity savings than the On/Off HP for heating and cooling without LED but the situation is reversed when the savings are evaluated in terms of PE calculated with the conversion factor of the 10-30-30 scenario. The renovation packages allowing high-energy savings with low additional cost are represented, in Stockholm and Stuttgart, by HP in combination or not with LED and PV and in Rome, by LED and PV in combination with electric heating. Battery in combination with PV, HP and LED brings, in all the climates, additional energy savings with high additional cost. Technologies, which will lead to higher savings in winter with lower availability of renewables and generally higher loads, will be more valuable and this can be quantified by the proposed method.

Abstract

Over the last 4 years, the IEA-HPP Annex 43 has worked on Sorption Gas Heat Pumps (GHP). GHP have been identified as an efficient solution for space heating and sanitary hot water preparation. There was advance on several ongoing developments both for ad- and absorption technology. A water-ammonia absorption GHP based on plate heat exchangers (PHE) is under development and shows promising results both in terms of compactness and efficiency. An absorption GHP for the residential market is being developed. Another participant is working on the development of an adsorption gas heat pump with active carbon and ammonia as working fluid, using a promising new adsorber design. The development of a zeolite-water based GHP is pursued with a consortium of industry and research partners. The open source SorpPropLib materials database allows evaluation of materials for sorption heat pumps in SorpSim or other platforms. A common view on market requirements and potential was found for different markets.

Keywords: Gas Heat Pump;Sorption;Fuel Driven Heat Pump

1. Introduction

Over the last 4 years, the IEA-HPP Annex 43 has worked on Sorption Gas Heat Pumps (GHP). GHP have been identified as an efficient solution for space heating and sanitary hot water preparation, mainly in existing buildings. They are a complementary technology to electrical heat pumps with potential to reduce requirements on the electric grid and to balance the energy consumption in the future energy mix. Annex 43 had the aim to support the technology through cooperation between industry and academia. At present, due to a lack of competitive commercially available products, the market share of sorption heat pumps on the total heating market is marginal. However, it is expected that a potential exists to assist the transition from completely fossil fuel based heating technologies towards technologies, including environmental heat sources and thereby decreasing the demand on fossil fuels.

2. Results on Gas Heat Pump R&D

There was advance on several ongoing developments both for ad- and absorption technology. At Polimi (Italy), a water-ammonia absorption GHP based on plate heat exchangers (PHE) is under development and shows promising results both in terms of compactness and efficiency. Also an Italian company is working on an absorption GHP for the residential market. University of Warwick (UK) is working on the development of an adsorption gas heat pump with active carbon and ammonia as working fluid, using a promising new adsorber

design. Fraunhofer ISE (Germany) works on the development of a zeolite-water based GHP with a consortium of industry partners. At ORNL, research is ongoing on a GHP with salts and ammonia as working pairs.

2.1. Water-Ammonia Absorption GHP based on plate heat exchangers

At Politecnico di Milano research is carried out with the objective of developing an air source gas-fired heat pump for space heating and DHW production for domestic applications. To assure a large potential for market penetration, the target of reducing specific costs and size compared to existing products is addressed. As an additional measure to ease the industrialization of the GHP, it has been decided to rely mainly on components derived from large series production, whose manufacturers actively collaborate to the project. In particular, all heat exchangers, except the desorber, are fusion-bonded plate heat exchangers.

The outcome of the development is a 7.5 kW GAHP prototype, whose diaphragm pump and desorber have been designed to reduce the appliance size to the dimensions of a standard domestic condensing boiler. The effectiveness of different configurations of the refrigerant circuit has been investigated, together with the potential benefits of controlling the flow rate of refrigerant and solution. The achieved performances, measured according to the European Standard EN 12309, are in line with the expectation: a sGUE based on the net calorific value ($sGUE_{NCV}$) of 1.5 has been reached for the average climate (design temperature of -10 °C) and for the high temperature application (supply temperature of 55 °C). However, a detailed analysis shows room for improvements on some of the component, which are expected to boost the $sGUE_{NCV}$ up to about 1.6.

2.2. Active Carbon – Ammonia Adsorption GHP

The overall objective of the research at Warwick was to develop a domestic air source gas-fired heat pump to replace standard condensing boilers cost-effectively. The working pair is ammonia (able to evaporate at sub-zero temperatures, as required for an air-source) and active carbon. A succession of sorption generators have been prototyped, culminating in the 'kebab' design in which monolithic carbon is compressed between aluminium fins on a steel tube containing pressurised water that either heats or cools the adsorbent in a two-bed cycle with heat and mass recovery. The ‘kebabs’ are illustrated in Figs. 1 and 2.

Figure 1: ‘Kebab’ schematic

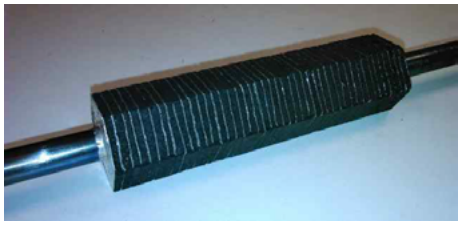

Figure 2: Sample ‘kebab’

A 10 kW system was built and tested. Initial results were poor with Coefficient of Performance (COP) a little above 1. This was due to mass transfer resistance in adsorption being too high, due to an excessive binder fraction. A new formulation has been tested in a single 'kebab' and the results are consistent with an internal COP of 1.40 when delivering 10 kW at 50°C and evaporating at 0°C or 1.34 when delivering 20 kW. Simulation results are given in Fig. 3, illustrating how power may be traded off against efficiency. It is clear that the sensitivity of GUE to power output is significant but there is the prospect of achieving an average GUE of > 1.2 in UK climatic conditions. Whether this is commercially acceptable will depend crucially on the production cost. Previous 4-bed configurations with enhanced internal heat recovery [1] show a GUE of 1.4 to be possible but at the expense of greater complexity and cost. The aim here is to explore simpler, low cost options if at all possible.

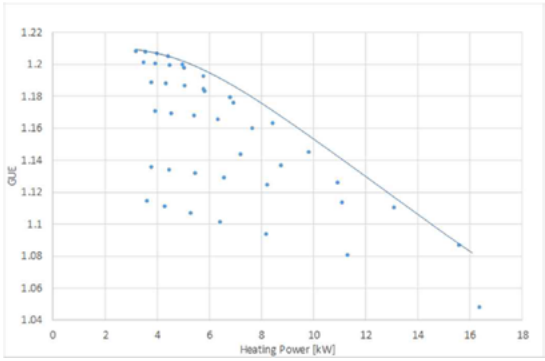

Figure 3: GUE(based on Gross Calorific Value) v. SCP for final design of 208C carbon + organic binder 'kebab'

2.3. Zeolite-water adsorption GHP

Two gas-fired adsorption heat pump products based on the working pair zeolite-water have been on the market by the companies Vaillant and Viessmann. Both are no longer market available, mainly due to high cost and not being able to sufficiently serve the retrofit market with higher needed supply temperatures at reasonable efficiency. Adsorption modules were based on a loose grain configuration and a binder based coating on stainless steel heat exchangers, respectively.

Promising developments with potentially much higher power densities have recently been made at Fraunhofer ISE together with the company Fahrenheit. The combination of an aluminium fibre structure and a direct crystallization coating of a thin zeolite layer on the extremely high surface of such a heat exchanger showed the feasibility of power densities which potentially allow for a wall hung GHP unit [2].

Activities on binder-based coated adsorbers are also being developed by CNR ITAE and University of Messina, mainly focusing on the intensification of heat and mass transfer efficiency with a low-cost and energy intensive manufacturing process [3].

There are yet unresolved issues concerning long-term stability, and proof has to be made that such adsorption modules can be manufactured in a cost-efficient way. One drawback of water as working fluid is the limitation to ambient source temperatures >0°C. A potentially feasible option is the use of exhaust air from a central ventilation unit. Compared to a compression heat pump, a gas heat pump needs only about a third of ambient source power. With a limitation of about 1 kW source power from exhaust air (typical ventilated apartment), a vapour compression heat pump with a COP of 4 could deliver a maximum power of about 1.3 kW, while a gas heat pump with a GUE of 1.3 could deliver about 4 kW.

2.4. Salt-Ammonia GHP

An ammonia-based triple-state sorption heat pump was developed and investigated by ORNL and SaltX to significantly improve the current gas heating efficiency in cold climates. The gas-fired heat pump extracts heat from cold ambient by absorbing ammonia onto salt held in a nano-coated matrix, and it supplies high-temperature heat from heat of adsorption and the heat of ammonia condensation when the salt is heated and desorbs ammonia. A simulation study identified the optimal heat pump sizing as 22-44% of peak heating load for the shortest payback under typical cold climate conditions in the U.S [4,5].

A laboratory prototype with design targets of delivering 54.4°C (130°F) hot water under ambient temperature of -20°C with GUE > 1.0 has been developed a Swedish company and ORNL and evaluated experimentally at ORNL. The prototype has a simple configuration including a salt-containing reactor and a salt-less combined condenser-evaporator. No pump or valves are needed in the fully hermetic ammonia system. The COP and capacity of the prototype progressed with insulation and improved controls in the shakedown tests, and a heating capacity of 4.4 kW at 55°C hot water supply with a cycle GUE of 1.02 was demonstrated in the laboratory with 8°C simulated ambient temperature. A dynamic model using finite-difference method has been developed for the salt-containing reactor and is now being validated with test results.

Another outcome of the Annex is the compilation of vapor pressure properties for sorption working pairs into the open source SorpPropLib materials database developed by ORNL and Purdue University. This allows evaluation of materials for sorption heat pumps in SorpSim or other platforms [6].

3. Performance potential study

A simulation study has been performed to provide performance numbers of gas fired sorption heat pumps in the residential sector in order to assess the impact of such systems with respect to environmental effects, compared to conventional heating systems.

3.1. Scope

A comparative approach is applied in this study: two different fuel driven sorption heat pump technologies based on currently developed technologies are compared with conventional heating technology, representing the exclusive use of a condensing gas boiler (reference system). The phrase ‘current technology’ in this context means one market available technology (ammonia-water absorption technology) as well as present laboratory test status of a water-zeolite adsorption technology. For these technologies, reliable data to execute the comparative calculations are available. Other technologies (e.g. ammonia-active carbon adsorption, ammonia – salt absorption, other ammonia-water absorption cycles) are still under development and may achieve promising performance results in the near future, see sections above.

To assess the potential of the heat pump systems, building loads from typical residential buildings are applied. The loads are generated through building simulation, but on base of well-defined building standards. The applied building models range from non-retrofitted multi-family houses (MFH) to new single family houses (SFH, present building standard). All calculations are executed for meteorological conditions of five European sites.

Economical aspects and life-cycle aspects are not topic of this study. An energetic and economic comparison of absorption and electrically driven compression heat pumps is e.g. shown in [7].

Thus, the performance figures and environmental savings presented in this study reflect the running system operation. The results are presented as annual values of performance (i.e., gas utilization efficiency) and environmental savings in comparison to the reference system (i.e., CO2 and primary energy savings and primary energy ratio).

3.2. Sites and thermal building loads

Climate data of five European sites (London, Potsdam, Paris, Strasbourg, Milano) were applied in the study, to determine the building heat loads. From a meteorological point of view, the sites correspond to the climate classification [8] of Cfb (warm temperate climate, fully humid, warm summer) with the exception of Milano, corresponding to Cfa (warm temperate, fully humid, hot summer) respectively.

Despite of identical or similar climate classification, the site dependent temperature conditions reveal large differences in heating demand for the buildings in the survey. For the calculation of the heat demand, hourly data of ambient temperature and humidity were generated for each site by use of the meteorological engineering software Meteonorm [9].

For four sites, the minimum ambient temperatures are still above -10°C and thus conform with the ‘average climate‘, as classified in the European Standard EN12309, part 7 [9], whereas the Potsdam site normally fits to the ‘cold climate‘ classification. Nevertheless, in the light of the very few hours of falling below -10°C at Potsdam site and for reasons of a better comparison of the results, the heating system temperature curve of the ‘average climate‘ was applied in the calculations to all sites.

The meteorological data set of Strasbourg is additionally used for the performance calculation of a representative European site (EU), applying European conversion numbers for primary energy use and greenhouse gas emission instead of individual national conversion numbers.

In the building sector, multi-family houses (MFH) play an important role in greenhouse gas avoidance strategies, as their share on building stock and on living space area is high. e.g., in Germany, 31% of the living space accounts to small and medium size MFH with 3 to 12 apartments [10]. Another reason for the interest in MFH in the context with this study is that the market available gas fired sorption heat pump from the manufacturer Robur with its capacity of 18 kWth or above yet does not fit to small residential buildings.

For the assessment in this study in the context with a larger gas driven heat pump, an MFH model was applied, which was defined within the activities in the Low-Ex project group [11]. The building model images an MFH with 3 floors and 3 apartments on each floor. The building standard corresponds to the construction period of 1959-1978, as compiled by the Tabula/Episcope Projects (see: http://episcope.eu); the total number of occupants is 13. The building model setup and calculation of thermal loads was performed in the simulation environment of TRNSYS, version 17 [12].

Two versions of the building are applied:

1. MFH as representative for an average German non-retrofitted building (building stock);
2. MFH+ retrofitted in a conventional way according to Tabula/Episcope specifications for Germany, which resemble the requirements of the German EnEV 2014/2016 [13].

The load data are transferred to hourly data of each hour of a representative year of meteorological data for the sites previously specified. Additionally, thermal loads for preparing domestic hot water (DHW) for the buildings are included. The annual share of heat demand for DHW preparation on the total heat demand is shown in Figure 4, revealing the distinctly higher significance of hot water preparation in buildings with higher energy saving standards.

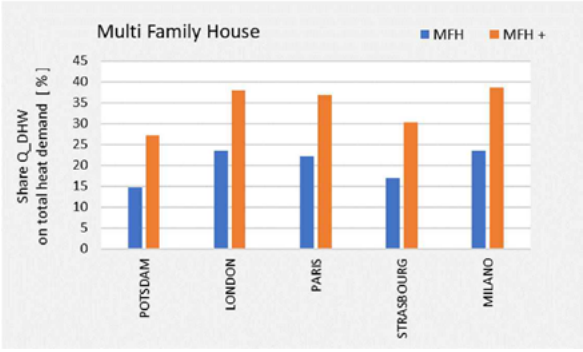

Figure 4: MFH: Share of heat demand for DHW preparation on the total heat demand.

For small capacity gas fired adsorption heat pumps, the market of single family houses (SFH) is of especial interest. Within this comparative study, two single family houses were modelled and heat loads for the sites given in Figure 2.1 have been determined:

1. SFH+ as representative for a retrofitted building with 120 m² living area;
2. SFH_{NEW} as representative of a new building with 150 m² living area.

The load calculations were carried out with a one-node building model according to DIN EN ISO 13790 [14]. The adopted U-values of the key building components are the averages of the published values of the respective countries.

The load data are determined as hourly data of each hour of a representative year of meteorological data for the sites previously specified. An overview on site dependent heating loads is given in Annex A1 of this study. The number of occupants in both buildings is 4; the DHW loads are calculated accordingly on base of the approaches, used for the MFH.

The annual share of heat demand for DHW preparation on the total heat demand is shown in Figure 5. In general, the set value of supply temperature in heating systems is expressed as a function of the ambient temperature. This heating system temperature is essential in the calculations, since the performance of sorption heat pumps as with all heat pumps is very sensitive to the supply temperature level.

In this study, the heating system temperature relations are derived from EN12309, part 7 [9]. The High Temperature curve (max. 55°C) requires moderate effort in exchange of e.g. appropriate radiators and is applied in the calculations of the multifamily buildings (stock and retrofit) in combination with the gas driven ammonia-water heat pump.

The Medium Temperature curve (max. 45°C) requires more ambition in the heating distribution system and is applied in the MFH+ and additionally in the calculations of the single family houses, where adsorption heat pumps are considered.

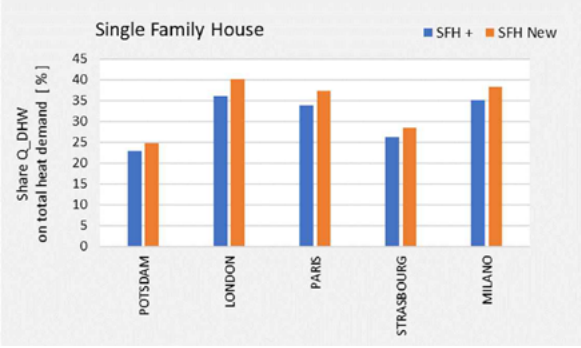

Figure 5: SFH: Share of heat demand for DHW preparation on the total heat demand.

3.3. Thermally driven heat pump models

Ammonia-Water absorption heat pump

The model is based on the gas fired absorption heat pump from Robur, model K18. The machine uses the fluid pair ammonia and water and requires ambient air as low-temperature source. Since the evaporator is integrated into the machine, the heat pump is designed for external installation. The K18 model provides a heating capacity of 18 kWth (some basic data are given in [3.1/1]). Due to the ability to deliver hot water of up to 60°C, DHW can be prepared beside space heating. The simulation model of the Robur K18 heat pump was developed by POLIMI [15] and has been applied in other comparative studies as well, such as [16, 7].

The simulation of the K18 heat pump system reflects a system setup where either the DHW buffer storage is heated or the space heating is served. In the latter case, a backup gas boiler is implemented to cover peak loads on demand. This is especially required in applications with a high exploitation of the heat pump and at colder sites (e.g., Potsdam, Strasbourg).

Water-zeolite adsorption heat pump

The adsorption heat pump model is based on experimental laboratory tests at Fahrenheit GmbH and modelling based on these results by Fraunhofer ISE; the machine is not market available yet. In the experimental setup, the working pair water with the zeo-type material SAPO-34 as adsorbent is applied. The adsorption module consists of two similar heat exchangers, one acting as combined evaporator/condenser (EC) and the other as adsorption heat exchanger (AdHX). The AdHX is coated with SAPO-34 with the partial support transformation technique as by Bauer et al. [17]. The experimental results and the component data were published by Wittstadt et al. [2].

A detailed numerical model of the adsorption module was developed at Fraunhofer ISE and validated with the experimental data. The model allows the variation of geometric key parameters of the components in order to optimize the adsorption module for a given application [18]. The data presented here are obtained with geometrically optimized components for the heating application. One important difference between the experimentally tested module and the optimized module is the size of the EC. The size of the EC was reduced significantly in order to improve the efficiency without worsening the overall dynamics of the module. The model takes into account important loss mechanisms such as condensation of the working fluid on the housing and heat flux from AdHX to EC.

The heat pump for this study is considered to be connected to a ground tube as low temperature source, as low temperatures < 5°C until now cannot efficiently be used with water as working fluid due to freezing in the evaporator.

The following operation boundaries were included in the model:

- Low temperature source temperature: 5°C - 9°C;
- Medium temperature (inlet into AdHP): 25°C – 43°C;
- Desorption temperature (driving heat from gas boiler): 80 °C – 120 °C

The source temperature is determined as a function of the ambient temperature in accordance with VDI 4650, which provides corresponding values for heating operation [19]. The maximum heating capacity of the

AdHP research unit is approx. 7 kWth. However, in the comparative study, the capacity is site dependently adjusted to the building load with the target to maximize the annual overall sGUE (heating and DHW, including gas boiler performance). Thus, the maximum capacity in calculations ranges from 7 to 11 kWth.

To emphasize a special advantage of adsorption modules, the cycling period of the sorption process can be controlled in a variable way. In the model, this period is varied between 75 s (high power output, but moderate to low GUE values) to 500 s, resulting in low power output in part-load situations, but performing at distinctively higher GUE values.

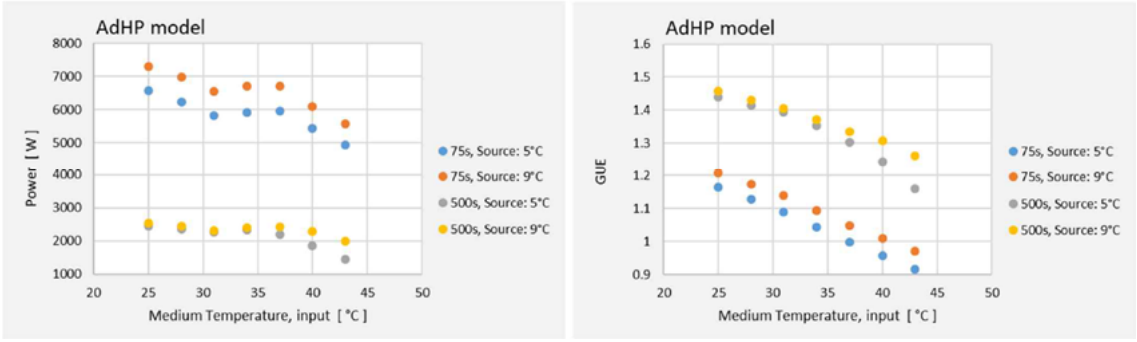

Figure 6: Performance of the AdHP versus the medium temperature input. Displayed for the minimum and maximum cycling period (75s and 500s resp.) and for the low temperature bounderies 5°C and 9°C. The lowest GUE values occur at medium temperatures close the upper limit and at lowest source temperature (5°C) and at short cycling period. In this operation mode, the efficiency is comparative to the gas boiler efficiency.

For the determination of the actual GUE in the simulation, the gas boiler runs in desorption with fixed efficiency of 85%, but additional heat recovery in the flue gas heat exchanger increases the heating capacity and thus the GUE. This is considered through an increase in overall boiler efficiency, using the relation between hot water temperature (Medium temperature) and efficiency as described.

To illustrate the scope of the AdHP performance, Figure 6 shows examples on modelled performance for the minimum and maximum low temperature source and for the minimum cycling period (high capacity) and maximum cycling period (low capacity, high GUE).

In the comparative study, a gas boiler, foreseen to be integrated into the AdHP and actually turning it into a hybrid heat pump being able to run in direct or heat pump mode, serves as high temperature source for desorption. Moreover, the boiler is used as peak-load and backup boiler (e.g., heating to the set point, in case the output temperature of the sorption unit is not matching the set value, given by the heating temperature curve). The boiler additionally covers all of the DHW heat demand, since the inlet temperature range into the heating circuit of the sorption unit is below the temperature levels of the DHW buffer: the lowest temperature level in the DHW buffer in the simulation is 45°C; this corresponds well with field monitoring results, gained in the German 'WP Monitor' project [20].

The system integration, applied in the comparative study for the AdHP development, is shown in figure 7.

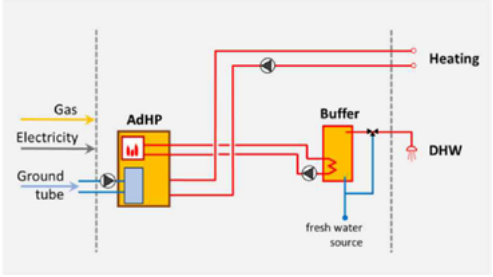

Figure 7: Sketch of the heating system with the Adsorption heat pump (AdHP).

Condensing gas boiler

The GAHP model returns the GUE for each time step; the model is based on test data. Thus, the internal boiler efficiency for heating and DHW preparation with the sorption module is indirectly included. For the external peak load boiler in the GAHP and for the gas boiler in the AdHP system (Figure 7), the efficiency (base: gross calorific value GCV) is simply calculated as function of the hot water input temperature into the boiler. The function is shown in Figure 3.6 and is derived from Haller et al. [21].

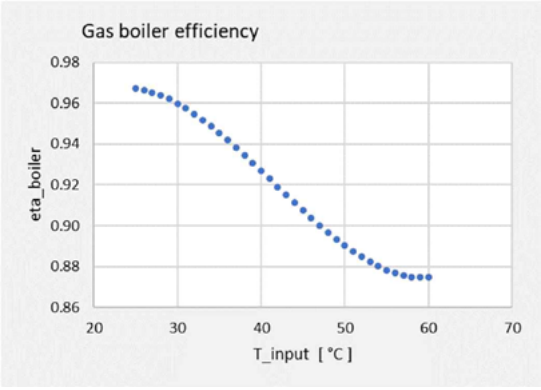

Figure 8: Efficiency model of the gas boiler (peak load use and DHW heating in the AdWP system).

3.4. Results

In the following, annual results from the simulations are depicted for the sites, buildings and heat pump systems as described. For the five sites, national conversion factors for primary energy use and CO_2 emissions were used to determine the environmental performance figures.

For each site and building, a reference calculation is carried out, considering a system without heat pump but with a gas condensing boiler as only heat source for heating and domestic hot water (DHW) preparation. Focus is on the performance (seasonal Gas Utilization Efficiency, sGUE) and on environmental benefits such as CO_2 and primary energy savings (relative to the expenditures in the reference system) and on the primary energy ratio PER. The total annual $sGUE_{total}$ is calculated by including all gas input into the heat pump and peak load boiler for both heating and DHW preparation.

The calculation of environmental benefits includes beside natural gas consumption the electricity consumption in the low temperature sources (fan of air source unit, pump of ground tube circuit respectively) and auxiliary electricity demands, e.g. for the gas boiler fan. Electricity demand for heat distribution in the building is not considered, as no substantial deviations from the reference system for this purpose are expected.

Table 1 summarizes the results by order of the building types. The range of the results expresses site dependent differences.

The results are interpreted in the following way:

Absorption heat pump system (ammonia-water):

- Highest performance is achieved at applications with a high degree of utilization (high workloads), as the heat pump performs more favorable in this operation mode. This is especially the case in the non-retrofitted MFH;
- The performance in combination with MFH+ is comparatively low due to unfavorable part-load operation of the heat pump, since the machine is oversized for this building loads (since the market available Robur 18 kW_{th} is modelled, the capacity is not varied in the simulations). Thus, in an additional calculation two buildings are served by one heat pump in order to achieve more appropriate workloads (case: MFH+, 2 units). This leads to increased performance, comparative to the results obtained in the MFH;
- If in the retrofitted MFH+ the heat distribution systems are additionally replaced by low-temperature distribution systems, allowing the Medium Temperature heating system curve. In this combination,

the highest system performance and environmental benefits are achieved (MFH+, 2 units; Medium heating temperature);
- In the most favorable applications, the sGUE (GCV) exceeds 1.35 and annual CO_2 savings up to 30 % are obtained;
- The high performance in nearly all applications is supported by the ability of the ammonia-water heat pump to cover the DHW demand as well. This is especially important in retrofitted buildings, which show a high share of DHW on the overall heat demand.

Table 1. Summary of the results for the two different heat pump systems, sorted by building types. The range of the results is due to site dependent differences. The most favorable applications are highlighted in blue.
The capacity factor indicates the adjustment of the heat pump capacity, in order to achieve an adequate heat pump operation. The factor is applied to the nominal capacity of the adsorption unit (7 kWth). The absorption heat pump model was not adjusted, as this unit is market available.

	Heating Curve	$sGUE_{total}$	Relative CO2 savings	Relative PE savings	PER / PER_{Ref}	Capacity factor
		-	%	%	%	-
Absorption: Ammonia-Water						
MFH	High	**1.30 – 1.36**	**22.9 – 28.8**	**21.5 – 26.0**	**27.4 – 35.1**	**1**
MFH+	High	1.22 – 1.30	19.2 – 26.3	19.5 – 24.0	21.3 – 31.5	1
MFH+, 2 units	High	1.29 – 1.35	23.0 – 29.2	21.6 – 26.5	27.6 – 36.0	1
MFH+, 2 units	Medium	**1.32 – 1.37**	**24.7 – 30.0**	**23.1 – 27.2**	**30.1 – 37.3**	**1**
Adsorption: Water-Zeolite						
SFH+	High	1.13 – 1.16	16.5 – 18.7	16.4 – 18.0	19.7 – 22.0	1
SFH^{NEW}	High	1.12 – 1.13	15.9 – 17.5	15.7 – 16.7	18.6 – 20.0	1
SFH+	Medium	**1.17 – 1.21**	**18.6 – 21.3**	**18.5 – 20.4**	**22.7 – 25.6**	**1**
SFH^{NEW}	Medium	**1.15 – 1.20**	**17.5 – 20.5**	**17.4 – 19.8**	**21.1 – 24.7**	**1**
MFH	High	1.07 – 1.12	9.8 – 14.6	9.8 – 14.5	10.9 – 16.9	1.5
MFH+	High	1.06 – 1.13	11.0 – 15.8	11.0 – 15.7	12.4 – 18.6	1.5
MFH+	Medium	1.12 – 1.15	14.9 – 17.7	14.9 – 17.1	17.3 – 20.6	1.5

Adsorption heat pump system (water-zeolite):
- The performance is lower than in the ammonia-water systems in some operation modes. However, in part-load operation modes, the adsorption system benefits from the possibility to increase the performance switching to higher cycle periods and thus showing in such operation modes an inverse behaviour than the ammonia-water heat pump. An appropriate layout and control of the adsorption system is therefore essential;
- The performance is affected due to the fact, that DHW demand is not supported by the heat pump, but completely served through the gas boiler. The latter fact is important, since in retrofitted or new buildings the DHW share on the total heat demand increases;
- The heating system temperature curve is more important in the application of this heat pump than in case of the ammonia-water heat pump. Thus, the highest performance is achieved in buildings, allowing the medium heating temperature curve;
- In the most favorable applications, the sGUE is in the range of 1.2 and annual CO_2 savings up to 21% are obtained.
- It needs to be kept in mind that a very simple configuration of an adsorption GHP has been modelled, which does not allow for any kind of heat recovery. Also, the limitations of the zeolite-water working

pair reflect in the fact that the device cannot be run in heat pump mode for LT source temperatures below 0°C due to freezing in the evaporator. Both issues might be overcome by recent technological developments e.g. with Active Carbon – Ammonia as working pair or by making use of an LT heat source >0°C, see above.

Table 2 presents the results by order of the sites. The range thus reflects the influence of building types and applied heating temperature curves.

Table 2. Summary of the results for the two heat pump systems and different buildings and heating system curves, ordered by sites. EU denotes the representative European site, using climate data of Strasbourg and default European conversion factors (primary energy use and CO_2 emissions in electricity consumption).

	Building, Heating Curve	$sGUE_{total}$	Relative CO2 savings	Relative PE savings	PER / PER_{Ref}	Capacity factor
		-	%	%	%	-
Absorption: Ammonia-Water						
Potsdam	all	1.22 – 1.32	19.2 – 24.7	19.5 – 24.9	24.4 – 33.3	1
London	all	1.30 – 1.37	24.3 – 27.6	24.0 – 27.2	31.5 – 37.3	1
Paris	all	1.28 – 1.36	26.3 – 30.0	20.7 – 24.8	26.1 – 33.0	1

Milano	all	1.27 – 1.36	22.4 – 27.1	22.6 – 27.0	29.2 – 37.0	1
EU	all	1.23 – 1.33	20.7 – 25.8	20.4 – 25.6	25.6 – 34.3	1
Adsorption: Water-Zeolite						
Potsdam	all	1.06 – 1.21	9.8 – 20.3	9.8 – 20.4	10.9 – 25.6	1 – 1.5
London	all	1.12 -1.18	14.6 – 18.9	14.5 – 18.8	16.9 – 23.1	1 – 1.5
Paris	all	1.11 -1.18	14.1 – 20.2	12.6 – 18.5	14.4 – 22.7	1 – 1.5
Strasbourg	all	1.07 – 1.20	11.6 – 21.3	10.1 – 19.4	11.2 – 24.1	1 – 1.5
Milano	all	1.08 – 1.17	11.8 – 18.6	11.7 – 18.6	13.3 – 22.8	1 – 1.5
EU	all	1.07 – 1.20	10.9 – 20.4	10.8 – 20.3	12.1 – 25.5	1 – 1.5

Considering the two heat pump systems (absorption and adsorption), a difference occurs at the ‘colder‘ sites Potsdam and Strasbourg: In the ammonia-water heat pump system, the performance at Potsdam and Strasbourg is below the performance at the other sites. This is due to the fact that higher heating supply temperatures in general affect the performance. In principle, this is true as well in the water-zeolite system, but the effect can be superposed by the DHW preparation: due to the high heating loads at these sites, the share of heat demand for DHW is smaller than at other sites. For this reason, the influence of the low-performance DHW preparation done by the gas boiler is smaller as well. Consequently, the overall performance achieves comparatively high values in some applications. In the ammonia-water system this effect is not appearing, since hot water is prepared by the sorption heat pump as well.

4. Summary, Discussion and Future Perspective

The results underline the capability of gas fired heat pumps to distinctly decrease environmental loads in terms of CO_2 emissions and primary energy demand. In currently available applications, savings of 30 % (CO_2)

and an improvement in PER of > 35 % can be obtained. This is a significant increase in efficiency of the overall heat supply in residential buildings.

The highest sGUE value close to 1.4, achieved in the GAHP system at London site in the MFH, corresponds very well to the simulation results of 1.37-1.38, published in the UK summary report on Annex43 [22] for UK houses.

Considering the EU site with default EU conversion factors, highest performance is achieved in the GAHP system, serving two units of the MFH+, and resulting in an annual sGUE of 1.33 and close to 26 % of CO_2 savings (Medium heating temperature).

However, differences between the analyzed technologies, i.e., ammonia-water absorption and water-zeolite adsorption, are obvious. Performance results for the AdHP are throughout below the performances of the GAHP system. The main reason for this difference is the necessity in the AdHP system to use the gas boiler for DHW preparation. This requirement, resulting from present laboratory tests with water-zeolite adsorption technology, lowers the efficiency considerably, as e.g. the share of heat demand for DHW preparation in well retrofitted or new single familiy houses is high. In the mid-term, the focus in the development of adsorption heat pump thus should allow to use the sorption unit for DHW preparation at adequate temperatures as well. It can be seen from the simulations, that the sGUE‘s for space heating only in the AdWP system are very promising and approaching to annual values of 1.4.

Likewise in many heating systems, an appropriate layout of the heating components is essential. As an outcome of this comparative approach, the different part-load behaviour of the heat pump technologies leads to oppositional performances: whereas the GAHP (the market available Robur K18) obviously performs better at high utilization and an oversizing therefore has to be avoided, the AdHP (test bench model) performs much better in part-load situation through the unique possibility of cycle variation in adsorption modules. Thus, undersizing of the AdHP decreases the annual performance.

In general, lower requirements on the heating temperature, e.g., application of the medium heating system temperature curve, improves the performance. This is especially true for the zeolite-water AdHP, which shows advantages in new or retrofitted buildings with fewer requirements on high heating temperatures.

Although the performance figures of the sorption heat pump technologies, analyzed in the context of residential building heating in this study are promising, many steps towards a higher share of market penetration have still to be done. With respect to the adsorption technology, a challenge remains in enabling domestic hot water preparation, i.e., to increase the supply temperature level, and further to allow the use of a more widely available low temperature source, in the best case ambient air or building exhaust air. Identifying proper materials and heat pump design allowing for this, will make the technology complementary to present absorption (i.e., ammonia-water) technologies in the residential sector.

Other obstacles in market penetration are connected with cost, awareness of building planners and building service companies and system integration. These topics are not touched in this study. However, gas fired sorption heat pump systems are still a new technology and demonstrate great potential to decrease the gas consumption considerably on the one hand without stressing the public electricity grids on the other hand. Thus, the technology can assist European and national efforts towards a low-carbon energy supply system transformation.

Gas (natural gas, biogas, hydrogen etc.) heat pumps for domestic use are potentially a huge market if they can become the successor technology to condensing boilers whose worldwide production exceeds 13 million/year. Sorption technology can reduce gas consumption for domestic heating by almost 40% (existing products) and might increase the saving to 60% with corresponding benefits in GHG emissions.

Abstract

Latent heat thermal energy storage (LHTES) bears the advantage of high energy storage density and balancing demand and supply. A promising application for residential buildings is the use of a compression heat pump (HP) in combination with a LHTES to generate domestic hot water (DHW) with the aid of the hot refrigerant compressor discharge. In this case the LHTES enables load shifting, heat pump operation harmonization and results in energy efficiency improvement. The setup investigated here is built of a compact combination of an air/water compression HP with R32 as refrigerant and a novel 3-media – Refrigerant, Phase Change Material (PCM) and Water – Heat EXchanger (RPW-HEX) which is directly integrated into the HP cycle between compressor and condenser. A key challenge of this combination is the dynamic system operation and control which is experimentally examined in this work. RPW-HEX charging and discharging as well as continuous operation is analyzed based on several weeks of operation. In this work it is proven that the proposed combination is capable to operate stable over a wide operating range and to generate DHW effectively.

1. Introduction

The demand for heating and cooling has seen a tremendous upswing in the past. Solely the cooling demand is reported to have five-folded between 1990 and 2014. For this reason, a great share (approx. 40%) of today's world's final energy consumption is used for heating and cooling applications in buildings as well as industries. In these applications about 65% is attributable to fossil fuels [1,2]. A cut in the fossil fuel consumption and switch to renewable energy sources is inevitable to reach the 20/20/20 target set by the European Union [3,4] and to limit the effects of climate change [5].

The trend towards energy sustainability is a key challenge and at the same time an opportunity for enabling technologies. Among others, the compression heat pump (HP) technology is traded as an enabling technology for a future carbon-emission free world. The technology enables efficient, carbon emission-free heat and cold when embedded into a renewable electricity grid. For this and other reasons the technology has seen a tremendous rise with continuously growing sales - three years in a row double-digit growth rates (2015-2017) have been reported - passing the 1-million-unit sales figure in the EU-21 end 2017 [6].

Compression HPs are particularly interesting in building applications where they serve to deliver cooling in summer, heating in winter and domestic hot water (DHW) all year long. Radiant heating and cooling by means of underfloor heating in office and residential buildings offer superior internal comfort compared to legacy air condition system for heating. The low temperature level for heating can be provided at excellent efficiency by HPs' [7]. On the other hand, DHW must be provided at elevated temperatures to tackle the risk of legionella [8]. These elevated temperatures go hand in hand with lower COPs and therefore with a significant higher electric energy consumption of the HP compared to the operation in heating mode. Hence, concepts, that can lower the electric energy consumption for DHW generation are more than welcome. This transient and high-temperature operation and the resulting inefficiencies for HPs' give rise to novel concepts which include thermal energy storage (TES). By means of load shifting and harmonization of the HP operation they can provide energy savings and result in a cost advantage [9]. TES systems can include sensible energy storage, e.g. water tanks, or latent heat thermal energy storage (LHTES) using phase change material (PCM). LHTES offer high thermal energy storage densities but the selection of the best-suited PCM material is a key issue to take advantage of the technology [10].

A promising application for residential buildings is the use of a compression heat pump (HP) in combination with a LHTES in residential buildings to generate domestic hot water (DHW) with the aid of the hot gas of the refrigerant at compressor discharge. The setup investigated here is built of a compact combination of an air/water compression HP using R32 as the refrigerant and a novel 3-media – Refrigerant, Phase Change Material (PCM) and Water – Heat EXchanger (RPW-HEX) which is directly integrated into the HP cycle after the compressor. High-temperature heat is transferred from the hot compressor discharge gas to the RPW-HEX to charge the PCM during heating or cooling operation. In DHW generation operation, low-temperature heat continues to be delivered from the condenser of the HP and only the remaining energy needed to reach the desired DHW temperature is covered by discharging the PCM inside the RPW-HEX to the water circuit.

The concept was originally presented by Emhofer et al. [11] who proved the considerable annual energy performance advantages compared to legacy systems. More than 120 potential suitable PCM materials for this concept were screened by Zsembinszki et al. [12] and, based on key performance indicators, the most suitable material was selected.

While a detailed techno-economic analysis of the systems is presented at this conference as well [13]. This contribution focuses on the experimental validation of the HP/RPW-HEX system including:

- RPW-HEX charging operation,
- RPW-HEX discharging operation,
- Continuous charging/discharging operation, and
- Continuous charging/discharging operation for DHW generation.

2. Technology

2.1. Heat pump technology

The heat pump is a water/air type heat pump with R32 as the refrigerant and comprises an inside unit, an outside unit, and the RPW-HEX. The schematic process flow diagram of the setup is depicted in Fig. 1.

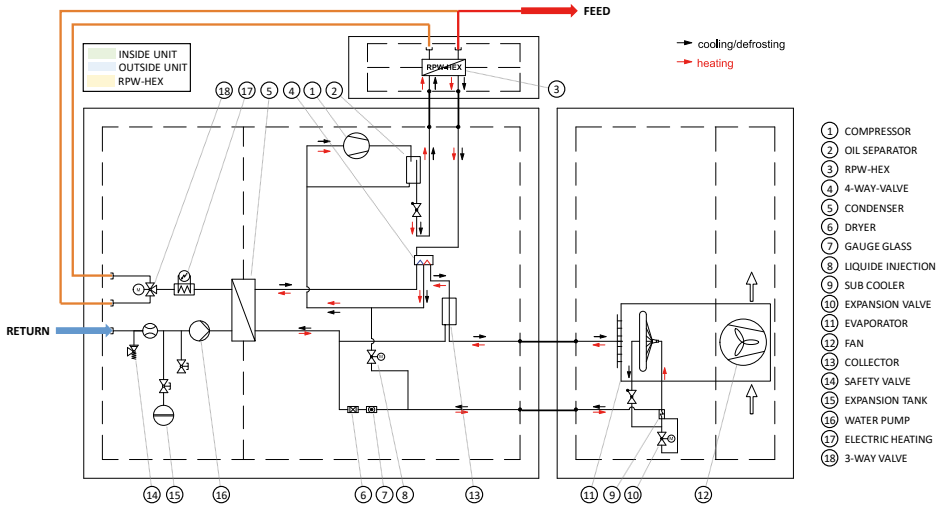

Fig. 1 Process flow diagram of the compression heat pump setup with the inside unit (light green), the outside unit (light blue) and the RPW-HEX (light orange).

In the inside unit, the compressor ① is placed which is driven by a variable speed drive. The frequency converter of the variable speed drive has a DC bus that is routed to the outside and therefore can handle AC and DC-supply as well. This allows for the direct use of DC energy from PV. After passing the oil separator ② the hot compressor exhaust flows to the RPW-HEX ③. Inside the RPW-HEX high-temperature sensible heat is effectively recovered from the refrigerant and stored mainly in the PCM. The 4-way valve ④ allows to reverse the flow of the refrigerant and facilitates either cooling or defrosting operation. In heating mode

operation, the hot refrigerant is directed to the condenser ⑤ to heat the process water flowing to the heat sink. After passing a filter dryer ⑥ and a gauge glass ⑦ the refrigerant is subcooled in the sub-cooler ⑨, expanded in the expansion valve ⑩ before entering the evaporator ⑪. The outside unit is equipped with a variable speed fan ⑫ controlled depending on the operating conditions. A small refrigerant collector ⑬ (pipe in pipe-type) is used to allow operation over a wide operating range while keeping the refrigerant volume low. The 4-way-valve closes the refrigerant cycle and directs the refrigerant to the compressor suction side. To limit the temperature at the compressor exit – a peculiarity of the R32 refrigerant cycle – liquid refrigerant is injected into the compressor suction side using the liquid injection valve ⑧. In cooling or defrosting operation, the 4-way-valve directs the hot refrigerant to the evaporator, where it condenses releasing heat. The cold refrigerant then passes the condenser where it evaporates absorbing low-temperature heat for cooling. In the water circuit a safety valve ⑭ is placed to avoid overpressure in the water circuit of the heat pump. To compensate for the density fluctuation, the expansion tank ⑮ is placed. The water pump ⑯ compensates for the pressure drop of the condenser. After passing the condenser an electric heater ⑰ would allow covering the demand whenever the heat pump delivers insufficient thermal power. However, this additional electric heating was never used in the experiments. To control the feed-water temperature the 3-way valve ⑱ is used allowing to mix the water from the condenser and the RPW-HEX.

2.2. RPW-HEX

The RPW-HEX is a novel 3-passage heat exchanger made of aluminum (110 kg empty mass) and includes a refrigerant passage, a phase change material (PCM) passage and a water passage (a cross-section is illustrated in Fig. 2 right).

The high-temperature heat is extracted from the compressor discharge and, depending on the operating condition, stored inside the PCM and/or transferred to the water directly. To enhance the heat transfer, aluminum fins are placed inside the PCM, the refrigerant passages, and the water passages. The RPW-HEX is filled in total with 40 kg of PCM. The PCM is manufactured by Rubitherm Technologies type RT64HC [14] which melts at 63-65 °C and has a total latent heat storage capacity of about 2.8 kWh. For the experimental evaluation, the RPW-HEX is equipped with in total 14 thin-film PT-100 temperature sensors class A (manufacturer RS-components type 70643577), which are directly applied to the surface of the RPW-HEX. A pressure transmitter is attached to the PCM section to capture the pressure caused by the volume displacement of the melting PCM. A schematic of the RPW-HEX including the position of the temperature sensors is shown in Fig. 2 left.

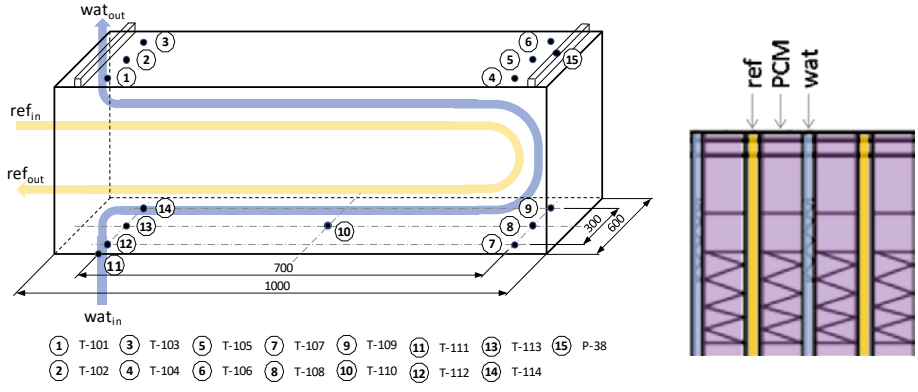

Fig. 2 Left: Schematic of the RPW-HEX showing the refrigerant pass (ref_{in} and ref_{out}) the water pass (wat_{in} and wat_{out}) as well as sensor positions (① to ⑮). Temperature sensors are attached to the surface of the RPW-HEX and include position ① to ⑭. A pressure sensor is attached to the PCM section indicated at position ⑮. Right: Cross-section of the RPW-HEX showing the refrigerant passage (ref), the PCM passage (PCM) and water passage (wat).

2.3. Energy balance calculations

Thermal energies were determined based on temperature, pressure, and flow rate measurements. Measurements were taken in the refrigerant cycle and the water circuit. The following thermal energies were determined:

- E_{Cond}: energy from the condenser either during charging $E_{\text{Cond charge}}$ or discharging $E_{\text{Cond discharge}}$ based on measurements in the water circuit directly at the inlet and outlet of the condenser.
- E_{RPWW}: energy from the RPW-HEX based on measurements in the water circuit directly at the inlet and outlet of the RPW-HEX.
- E_{RPWR}: energy from the RPW-HEX based on measurements in the refrigerant cycle directly at the inlet and outlet of the RPW-HEX.
- E_{RPW}: energy from the RPW-HEX itself (PCM and aluminium) derived from

$$E_{RPW} = E_{RPW_W} - E_{RPW_R} \tag{1}$$

- E_{tot}: energy transferred from the HP/RPW-HEX system to the water circuit based on measurements in the water circuit at the inlet and outlet of the entire system.

3. Experiments

3.1. Experimental setup

To assess the performance of the RPW-HEX integrated in the HP cycle, the system was placed in a controlled laboratory environment at the AIT Austrian Institute of Technology. The laboratory infrastructure allows for high precision control of the temperature and flow rate of water to the system. The outside unit of the heat pump was placed in a climate chamber enabling air temperature and humidity control over a wide range (down to -20 °C). Calibrated water temperature, pressure/pressure drop and flow sensors, air humidity and temperature sensors, as well as electric consumption meters, were used. A mass flow meter (Coriolis type), positioned after the gauge glass ⑦ (see Fig. 1), allows measuring the refrigerant mass flow rate. Note, the refrigerant mass flow rate was not always accessible because of 2-phase flow in the sensor at certain operating conditions. In addition to these sensors, heat pump internal sensors (mainly temperatures, pressures, and flows) were integrated into the laboratory control and data acquisition system via Modbus interface to allow for control and real-time monitoring of the system operation.

For testing, the system was filled with 3.9 kg of R32 and water was used in the hydraulic circuit. The arrangement of the HP and RPW-HEX including hoses and measurements is shown in Fig. 3.

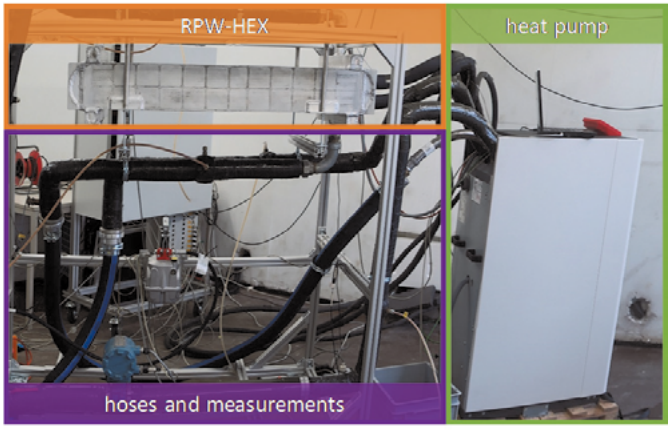

Fig. 3 Experimental setup showing the heat pump inside unit (green), the RPW-HEX (orange) and hoses and sensors for the flow rate measurements (violet).

3.2. Experimental campaign

To gain an understanding of the operation of the HP with an integrated RPW-HEX a series of experiments have been conducted. For these experiments the climate chamber, where the outside unit of the heat pump was located, was operated at -7 °C dry/-8 °C wet bulb temperature, which reflects the requirements prescribed by the EN 14511 for HP testing. The water inlet temperature of the heat pump ("RETURN" in Fig. 1) was held constant to 33 °C while the water mass flow was changed depending on RPW-HEX charging or discharging operation. In the first measurement series solely charging or discharging was investigated, while in the second series the system was operated cyclical (continuous charging/discharging operation). Furthermore, the water mass flow through the RPW-HEX controlled by the three-way valve (⑱ in Fig. 1) was once switched between on/off only (*discharging I* operation) and the other time varied to guarantee a stable outlet temperature to the heat sink (*discharging II* operation). The water flow rates have been selected to meet the requirements in typical operation of such a system. An overview of the experiments is shown in Table 1.

Table 1. Overview of experiments

Series	Description	Compressor speed in %	Water mass flow in kg/s		Flow rate through the RPW-HEX during discharging
			charging	discharging	
1	charging	90	0.245	-	none
1	discharging I	0	-	0.14	constant
1	discharging II	90	-	0.14	constant
2	cyclic operation I	90	0.245	0.14	constant
2	cyclic operation II	90	0.245	0.14	variable

4. Results

4.1. Experiments Series 1

Series 1 focused on the complete charging and discharging behavior of the system considering long term charging and discharging to assess the operating limits of the RPW-HEX.

For the first charging experiment (cf. *charging* in Table 1) the system was operated for more than 20 hours where the measured RPW-HEX temperatures, as well as RPW-HEX refrigerant outlet temperature, is shown in Fig. 4. The RPW-HEX was pre-heated to 33 °C at the beginning with the aid of the external water cycle. The refrigerant inlet temperature to the RPW-HEX was almost constant at approx. 110 °C. After approx. 4, 10.5, and 17 hours of operation, the HP switched to defrosting operation (refrigerant cycle

operated in reverse mode) due to icing of the outside unit. The defrosting operation caused a sharp decrease of RPW-HEX temperatures T-101 to T-103 as well as RPW-HEX refrigerant outlet temperature (T-06) attributable to the drop of compressor outlet temperature in this operating mode. After about 6.5 hours of operation all RPW-HEX temperatures passed the melting temperature of 64 °C of the PCM. The steep increase of T-107 to T-109 (blue lines) as well as T-06 after this event can interpreted as the end of melting of the PCM inside the RPW-HEX.

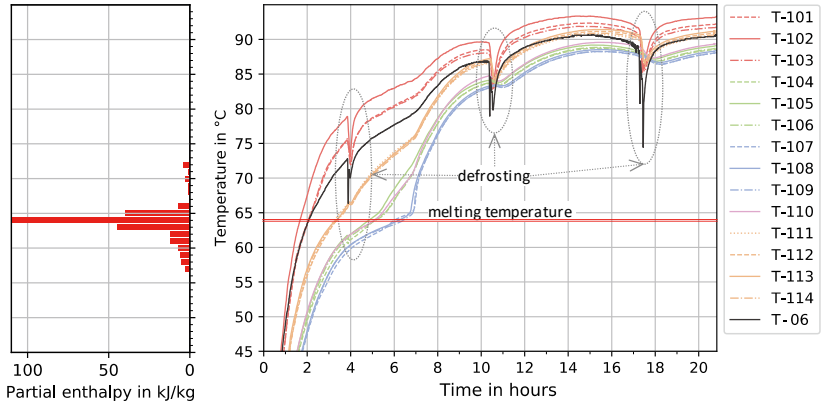

Fig. 4 Experimental results for the *charging* test in Series 1. Left: Partial enthalpy diagram PCM melting [14]. Right: Measured temperature profiles of RPW-HEX surface temperature measurements (T-101 to T-114, cf. Fig. 1) as well as RPW-HEX refrigerant outlet temperature (T-06).

To obtain the thermal energy stored in the RPW-HEX for the first discharging experiment (cf. *discharging I* in Table 1), the heat pump was switched off and the entire water was directed to the RPW-HEX using the 3-way valve (cf. ⑱ in Fig. 1) in the water circuit. Discharging was stopped once the RPW-HEX temperatures reached the level of the water inlet temperature (33 °C) – after about 1 hour. The PCM has two solidification peaks: at 64 °C and 61 °C (cf. Fig. 5 left). The 64 °C solidification peak was very well observed from the RPW-HEX temperature measurements while the second solidification peak at 61 °C appeared later in the experiments at about 57°C (cf. Fig. 5 middle). This may be an indication of delayed solidification which has been observed by others as well [15-17]. The same melting/solidification behaviour was found for a different LHTES application and phenomenological modelling was presented in [18]. However, the experiments revealed that the water temperature at the RPW-HEX outlet can reach up to 85 °C (cf. Fig. 5 right) if the three-way valve is fully open. This must be considered for the implementation in residential buildings where often plastic-compound pipes with a maximum operating temperature of 75 °C are used today. After the 85 °C peak the water reaches a plateau at about 57 °C, which can be attributed to the second solidification peak of the PCM. At the end of the discharging experiment, in total 6.3 kWh thermal energy was extracted from the RPW-HEX if it is cooled from initial approx. 90 °C to 33 °C.

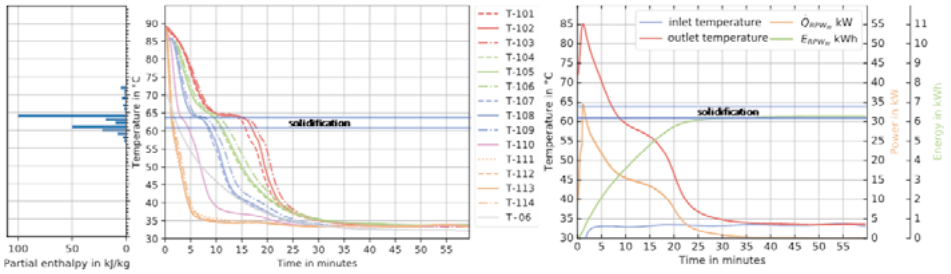

Fig. 5 Experimental results for the *discharging I* test in Series 1. Left: Partial enthalpy diagram PCM melting [14]. Middle: Measured temperature profiles of RPW-HEX surface temperature measurements (T-101 to T-114, cf. Fig. 1) as well as RPW-HEX refrigerant outlet temperature (T-06). Right: Water temperatures at the inlet and outlet of the RPW-HEX as well as thermal power and energy from the RPW-HEX.

The discharging experiment with running compressor (cf. *discharging II* in Table 1) is shown in Fig. 6. Similar solidification plateaus were observed compared to the *discharging I* test. However, for this test the solidification plateau appeared even more pronounced because the water, in this case, was pre-heated by the condenser to about 45 °C and therefore, less energy was drawn from the RPW-HEX compared to *discharging I* at the beginning (cf. orange lines in Fig. 5 and Fig. 6 right). The experiments showed that with running compressor the RPW-HEX is not only discharged but also allows to direct exchange heat between the refrigerant and the water side, transferring approx. 2.5 kW (see $\dot{Q}_{\mathrm{RPW_w}}$ in Fig. 6 right after about 50 minutes).

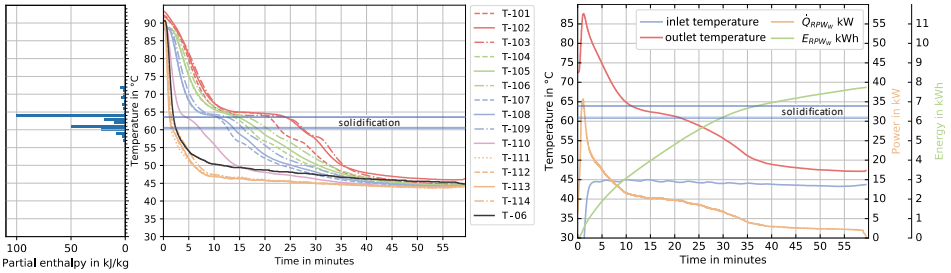

Fig. 6 Experimental results for the *discharging II* test in Series 1. Left: Partial enthalpy diagram PCM melting [14]. Middle: Measured temperature profiles of RPW-HEX surface temperature measurements (T-101 to T-114, cf. Fig. 1) as well as RPW-HEX refrigerant outlet temperature (T-06). Right: Water temperatures at the inlet and outlet of the RPW-HEX as well as thermal power and energy transferred from the RPW-HEX to the water circuit.

4.2. Experiments Series 2

To test the continuous operation of the system, it was operated in subsequent charging/discharging cycles. Based on the results from complete charging/discharging tests both the optimal conditions for switching between both operating modes was identified. Charging of the RPW-HEX should preferably end if all the PCM is molten. As an indicator for this event, the point in time when the average value of T-107, T-108 and T-109 exceeds 70 °C was identified (cf. Fig. 2). Discharging was stopped once the water temperature at the RPW-HEX outlet dropped below 55 °C. This limit was selected since a lower temperature is considered useless for DHW generation and most of the latent energy should already be released from the RPW-HEX at this point (cf. outlet temperature in Fig. 6 right), too.

For the first cyclic operation test run (cf. *cyclic operation I* in Table 1), the 3-way valve (cf. ⑱ in Fig. 1) in the water circuit was not controlled, but rather fully opened or closed. To meet the requirements in a real application, the water flow to the system was reduced for RPW-HEX discharging operation.

For *cyclic operation I* the system was operated for more than 50 hours covering 7 RPW-HEX charging and discharging cycles (see Fig. 7). While the charging cycle took between 6-7 hours, depending on how many defrosting cycles were needed, the discharging cycle always took approx. 30 minutes.

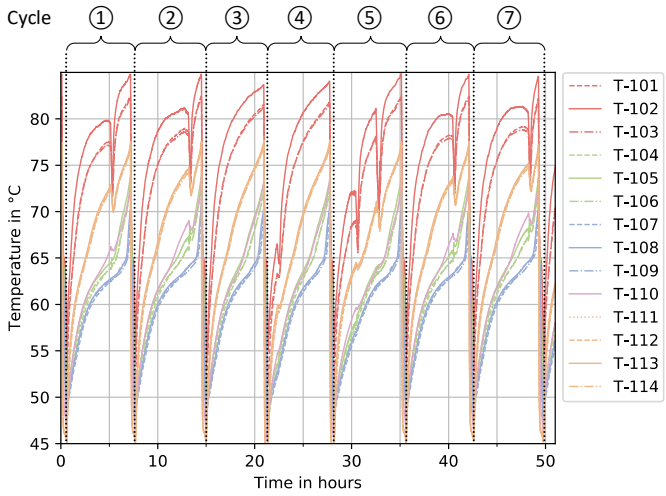

Fig. 7 Experimental results for the cyclic charging I test in Series 2. Shown are the RPW-HEX surface temperatures.

The energy balance for one typical charging/discharging cycle in test run *cyclic operation I* is depicted in Fig. 8 left. While charging the RPW-HEX, about $E_{\text{Cond charge}}$=49.2 kWh is delivered from the condenser, which can be used for heating purposes. During discharging of the RPW-HEX about 60% of the energy is attributable to the RPW-HEX (E_{RPWW}=5.36 kWh). Only about $E_{\text{Cond discharge}}$=3.5 kWh is covered by the condenser which, however, is crucial for efficient DHW generation. During the complete charging/discharging cycle, about E_{tot}=56.7 kWh is delivered to the water circuit, which is 1.37 kWh less than what is recovered from the condenser and the RPW-HEX. This discrepancy is caused by thermal losses in the piping system.

A detailed analysis of the energy balance during discharging is given in Fig. 8 right (shown as stacked plot). Based on the measurements, it is obvious that a share of about 11% is attributable to direct heat transfer from the refrigerant – the hot gas from the compressor – to the water. The analysis also reveals that about 0.86 kWh appears as thermal loss, which is relatively high compared to the total cycle (1.37 kWh). This is because the thermal energy loss is attributable to stagnant water in the piping system to the RPW-HEX, which becomes effective during discharging operation only.

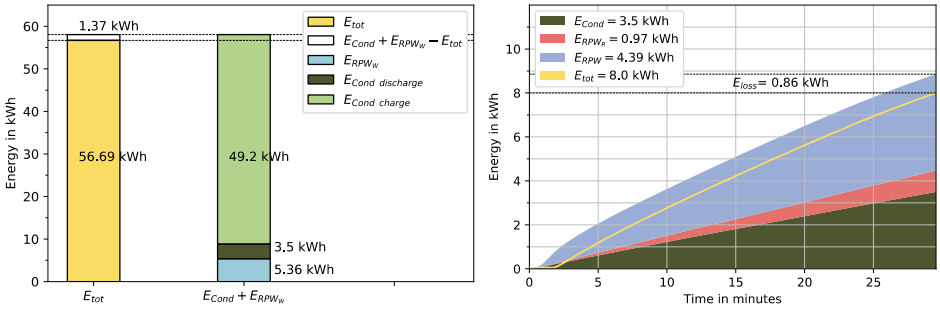

Fig. 8 Energy balance considerations for one typical charging/discharging cycle for test run *cyclic operation I* in Series 2. Left: Energy transferred to the water cycle for one complete charging/discharging cycle. Right: Energy transfer during discharging illustrated as stacked plot.

For the efficient use of the thermal energy stored in the RPW-HEX, the temperature at the outlet of the system must be controlled. This is obtained by controlling the 3-way valve (cf. ⑱ in Fig. 1) and mixing

warm water from the condenser outlet with hot water from the RPW-HEX outlet. Therefore, a control loop was implemented (cf. *cyclic operation II* in Table 1) to reach a target temperature of 55 °C at the system outlet for the use as DHW.

Measured water temperatures for one representative discharging cycle for test run *cyclic operation II* are shown in Fig. 9 left. The discharging time is longer, compared to the test run *cyclic operation I* since only a part of the water passes the RPW-HEX. Due to the reduced water flow for discharging, the condenser outlet temperature immediately increased from 41 °C to 45 °C and then drops to 43 °C later due to increased heat transfer inside the RPW-HEX caused by decreasing PCM temperature during discharging. Similarly, the discharging experiments presented before the RPW-HEX water outlet temperature increases quickly and reaches about 82 °C after about 2 minutes. The water temperature at the system outlet at the beginning decreases quickly reaching a mere at 38 °C due to the stagnant water in the piping system of the RPW-HEX – as mentioned before here as thermal energy loss. However, after about 5 minutes the setpoint (55 °C) at the system outlet is reached and DHW is obtained for about 42 minutes.

The detailed analysis of the energy balance is given in Fig. 9 right. Compared to the test run *cyclic operation I* (cf. Fig. 8 right) the total energy available for DHW increases by 22%, while the contribution from the RPW-HEX (E_{RPW}) is almost equal. This is caused by the increased contribution from the condenser ($E_{Cond\ discharge}$) and the direct heat transfer from the hot gas (E_{RPWR}).

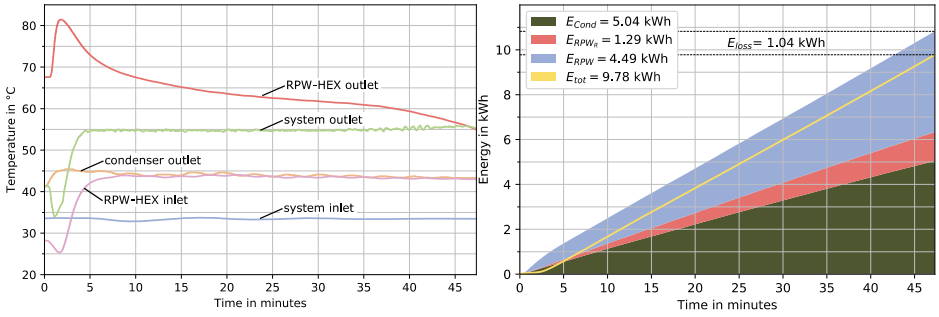

Fig. 9 Left: Temperature profiles in the water circuit for a typical discharging cycle for test run *cyclic operation II* in Series 2. Right: Energy transfer during discharging illustrated as stacked plot.

5. Conclusions and Outlook

In this work, it was experimentally verified that the proposed setup, a LHTES – in the form of an RPW-HEX – integrated in the hot gas section of the refrigerant cycle of a compression HP, allows for effective, parallel generation of heat and DHW for residential buildings at a beneficial *COP*. Startup, normal operation, reverse cycle operation, i.e. outside unit defrosting, shutdown and restart operation were successfully tested without major difficulties. However, it was found that care must be taken to avoid condensation of refrigerant inside the RPW-HEX – a safety measure to avoid refrigerant, and potentially also oil accumulation inside the refrigerant section of the RPW-HEX. This requirement demands adapted startup and operation procedures which shall be implemented on the level of the HP controller.

The RPW-HEX surface temperature measurements turned out to be effective to trigger discharging in an automated system. Certain temperatures can give an idea for the melting and solidification peaks of the PCM inside the RPW-HEX.

The continuous charging/discharging operation of the system revealed that for the selected operating conditions the current design of the RPW-HEX can deliver approx. 8 kWh of DHW per discharging cycle and 3 discharging cycles can be obtained per day. Compared to what is needed according to EN16147 (2017), this is 1.36 times the daily DHW consumption of an average apartment (5.845 kWh) per discharging cycle. Therefore, the RPW-HEX with decentral sensible DHW storages (cf. [11,13]) may serve DHW to in total 4 apartments if a constant return water temperature of 33 °C is assumed. Note, that the return water temperature from the sensible DHW storages in a real-life application strongly affects this temperature value. Switching between heating and DHW generation was smooth and HP operation itself was uninterrupted neither had to be adjusted. This clearly underlines the ability of the system for effectively shifting thermal loads, harmonizing the operation to run the HP at high efficiency although generating high-temperature heat.

Based on the knowledge gained from the experimentation the design of the RPW-HEX, the defrosting operation procedure, and the startup-procedure were adapted. A new optimized design of the RPW-HEX is currently being manufactured to be tested in near future.

Abstract

Heat pumps (HP) are a key technology to reduce CO_2 emissions in buildings. Yet, profitability of HP-based systems is often poor due to high electricity prices compared to gas prices. Consequently, HP-based systems in new non-residential buildings in Germany only accounted for 17 % in 2018 [1]. However, the German government intends to introduce carbon pricing which could increase HPs´ market penetration.
To evaluate the profitability of all-electric systems in non-residential buildings, the energy system of an old military hospital, which is transformed into a technology and laboratory center called FUBIC, is designed.
We create the building model and analyze the building´s thermal demand using Modelica. Based on this, a HP-based all-electric and a conventional supply scenario are modelled. As KPI, we calculate the annuity and CO_2 emissions in both 2018 and 2030 based on three carbon pricing scenarios.
Results show that, despite its lower emissions, HP-based system´s annuity is lower than that of the conventional scenario regardless of the carbon pricing scenario. The main cost drivers are the demand-related costs which can be decreased by advanced operating strategies.

1. Motivation

Over the last years, the German government introduced measures in order to reduce CO_2 emissions. These measures mainly focus on the electricity sector representing 21 % of the final energy demand in Germany [2]. Here, the share of renewable energies (RE) in total electricity generation reached 37.8 % in 2018, aiming at 80 % by 2050 [3]. In contrast to that, in the heating and cooling sector, which has a share of 50 % of the final energy demand, RE sources only accounted for 14 % in 2018 [2,4]. Obviously, implementing RE sources in the heating sector would contribute strongly to a decrease in total CO_2 emissions in Germany. This is why the German government set the aim for an almost climate-neutral building stock by 2050 [5]. One measure to achieve this is to substitute fossil-based heat generation systems by those utilizing RE sources [5]. In this context, sector coupling plays a key role. By coupling the electricity and the heating sector, the already realized shift towards REs in the electricity sector can be exploited even more. This is why according to [6] and [7], the electrification of the heating sector is crucial for achieving a holistic energy transition and reach the set aims for 2050. In this study, we refer to heating and cooling systems merely utilizing electricity as energy source as all-electric systems.

E-mail address: laura.maier@eonerc.rwth-aachen.de.

In the context of all-electric systems, heat pumps (HPs) and chillers are key technologies as they can utilize RE sources (electricity supply and ambient energy) and enable sector coupling. However, in non-residential buildings, the primary energy source is gas and HP-based systems only account for 17 % in new buildings, assuming even lower ratios in the building stock [1]. Nevertheless, non-residential buildings´ share in the total energy demand in the building sector was 37 % in 2014 [8]. This trend is also reflected in the poor amount of current research activities on all-electric systems in the non-residential building sector [9].
A major obstacle to the prevalence of all-electric systems is their profitability. Compared to oil or gas prices, electricity is approximately 4 to 5 times more expensive in Germany [10]. However, fuel prices are strongly fluctuating and their development is uncertain. In addition, there have been some recent developments towards pricing of carbon dioxide, which would strongly influence the given comparison.
This paper contributes to the economic profitability of all-electric systems based on HPs by following steps:

- In chapter 2, an overview of typical energy supply systems in non-residential buildings as well as current and future regulatory boundaries are given.
- We present the developed simulation-based approach for economically and ecologically assessing two supply systems in chapter 3. In addition, future scenarios regarding the development of CO_2 factors and CO_2 pricing are discussed.
- In chapter 4, we show that profitability of HP-based all-electric systems strongly depends on regulatory and economic boundary conditions. Despite their potential to reduce CO_2 emissions, all-electric systems are not necessarily profitable regardless of the carbon pricing scenario applied.
- Based on the results, we deduce a break-even point for CO_2 pricing as well as electricity and gas prices and derive measures in order to support the spread of HP-based all-electric systems.

2. State of the art: Energy supply systems and price development

2.1. Energy supply systems in non-residential buildings

In Germany, the majority of energy systems in non-residential buildings is fossil-based [11]. Besides agriculture, gas is the primarily used energy source. District heating is the second leading source whereas electricity has only small shares. Considering the prediction for the shares of energy sources used for space heating given in [12], we detect a decreasing amount of used gas whilst at the same time increasing renewables such as biomass or geothermal energy. According to the forecast, the absolute consumption of electricity used for space heating remains almost constant between 2009 and 2050 indicating that HPs´ share will remain constant as well.

According to the forecasts presented in [12], electricity will not dominate future heating supply. One reason are high electricity prices in comparison to the other energy prices [10]. This results in the decreased integration of HPs despite their higher efficiency in comparison to conventional heat generators. In addition, HPs have higher capital-related cost when compared to conventional boilers even reinforcing this effect. One aspect which might increase the profitability of HP-based energy systems, however, is the development of carbon pricing. Over the last years, different measures to price CO_2 emissions have been introduced which will greatly influence the profitability of energy systems and thus the choice of energy sources. As HPs support the integration of REs, carbon pricing would encourage their implementation.

2.2. Current and future energy and CO_2 prices

When assessing the profitability of energy systems, regulatory and economic boundary conditions strongly influence the results. The following chapter summarizes current and future energy price developments as well as methods of carbon pricing.
A major reason for the prevalence of gas-based heating systems are low gas prices as well as their well-known technology. Over the last 10 years, gas prices even dropped favoring the integration of gas-based energy systems. In 2018, regular customers (20 – 200 GJ/a) paid 6.08 ct/kWh (all taxes included), whereas industrial customers (100 – 1.000 TJ/a) paid 2.65 ct/kWh including consumption taxes (excluding value added tax (VAT)). Since 2009, an average annual gas price decrease of 0.64 % for regular customers and 2.99 % for industrial customers is observed. [7]
In contrast, increasing prices were recorded for electricity. Prices for the German regular customer (2.5 – 5 MWh/a) have risen by an average of 2.77 % per year over the past ten years. In the large customer segment (2

– 20 GWh/a) the increase was slightly lower at 2.19 % per year. In the second half of 2018, German electricity prices amounted to 12.44 ct/kWh for industry (consumption taxes included, VAT excluded), respectively. [7] Obviously, gas prices are 4 to 5 times lower than electricity prices given the current regulatory and boundary conditions. Therefore, HP-based energy systems would have to reach a SCOP of 4 to 5 in order to achieve equal operating costs which is usually not realistic [13].

Nevertheless, the current regulatory and economic boundary conditions are under constant change. A factor which could strongly influence the given conditions is carbon pricing. Over the last years, various forms of carbon pricing have been introduced as a measure to beat climate change in many countries. There are currently two types of CO_2 pricing systems [14]:

- Direct pricing by applying e.g. taxes
- Indirect pricing by introducing certificate trading [15]

In Europe, the latter is realized by the EU Emissions Trading System (ETS). Sectors which are covered by the system are the energy, industrial and EU-aviation sector. Sectors like the traffic, building, small industry, agriculture and waste sector are referred to as Non-ETS sectors. For these, EU member states set the goal for 2030 to reduce emissions by 38 % compared to 2005. In 2018, however, the German government decided to extent the ETS to the heating and traffic sector. They intent to introduce 3 phases in Germany [16]:

1. From 2021 to 2025: CO_2 certificates are sold for fixed prices starting from 10 €/t in 2021 to 35 €/t in 2025.
2. In 2026: A certificate auctioning system is introduced with prices ranging from 35 to 60 €/t combined with a fixed upper limit for overall emissions.
3. From 2027 onwards: Based on the findings of the former phases, the necessity of upper and lower boundary prices is checked and the system will be adapted accordingly.

In contrast to the implemented trading system in Germany, other countries like Switzerland have introduced a direct pricing system realized by a carbon tax. Starting from 2008, the Swiss government has taxed fossil fuels like gas and oil, gradually adapting the price per ton CO_2 depending the overall emission level.
This development will strongly influence the profitability of all-electric systems in comparison to conventional heating systems and might favor the spread of HP-based energy systems.

3. Methodology

In order to economically assess HP-based systems in the non-residential building sectors, a simulation-based approach is adopted to compare two supply scenarios for the refurbishment process of an office and laboratory building called FUBIC. One scenario represents a state-of-the-art set up based on a condensing gas boiler (CGB) whilst the other scenario is a HP-based all-electricity scenario and thus is not common in non-residential buildings.

3.1. Simulation-based assessment of FUBIC

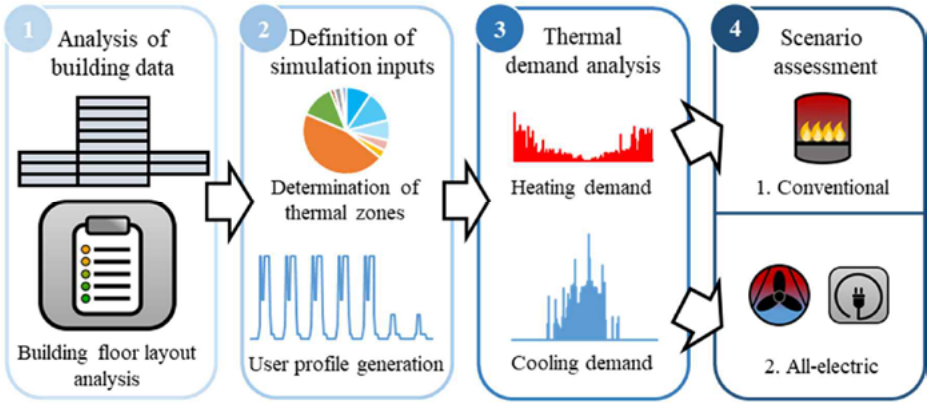

Fig. 1. Simulation-based assessment of a conventional and a HP-based all-electric supply scenario.

The use case is a former military hospital in Berlin, which is transformed into a business, laboratory and innovation center called FUBIC. The center will host start-ups and young companies of the sectors life science, health, communication and IT. FUBIC´s area will be divided into 30 % laboratory spaces, 60 % office spaces and 10 % ancillary areas.

In an early planning phase within the construction process of a building, the operating costs have to be estimated. In practice, this is usually done by applying static calculation methods. However, once the building operation starts, it becomes obvious that a priori estimated energy demand and actual energy consumption often differ greatly [13]. This is especially true for HP-based systems. HPs' efficiency strongly depends on external boundary conditions such as supply and ambient temperatures impeding the prior estimation of energy consumption and thus operating costs.
In this context, dynamic simulations are a promising tool to overcome this obstacle. Dynamic models enable a more realistic assessment of building and energy system performance and behavior. In order to compare the two supply scenarios described before, the two energy systems are implemented in the modelling language Modelica. The used models derive from either the Modelica Standard Library or the AixLib [16]. In this way, we can depict the physically implied dynamics.

In this study, we apply a 4-step approach (s. figure 1). In a first step, we analyze FUBIC´s floor layout deducing zones with similar utilization and boundary conditions (e.g. laboratories, group office, etc.). As a result, we obtain 9 zones which are the basis of the following energetic analysis. For each of these zones, we estimate people presence influencing the use of lights and other electrical devices based on weekly profiles from the Swiss standard SIA 2024 [17]. These boundary conditions serve as inputs for the simulation program and result in both an electrical and a thermal demand in step 3. In the final step, these demands are covered by the supply scenarios. Finally, we can estimate the annuity as well as CO_2 emissions based on the resulting energy demand and maximum thermal loads of the whole system.

3.1.1. Step 1 to 3: FUBIC´s thermal demand
A building model representing the demand side is the first model to be used for the simulation of a building energy system (s. figure 1). It considers various usage purposes of areas inside FUBIC. For modeling such a large multi-zone building, considering various usage purposes of its areas, a reduced order model approach developed by Lauster et al. [17] is applied. The model, which is available in AixLib [16], joins the building physics based on the German Guideline VDI 6007 [18] and the models for internal gains caused by persons, machines and lighting. As described in the guideline, the thermal response of the building can be calculated by using an electric equivalent model with resistances and capacities. In this way, the computation time is reduced considerably resulting from fewer parameters and equations.

For the parametrization of the electric equivalent model, the open-source software tool TEASER [19] is applied. It is used to calculate the resistances and capacities based on information about the geometry and physical properties of the building. Furthermore, TEASER includes a statistical database of representative building setups und thus enables a quick generation of archetype buildings with little input data. The parameters are exported by TEASER in such a structured format that they can be automatically imported into AixLib [16], with which the building model is set up.
The FUBIC building model is extended from an institute building archetype with laboratories. The input data for this archetype is summarized in table 1.

Table 1. Input parameters for simulation tool TEASER for the FUBIC building: Geometry and physical properties.

Number of floors	6 above-ground floors
Net leased area	11,112 m²
Zone layout	Elongated, h = 1 floor
Construction type, year	Heavy, 2018
Ventilation	Mechanical ventilation

With the information extracted from the floor plans, rooms of an equal or similar usage type are classified into one thermal zone, which is assigned with use conditions based on the German standard DIN V 18599 and SIA 2024 [17,20]. The various use conditions determine features like the room set temperatures, air exchange rates, occupancy profiles, internal gains and others. Figure 2 visualizes the resulting zoning of FUBIC

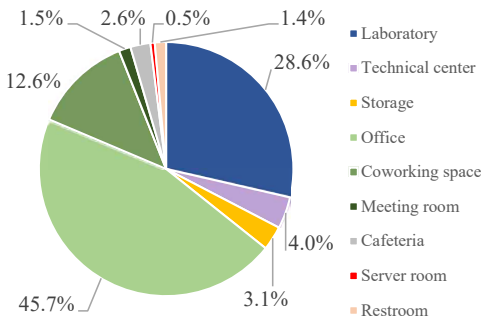

Fig. 2. Classification of FUBIC into thermal zones of equal usage.

The internal gains in the building model include the occupancy of persons, usage of machines and lighting with schedules. The schedules are based on Swiss standard SIA 2024 [17] and are modified for the FUBIC building. For each zone a week profile is defined, considering the difference between weekdays and weekends. The German standard DIN V 18599 [20] also defines the range of indoor comfort temperatures, air exchange rates and conditions of the supply air for each zone. Reference room temperature set points for cooling are given by the German guideline VDI depending on the outdoor temperature to reduce energy demand. [21]
External loads are estimated with weather data given in Test Reference Years (TRY) for Berlin. Germany's National Meteorological Service [22] offers localized weather data of an intermediate TRY as well as special TRYs with a cold winter or a hot summer.
As a simulation result, 4 different thermal demand types are determined in step 3, which are covered by the supply scenarios. The 4 thermal demand types are distinguished as follows:

- Dynamic heating via the ventilation system and static heating via the floor heating system (FHS)
- Dynamic cooling via the ventilation system and additional cooling via recirculation coolers

All in all, 67 % of the heat demand and 22 % of the cooling demand are supplied via the central air handling unit whilst the residual demand is covered by the FHS and the recirculation coolers respectively.

3.1.2. Step 4: Scenario assessment

The main difference between the assessed scenarios is the heat generation system. In the conventional scenario, a CGB is used whilst in the all-electric scenario an air-to-water HP and an electrical backup heater cover FUBIC´s heat demand. The electrical backup heater supports the heat when outdoor temperature drops below a predefined bivalence temperature of -2 °C [23]. Furthermore, the HP is equipped with a modulating compressor (30 to 100 % of design load) as thermal demand is strongly dynamic and thus heat demand can be covered more precisely. In order to guarantee more flexibility, a buffer storage is implemented connecting the HP and the air handling unit (AHU) in parallel. The buffer storage is loaded based on a hysteresis of 5 K while the FHS is controlled by a supply temperature control and a PID controller.
The implemented HP model is taken from the open source library AixLib [16]. It represents a grey box model in which the HP´s COP is based on the Carnot efficiency. The HP´s COP is calculated as follows [16]:

$$COP = \eta_{Carnot} \frac{T_{con}}{(T_{con} - T_{evap})} \quad (1)$$

In equation 1, T_{con} and T_{evap} represent the condenser and evaporator leaving temperatures. The Carnot efficiency η_{Carnot} is assumed to be 50 % and describes the ratio of the HP´s actual COP to the theoretical maximum COP [24]. The implemented model computes transient behaviour using a first order differential relation for the condenser and evaporator water and air volumes. For further information, see documentation of open source model AixLib.Fluid.HeatPumps.Carnot_y [16].

In the given use case, heat has to be supplied at two temperature levels: 50 °C to provide for the AHU´s heat demand and 35 °C for the FHS. These low temperatures support the utilization of HP-based systems, as HP´s COP increases with decreasing supply temperatures (s. equation 1). However, HP´s COP is more significantly influenced by external factors such as the ambient temperature as well as the operating point. In addition, process heating and cooling demand are less flexible demands compared to e.g. space heating. These boundary conditions pose additional requirements for the energy system which is why conventional heat generators are more common in cases like that. Their efficiency does not depend strongly on supply temperatures making prior estimation of energy demands easier. The adopted simulation-based approach, however, enables the detailed analysis of HP´s operation and thus overcomes this obstacle.

3.2. Energy market scenarios

When evaluating the profitability of energy systems, the economic and regulatory boundary conditions strongly influence the outcome. In the following chapter, we analyze important factors that influence the economic assessment of HP-based energy systems focusing on energy prices and CO_2 emissions in Germany.

3.2.1. Development of energy and carbon pricing

Based on the recent development of electricity prices (s. chapter 2.2), a price increase for electricity is assumed for future-related evaluations in this study. Despite the observed decrease in gas prices, the World Energy Outlook New Policies Scenario predicts that gas prices will increase as of 2020 [25]. In the following use case, an increase to 5 ct/kWh for industry (≙ large customers) by 2030 is presumed. Regarding electricity prices, the past trends are extrapolated, resulting in 16 ct/kWh for industrial customers.

Apart from that, carbon prices also influence the economic assessment of energy systems. However, their future development is uncertain as they have just or not yet been introduced in some countries. Nevertheless, they will strongly influence the profitability of energy systems and should thus be included in an economic assessment. In this work, the focus lies on the development in Germany and three scenarios are deduced.
The first scenario reflects an old policies scenario. Here, no carbon pricing is introduced which is referred to as the no costs scenario (NC scenario). In addition, a low costs scenario (LC scenario) is introduced. As the German government discusses the option to introduce a lower boundary of 35 €/t for carbon pricing starting in 2027. In the LC scenario, this is assumed to stay constant until 2030. In contrast to that, a third scenario is evaluated in which the future trend for pricing carbon from 2021 until 2025 is extrapolated resulting in a price of 66 €/t in 2030. We refer to this scenario as high costs scenario (HC scenario).

3.2.2. Future CO_2 factor

When evaluating the costs for carbon, it is necessary to predict the mass of CO_2 emissions caused by the respective energy system. In this context, CO_2 factors play an important role as they allow to estimate the CO_2 emissions per kWh of an energy source.
Since it depends on the chemical properties of an energy source, its CO_2 factor does not underlie time-dependent changes in most cases. This applies, for example, to natural gas (approx. 202 g/kWh) and heating oil (approx. 266 g/kWh).
Due to the Energiewende the composition of the so called electricity-mix in Germany and likewise its CO_2 factor are subject to steady changes. The past development and a prediction of this CO_2 factor is shown in figure 3. As the share of RE in the electricity mix has the highest impact on the CO_2 factor, the prediction is calculated with a linear function of this share. This function is based on past data points of the CO_2 factor and RE share in Germany. The future development of the RE share itself is also a linear function with the goals of the German government being the interpolation points. Obviously, the CO_2 factor will decrease in the next years due to an increasing RE share. Additionally, it is shown that by 2042 the CO_2 factor of electricity will be lower than the factor of gas.

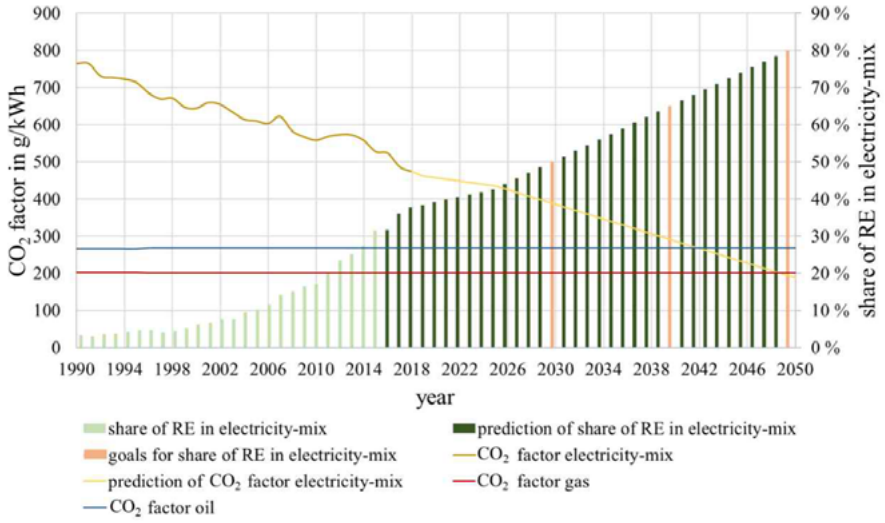

Fig. 3. Development of the CO_2 factor of the average German electricity mix in recent years and in the future. The CO_2 factors of gas and oil are given as benchmarks.

The presented methodology enables the simulation-based assessment of the two developed supply scenarios. As a result, we obtain the operating costs of the system which depend on the energy prices and the CO_2 factor respectively.

3.2.3. Key performance indicators

Based on the deduced energy prices and CO_2 factors the two scenarios are compared. In order to evaluate the systems from an ecological point of view on the one hand, the annual CO_2 emissions caused by the cooling and heating system are calculated. On the other hand, the system´s annuity is used to compare the profitability of the two scenarios. The annuity calculation bases on the German guideline VDI 2067 [26]. According to VDI 2067 the annuity consists of 3 cost types: the capital- (cap), demand- (dem), and operation-related costs (op). The capital-related costs are based on a market analysis on component investment costs. The demand-related costs derive from the simulation results and the electricity, gas as well as carbon prices of the respective year (s. chapter 3.2.1. and 3.2.2.). The operation-related costs are calculated as a fixed percentage of the capital-related costs which depend on the component type [26]. The annuity-based capital-related costs depend on the component service life. The components considered are the HP, the chiller, the CGB and the electrical heater.

Results and discussion

The resulting thermal demands of the FUBIC building are shown in figure 4. The heating power is mostly required in the cold season (September to April). At the start of the simulation, a considerable heat demand is detected as a result of the initialization process but not taken into account for the demand analysis.
Regarding the cooling demand, a base load of around 80 kW covered by the additional cooling can be identified throughout the entire period (additional cooling). This is caused by the cooling demand of the servers. The dynamic cooling demand, however, is primarily required for cooling and dehumidification of the outdoor air in the warm season (May to August).

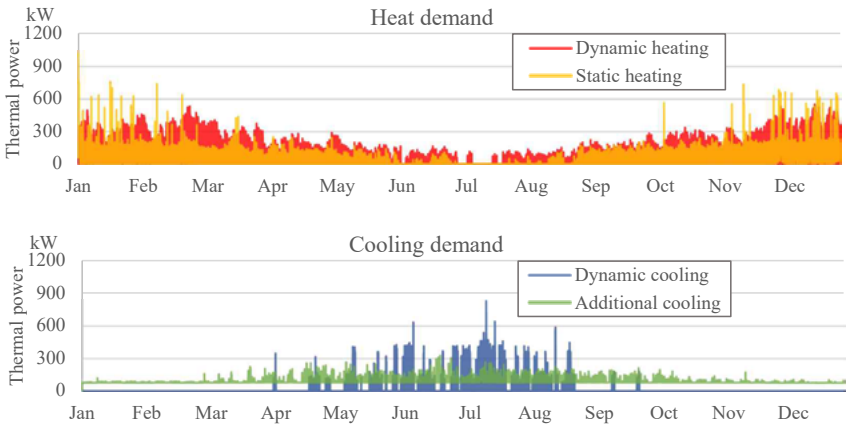

Fig. 4. Simulated heat (above) and cooling (below) demands of the FUBIC building using a TRY with a cold winter.

The presented thermal demands are the basis for the choice of a supply system. The simultaneous occurrence of heating and cooling demand e.g. impedes the use of a reversible HP. This is why a chiller has to be implemented in order to meet the cooling demand throughout the whole year. Nevertheless, a major advantage of HPs over CGBs is that while generating heat at a high temperature level at condenser site they extract heat at evaporator site at a lower temperature level at the same time. Usually, the extracted heat is taken from the ambient air or ground. However, as FUBIC´s heating and cooling demand occur simultaneously, the extracted heat can be used to partially cover the cooling demand. In this use case, the interaction is realized by a hydraulic connection via the ice storage. Here, the HP´s evaporator as well as the chiller´s evaporator are hydraulically connected via the ice storage. Hence, both the HP and the chiller can cover the cooling demand and synergy effects can be realized.

Based on the given energy demand structure, the two presented supply scenarios are assessed. Figure 5 depicts the simulation results. We compare the annual CO_2 emissions as well as the resulting negative annuity of the conventional (C) and the HP-based all-electric scenario (AE) in 2018 and in 2030. The annuity is negative in all scenarios as only costs are considered in this study. The biggest share in total costs are the demand-related costs. They make up 82 to 90 % of the annuity depending on the regarded scenario.
In 2018, the annuity of the conventional scenario is 35 % lower compared to the all-electric scenario. This effect is explained by lower gas prices per kWh in comparison to electricity prices in Germany as well as lower capital-related costs. CBGs´ capital-related costs are 50 % lower than those of HPs.
From an ecological point of view, the conventional scenario leads to an increase in CO_2 emissions of 2 % in 2018. However, this does not have any effect on the operating costs as carbon is not priced yet in Germany. Consequently, given the present boundary conditions, the all-electric system is not more profitable than the conventional scenario. The savings in CO_2 emissions are negligible as the current electricity mix in Germany is still mainly based on conventional energy sources.

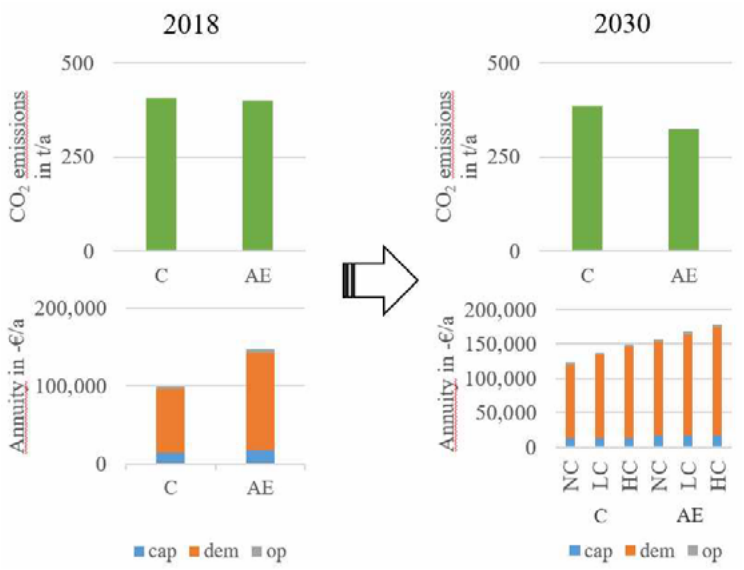

Fig. 5. Comparison of CO_2 emissions and annuity of the conventional and HP-based all-electric scenario for 2018 (left) and 2030 (right). In 2030, two scenarios for future CO_2 pricing are considered (NC = no costs; LC = low costs; HC = high costs). The system annuity is divided into the annual capital- (cap), demand- (dem) and operating-related (op) costs.

In 2030 however, the three introduced carbon pricing scenarios (NC, LC, HC) are taken into consideration which have an effect on the demand-related costs. As the share of REs in the German electricity mix increases, overall CO_2 emissions for both scenarios decrease. So even if the electricity consumption remains the same in 2030, overall emissions will be lower as the CO_2 factor of electricity decreases (s. figure 3). This effect is not applicable for the CO_2 emissions caused by the CGB. As explained in chapter 3.2.2., the CO_2 factor of gas depends on the chemical structure only and thus will remain constant in the future. As a result, the difference in CO_2 emissions in 2030 between the regarded scenarios increases to 18 %. Obviously, all-electric systems lead to higher CO_2 emission savings in the future. The reduction of CO_2 emissions simultaneously leads to decreased operating costs in 2030 due to carbon pricing.

Despite this effect, the system annuity of the conventional system is lower compared to the HP-based all-electric system in all of the regarded carbon pricing scenarios. This can be explained by the low percentage of carbon costs in the total demand-related costs. In the conventional scenario, costs for CO_2 emissions make up 11 and 19 % in the LC and HC scenario respectively. In the HP-based all-electric scenario, however, carbon costs only account for 8 and 14 % (LC and HC scenario respectively). Obviously, even though the carbon costs double in the HC scenario compared to the LC scenario, they do not influence the overall trend significantly.
For the given comparison, we calculate a break-even price for CO_2 of 559 €/t which results in equal annuity in the conventional and the all-electric scenario. Based on the researched forecasts for carbon pricing in 2030, we assume this to be unlikely.

Based on the results, regarding external boundary conditions the development of electricity and gas prices will more importantly influence the profitability of energy systems. In our use case, costs for gas and electricity make up 81 to 92 % of the demand-related costs. Even though the energy price´s influence decreases in the future as CO_2 prices will presumably be introduced, they still account for the biggest percentage in annuity. Nevertheless, in the conventional scenario, the demand-related costs increase by 80 % in the LC and by 99 % in the HC scenario. In the LC (HC) scenario, this increase is caused to an extent of 61 % (66 %) by the introduction of carbon pricing and to 39 % (34 %) by the rising gas prices.
Given the two regarded scenarios, the break-even gas price is 7.2 ct/kWh and the break-even electricity price is 11.1 ct/kWh.
Consequently, the HP-based all-electric scenario can be profitable only considering external boundary conditions in the future if either the gas price increases or the electricity price decreases in the large customer

segment. Another key factor is the system efficiency. HPs´ COP strongly depends on external influences such as the ambient temperature. In our case, a test reference year with a cold winter was chosen which decreases HP´s COP significantly. Advanced energy management systems can increase system efficiency by shifting HP´s operation e.g. to times of higher ambient temperatures. In addition, they enable the efficient coordination of heating rod and HP as we focus on a bivalent system.

4. Conclusions and Outlook

In this study, the assessment of a common conventional CGB-based and a HP-based all-electric energy supply scenario reveals that HP-based energy systems are not necessarily more profitable in the future. It becomes obvious that considering the regarded three cost types, the demand-related costs (CO_2 emissions costs and costs for electricity/gas) make up the highest percentage.
Irrespective of the carbon pricing scenario, the conventional scenario´s annuity is lower despite its higher emissions. The break-even price for CO_2 is 559 €/t which is assumed to be unrealistic. Hence, carbon pricing should be taken into consideration as it influences economic evaluation but it is not the main cost driver. In addition, we calculate the break-even gas price which is 7.2 ct/kWh and the break-even electricity price which is 11.1 ct/kWh for the large customer segment. Obviously, HP-based all-electric supply systems become more profitable once gas prices increase or electricity prices decrease.

Apart from that, we prove that conventional supply systems are not necessarily more suitable for non-residential buildings with complex energy demand structures. In the presented use case, heating and cooling demand occur simultaneously and are highly fluctuating. In this context, a HP-based energy system enables the exploitation of synergy effects between the heating and cooling systems. As HPs supply heat on condenser site while extracting heat on evaporator site, heating and cooling demand can be covered simultaneously. Nonetheless, a chiller and an electrical heater should be integrated to ensure secure energy supply throughout the whole year. This synergy effect cannot be accomplished by a conventional technology such as the CGB and needs an advanced energy management system for efficient operation.

All in all, profitability of HP-based all-electric systems mainly depends on the demand-related costs. Besides from external boundary conditions such as the given prices for electricity and gas, these costs can be decreased by high system efficiency. Intelligent operating strategies and an advanced energy management system support the profitability of HP-based all-electric systems. For the use case presented in this study, the focus should lie on the complex interaction of the heating and cooling system as they are coupled via an ice storage.

Abstract

IEA Annex 52 is the first long-term evaluation of large-scale heat pump systems. The Annex aims to survey and create a library of quality long-term measurements of GSHP system performance for commercial, institutional and multi-family buildings. The IEA Annex 52 also aims to provide a set of benchmarks for comparisons of such GSHP systems around the world.

The GSHP system in this report consists of two serial coupled heat pumps connected to a four-well aquifer and produces both heating and cooling. Total heating capacity is 0.3 MW. Due to a complex system with poor control system the Seasonal Performance Factor, SPF_{H4} is as low as 2.5 for the first year. Several control errors have been identified, including a potential short circuit of the serial DHW heat pump, erroneous operation of it for heating purpose and probable unnecessarily high condensation temperatures of the main heat pump.

The cooling system has high Seasonal Performance Factor, SPF_{C4} is 5.7 the first year. The system mainly uses free cooling, but performance decreases significantly at low load, possibly due to poor pump control. All system boundaries used are the IEA Annex 52 proposal

1. Introduction

1.1 Background

Measured long-term performance data for ground source heat pump systems serving commercial, institutional and multi-family buildings are rarely reported in the literature [1].

IEA HPT Annex 52 [2] is focused on long term performance measurement of GSHP systems serving commercial, institutional and multi-family buildings. Performance varies between different plants, and there is a need of more knowledge of the underlying causes. An important part of Annex 52 is to develop a methodology for measurement strategies and common system boundaries for larger heat pump systems. To achieve this 40 GSHP monitoring case are studied, covering a range of applications, located in seven countries.

It is important to make analyses based on a large amount of data and to identify key performance indicators when comparing different heat pumps.

More information with focus on factors that influence the performance is needed, identifying causes of low performance and unnecessary errors that can be avoided in the future. One example that causes low

performance of a GSHP system is for example dimensioning issues and suboptimal control systems. Reasons of low performance needs to become visible, in order to get knowledge and understanding.

The over-all performance of a GSHP system is affected by the performance of the source side ground circuit, as well as the heat pump unit performance and the load side circuit performance, including supplementary heating and cooling. The varying design and complexity of GSHP systems poses challenges in comparable performance factors.

Detailed long-term analyses of large GSHP systems for commercial, institutional and multifamily buildings are rare. This article describes one of the 40 GSHP monitoring case studies and focuses on evaluating an aquifer heat pump system. The system design is described, and Seasonal Performance Factors (SPF) are analyzed from 2 years of measurement data.

1.1.1 System boundaries

The IEA Annex 52 project has identified the need of and proposed system boundaries for large-scale GSHP system [3] based on the 2012 SEPEMO work [4]. The system boundaries are shown in Figure 1 below. The system boundaries used in this report are 0, 1 and 4. System boundary 0 is the aquifer system, including pumps and are discussed in chapter 3.1, system 1 is inside the heat pump cabinet and is estimated in chapter 3.2. The project has good measurements for system boundary 4, this is examined in chapter 3.3

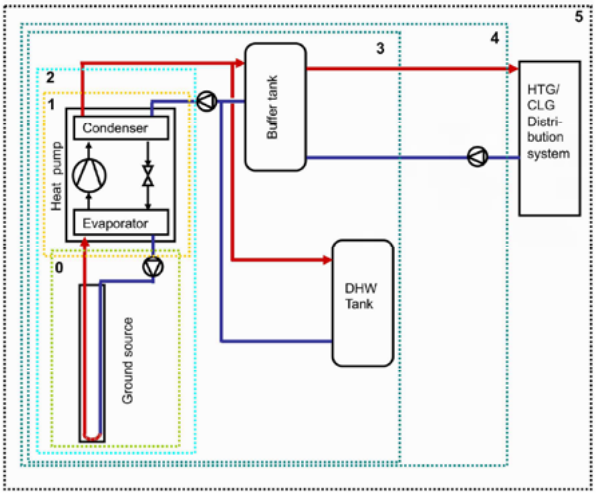

Figure 1 System boundaries according to the IEA Annex 52 project proposal (preliminary)

2 Methodology

One aim of the project is to aid the Annex 52 project in finding relevant system boundaries and test them. Another is to evaluate the performance of the GSHP system and find Performance Factors on the different system boundaries, whenever possible to calculate. This project has historic data from 2012-2014, data that previously was analyzed by RISE in an earlier, different project. No newer measurements have been used, but few changes have been made to the system until today, meaning the data is still valid for the system. The data set consist on electrical energy metering on each heat pump and summed on all circulation pumps and energy metering on aquifer, cooling, heating, subcooler heat and Domestic Hot Water, DHW, all on hourly basis. Temperatures were only measured at the four wells of the aquifer; no additional temperature data is available. Outdoor temperatures were taken from the SMHI [5] weather station at the nearby airport, corrected due to the site's much closer distance to a large lake and the elevation difference (140 m). The temperature was corrected +0,8°C, which was the annual temperature difference between the now closed city weather site and the still operating airport weather site, when comparing historic data. This approach is not perfect, as the variation is great and the temperature difference is slightly higher in the winter, but no better correction was found.

To understand the project a site visit was performed in October 2019.

2.1 Object

The heat pump and aquifer system serving an office building is located in southern Sweden, with undisturbed ground temperature of about 6 °C. One advantage offered by aquifers is the seasonal storage and another that different temperatures effectively could be stored separately, by using cold and warm wells. Essential for good performance is to optimise temperature-levels, for optimal use of the advantageous temperatures of aquifers. The system is described in Figure 2.

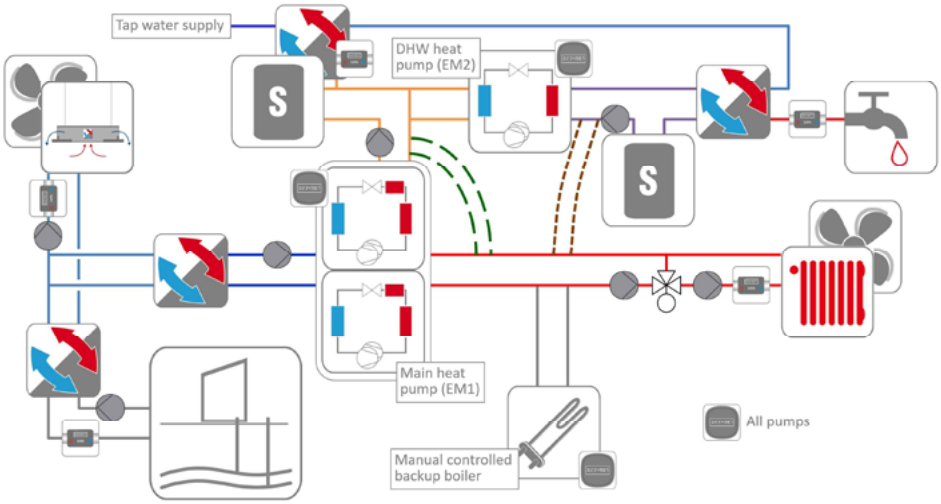

Figure 2 The heat pump and aquifer system. The Main heat pump (EM1) is using the aquifer as its heat source, while the DHW heat pump (EM2) is using the subcooler of the Main heat pump as its heat source. Dashed green and brown lines show possible heat flows, flows that are not intended according to the documentation, but are fully possible. All functionality is not described and especially the dashed lines are symbolically drawn. Pictograms by TU Braunschweig IGS, used with permission within the course of IEA HPT Annex 52

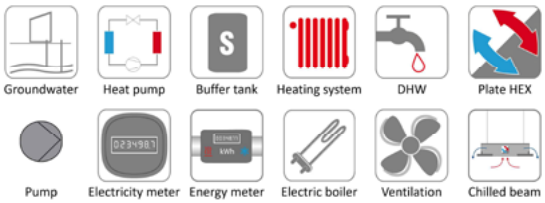

Figure 3 Explanation of pictograms used in Figure 2. Note that the heat pumps used are all dual compressor heat pumps and the main heat pump has subcooler heat exchangers. Pictograms by TU Braunschweig IGS, used with permission within the course of IEA HPT Annex 52

The main heat pump (EM1) has a heating capacity of about 300 kW and has four compressors in two refrigerant circuits, see Figure 2. The main heat pump (EM1) uses the aquifer as the heat source, while the Domestic Hot Water (DHW) heat pump uses the subcooler of the main heat pump as the heat source. The condenser of the main heat pump (EM1) heats the building, but with a change of two valves, the DHW heat pump can also heat the building. At times with to low heating capacity of the subcooler, the condensor has the possibility to heat the DHW as well, see dashed curved lines of Figure 2. The cooling system in the building is, via two heat exchangers, connected to the aquifer and the evaporator of the main heat pump. According to design documentation the main heat pump is used for heating, with temperature aid from the DHW heat pump during winter conditions with need of high heating system temperatures. The subcooler has a setpoint of 20°C, giving the DHW heat pump the possibility of high Coefficient of Performance (COP) when producing DHW.

The setpoints of the heating system is 35°C at an ambient temperature of 0°C and 50°C at dimensioning ambient winter temperature (-18°C), meaning a relatively low temperature system.

The strategy of the control system is to keep the condensing temperature of the Main heat pump (EM1) as low as possible. The main heat pump is used for heating only, the control system can not start it for cooling purpose, regardless of cooling demand. The cooling capacity is regulated by the flow from the aquifer, it has no dependency control wise to the heat pump. There is a need of cooling all year round. The cold wells of the aquifer are used at ambient temperatures above 12 °C, while the warm wells are used below 10 °C. There is no other hysteresis in changing the well of the aquifer, meaning the wells will be changed many days of the year. According to the site visit the wells are now (2019) changed manually instead.

2.2 Method

2.2.1 Calculation method

An estimated Performance Factor for heating on system boundary 1, PF_{H1}, for the main heat pump was calculated using the following formula:

$$PF_{H1} \approx \frac{Q_{Heating\ system} + Q_{Subcooler\ DHW} + Q_{DHW} - P_{EM2}}{P_{EM1}} \quad (1)$$

The only measurement done on the system boundary 1 for the main heat pump (EM1) is its own power consumption, P_{EM1}. The heat from the subcooler to preheat the DHW, $Q_{Subcooler\ DHW}$ and the heat to the heating system, $Q_{Heating\ system}$, are measured on system boundary 4. All energy supplied by the system originates from the main heat pump, the DHW heat pump is only increasing the temperatures. This means that the power consumption of the DHW heat pump, P_{EM2}, should be subtracted from the total heat supplied to calculate the performance factor of the main heat pump (EM1), PF_{H1}. As losses in the system are not stringently taken into account this can only be considered an estimate.

To be able to calculate Performance Factors on system boundary 4 the power consumption of the circulation pumps and the heat pump compressors must be allocated to the heating and the cooling side. This is done based on the heat and cooling produced for each hour of the year, according to the consensus in the Annex 52 project group. Power consumption allocated for cooling is calculated according to:

$$P_{Cooling\ ,allocated} = \left[\frac{Q_{Cooling}}{Q_{Cooling} + Q_{Heating\ system}}\right] \cdot \left(P_{EM1} + P_{pump\ ps}\right) \quad (2)$$

While power consumption allocated for heating is calculated according to:

$$P_{Heating\ ,allocated} = \left[\frac{Q_{Heating\ system}}{Q_{Cooling} + Q_{heating}}\right] \cdot \left(P_{EM1} + P_{pump\ ps}\right) + P_{EM2} \quad (3)$$

All circulation pumps are measured combined with one electrical energy meter; thus, the dedicated cooling or heating system pumps could not be allocated directly to their side of the system. All circulation pump power consumption is thus allocated according to the formulas, as this was the best possible method. The compressor power consumption of the EM2 is only used to produce DHW and does not cool the aquifer, all that power consumption is allocated to the heating side.

The calculation of the Performance Factor for heating on system boundary 4, PF_{H4}, is calculated with the following formula:

$$PF_{H4} = \frac{Q_{Heating\ system} + Q_{Subcooler\ DHW} + Q_{DHW}}{P_{Heating\ ,allocated}} \quad (4)$$

The calculation of the Performance Factor for cooling on system boundary 4, PF_{C4}, is calculated with the following formula:

$$PF_{C4} = \frac{Q_{Cooling}}{P_{Cooling\ ,allocated}} \quad (5)$$

In this paper performance factor SPF and DPF are used, were SPF is calculated over one year and DPF is calculated over 24 hours.

3 Results (Discussion)

The office building has a heating and cooling load according to Figure 4 below, the diagram has 24h average values due to low resolution of energy data.

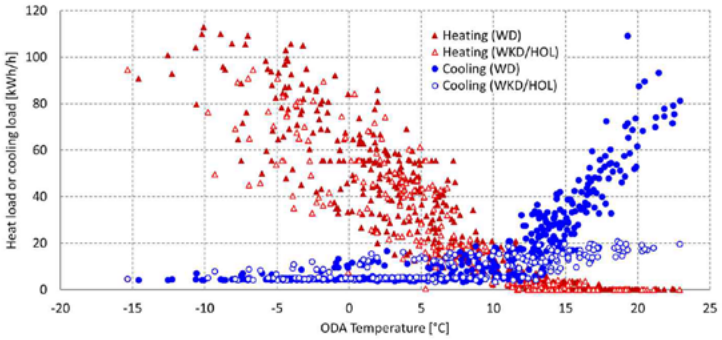

Figure 4 Heat and cooling load as a function of outdoor temperatures, average over 24h

As seen in Figure 4 the cooling load is highly dependent on the activities of the employees, during weekends and holidays the cooling load is a fraction of the workdays. The same is not seen in heating, but the variations at the same outdoor temperatures is very large. This could be due to the weather (sun/cloud) as the building has very few shadowing buildings surrounding it, but no data could verify this.

A thermal balance of the entire system was done, showing good results, see Figure 5. The negative side is sources of heat: The warm well of the aquifer, the compressors of the two heat pumps and the pumps in the system. The positive side is the sink of heat: The cold wells of the aquifer, the heating system and the Domestic Hot Water (DHW)

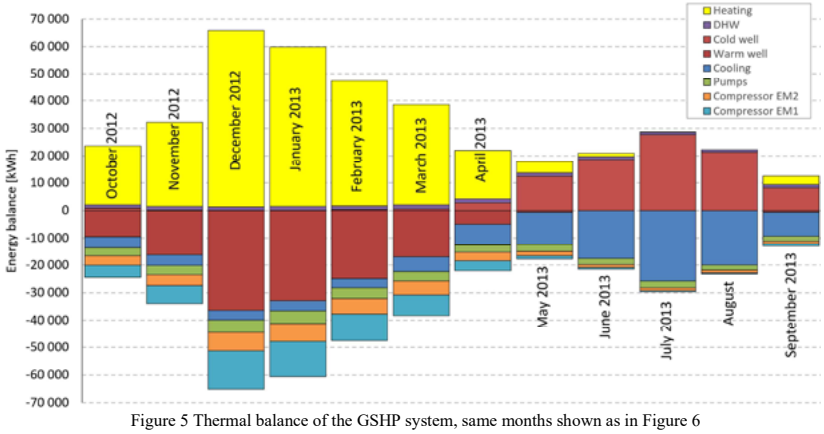

Figure 5 Thermal balance of the GSHP system, same months shown as in Figure 6

Total pump power consumption is high at low load conditions, especially compared to compressor power consumption.

3.1 IEA Annex 52 system boundary 0

The energy extracted and injected into the aquifer was measured, but as seen Figure 6, the resolution is low (100 kWh per pulse). As the pump of the aquifer were not measured separately no Performance Factor could be derived. In order to express the energy in kWh/h a 24-hour average value was calculated.

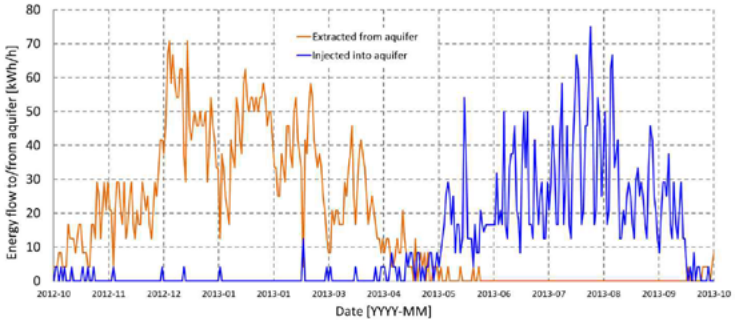

Figure 6 Heat extracted from and injected into the aquifer during one full year, mainly the first year in the time series, 24h average.

As seen in the diagram the pumps are at several occasions reversed, especially in April, May, September and October. The16th of February, a cold day, the pumps reverse, and the cold well was used, clearly seen in Figure 6. The control system didn't handle the aquifer optimal, as mention in chapter 2.1 the flow direction of the aquifer was change just according to ambient temperature, meaning the flow direction changes often in the spring and autumn. According to a site visit (2019) this was now handled manually instead.

3.2 IEA Annex 52 system Boundary 1

3.2.1 Heating

The measured data of the office building is not enough to calculate the performance on individual heat pump level but it could be estimated by subtracting the power consumption of the DHW heat pump (EM2) from the total heat produced, see equation 1 in chapter 2.2.1. The only function of the DHW heat pump is to increase the temperature from the main heat pump (EM1), EM2 has the main heat pump (EM1) as its only heat source, see Figure 2. The heating Seasonal Performance Factor on system boundary 1, SPF_{H1} is estimated to 4.2 the first year and 3.7 the second year, when the DHW heat pump has a better control strategy. See chapter 3.4 for further details and discussion.

3.3 IEA Annex 52 System Boundary 4

On system boundary 4, see to Figure 1 for definition, meaning the entire heat pump installation, excluding the heating, cooling and ventilation system of the building itself, all necessary data has been measured over the period September 2012 to August 2014. The allocation of pump and compressor power consumption is seen in equations 2 and 3, while the Performance Factors are calculated according to equations 4 and 5, all in chapter 2.2.1

3.3.1 Heating

The following diagram over Daily Performance Factor, DPF, see Figure 7, has been developed to fully understand the performance of a heat pump system at a glance. It directly shows that the heat pump system, with four compressors in the main heat pump (EM1) and a total heating capacity of 300 kW, is oversized and only uses one compressor in on/off mode most of the year. The maximum capacity used is 110 kW or 37 % of installed capacity, despite both winters during the period having low temperatures. It also directly shows that the heat pump system has almost the same performance factor regardless of heat output and that it at very low output mainly collapses in performance.

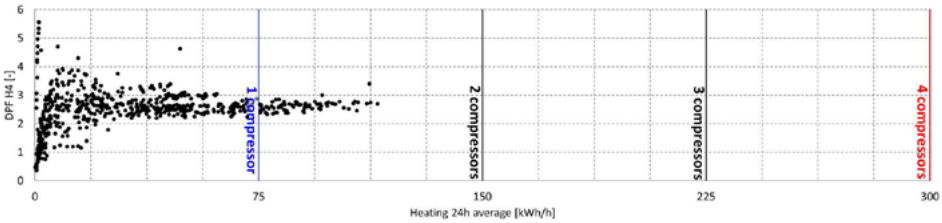

Figure 7 Overview of heat pump system performance factor H4 as a function of heat provided to the office building, blue line shows lowest capacity without ON/OFF operation, red line maximum heating capacity at highest heating system temperatures (winter)

The heat pump system has been compared to a state-of-the-art heat pump system produced by a major Swedish manufacturer in order to show the expected performance for a well-designed system, see Figure 8 below.

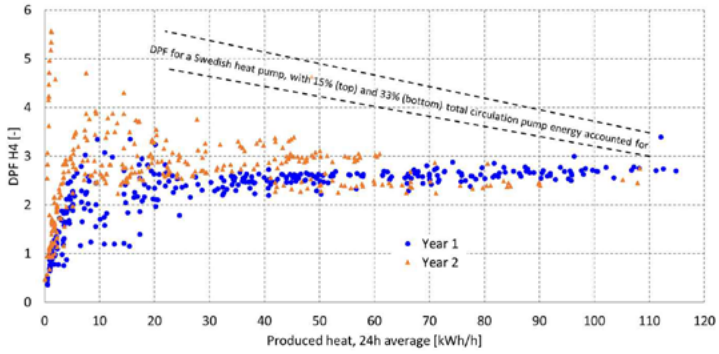

Figure 8 The heat pump system heating Daily Performance Factor, DPF_{H4}, compared a state-of-the-art heat pump system

The second year the control system is changed September 16th, 2013, it is noted as a significant decrease of power consumption of the DHW heat pump (EM2), but exact implication of the change is not known. This clearly increases performance in the medium output region, but the change is reversed between January 15th 2014 and March 4th 2014, giving poor performance in the high output region again. The change is likely done for the system to be able to deliver high enough temperature to the heating system, but that has not been possible to verify, as temperature data is not available.

The heat pump system is within the range of the total pump energy seen in Figure 8 above (dashed lines), 15-33 % of total compressor power consumption, above 40 kWh/h average produced heat. Below 40 kWh/h pump energy increases dramatically and is 90% at lowest heating load. This indicates a systematic error in the control of circulation pumps, which could not be explained by the nature of the aquifer system.

It is difficult to understand that the DPF_{H4} is below one (1) at low capacity, worse than resistive heating, but the control of the aquifer pumps is likely a major cause. The exaggerated pump power then gives very little heat to the brine system, as little is being needed, the losses in the water-cooled pumps basically heats the aquifer instead.

The Seasonal Performance Factor, SPF_{H4}, is calculated to 2.5 for the first year and due to the change in the control system the SPF_{H4} increased to 2.7 the second year. For a well-designed heat pump system, the SPF_{H4} is estimated to be able to reach 4 in the office building, around 50 % higher than the system used.

3.3.2 Cooling

The heat pump system is used to cool the building, it has a fairly constant equipment cooling load of 4-6 kWh/h clearly seen during heating season, but the main cooling load is during the short Swedish summer in June, July and August.

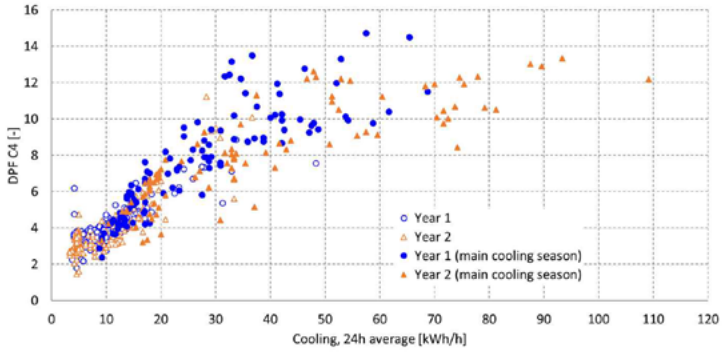

Figure 9 The heat pump system cooling Daily Performance Factor, DPF_{C4}

As seen in Figure 9 the Daily Performance Factor, DPF_{C4}, is high or very high during most of the year, but at low load the performance is in parity with conventional chiller performance. It is clear from the data that the cooling is mainly produced directly from the aquifer, by means of free cooling, else this high performance would be impossible. The low performance at low load is likely due to poor control of the aquifer pumps, note that the performance is low at low load even at the main cooling season, with very low heating demand, see filled markers in Figure 9. The performance is thus not mainly an effect of the method used for allocating the pump electricity. Note that the power consumption of the DHW heat pump (EM2) is not affecting the cooling Performance Factor, it is accounted on the heating side only, see chapter 2.2.1.

A well performing aquifer system, with good pump management at lower load, could perform at the top performance seen in Figure 9 most or all of the cooling season.

The Seasonal Performance Factor, SPF_{C4}, is calculated to 5.7 for the first year and slightly higher 5.8 the second year

3.4 The serial DHW heat pump (EM2)

The DHW heat pump (EM2) has the subcooler of the main heat pump (EM1) as its main heat source, it can not use the aquifer directly as a heat source. The DHW heat pump (EM2) is designed to mainly produce Domestic Hot Water, DHW, but can aid the main heat pump (EM1), only producing heat, to keep high enough temperature in the heating system. This means that the DHW heat pump (EM2), at DHW production, should use significantly less power than the main heat pump (EM1), else the thermal balance is not fulfilled. The reason being the subcooler of the main heat pump produce a fraction of the total condenser heat and varying depending on condensing temperature. The DHW heat pump has temperature wise good possibility to perform well, meaning with low power consumption.

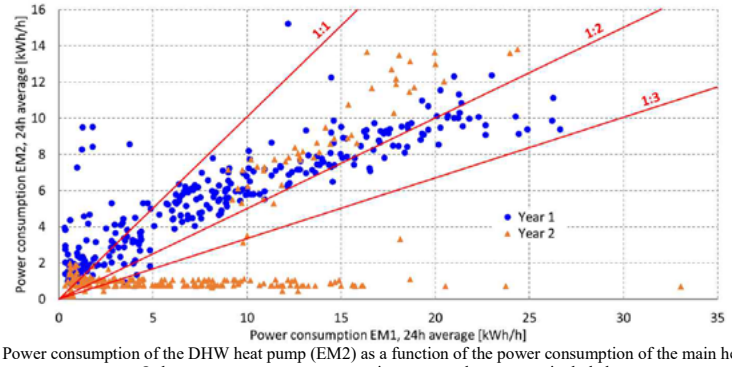

Figure 10 Power consumption of the DHW heat pump (EM2) as a function of the power consumption of the main heat pump (EM1). Only compressor power consumption measured, no pumps included.

Looking at the power consumption of the DHW heat pump (EM2) compared to the power consumption of the main heat pump, see Figure 10, the DHW heat pump (EM2) has too high power consumption. With all heat coming from the subcooler of the main heat pump, in a well-designed system, the ratio would be below 1:3 or at least 1:2 at all time, but mostly significantly lower. This is not the case, the main part of operation is at higher ratios, especially the first year and during the winter the second year. This likely means that the EM2 is heated by the condenser of EM1, causing the lower than necessary Performance Factor seen in Figure 7 and Figure 8. This is possible, circuit and control wise, see green long-dashed lines of Figure 2. Noteworthy is the extreme low ratio in the left side of Figure 10. It is identified that the condenser of the DHW heat pump (EM2) has the possibility, control and circuit wise, to heat its own evaporator, this possible short circuit could be the reason for this extreme operation, see green long-dashed lines in combination with brown dashed lines of Figure 2.

The line of orange rectangles along the x-axis in Figure 10 is likely when the EM2 is focused on producing DHW, meaning the control system is operating correctly. In Figure 11 the DHW production as a function of power consumption of the same heat pump is seen.

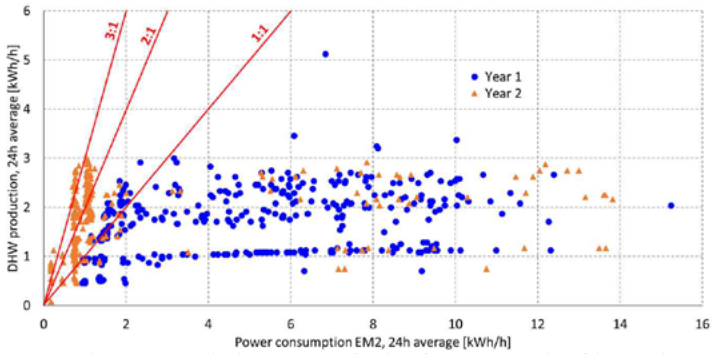

Figure 11 Domestic Hot Water production (DHW) as a function of power consumption of the DHW heat pump (EM2)

It is clear that the DHW heat pump (EM2) is operating in heating mode most of the first year and during the winter of the second year, as the ratio is well below 1:1, meaning extensive unaccounted losses in the DHW system as the only other possible solution. As far from full heating capacity of the main heat pump is not used, see Figure 7, this is not optimal. One possible answer to this poor operation could be found on the nameplate of the main heat pump, it is a chiller with a maximum return temperature of 45°C, meaning the DHW heat pump possibly must aid it at higher heating system temperatures.

According to the nameplate of the DHW heat pump it is also a chiller, not a dedicated heat pump. It has the same maximum return temperature (45°C), meaning about 5-10°C lower than what is necessary to handle legionella temperatures according to Swedish legislation. This means the DHW heat pump continuously is operating outside the envelope stated by the manufacturer, to handle the legionella temperatures, if it does. At the site visit the return DHW circulation temperature was 8°C lower than the legislative requirement, and the cover of the heat pump was removed for simple reset when the machine tripped a high pressure side alarm.

The building used about 15 MWh of DHW per year, including DHW circulation losses, a fraction of the heat supplied (210-290 MWh). The DHW heat pump (EM2) is largely oversized for the purpose, giving it low possibility to handle DHW temperatures accurately.

3.5 The three-port rotary control valve

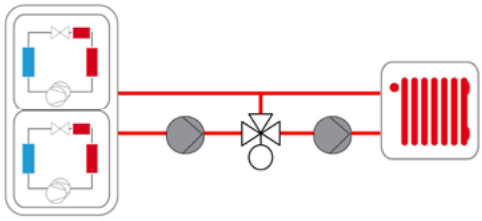

Figure 12 The three-port rotary control valve solution within the heating system, simplification of Figure 2. Pictograms by TU Braunschweig IGS, used with permission within the course of IEA HPT Annex 52

The three-port rotary control valve used between the main heat pump and the heating system, see Figure 12, leads to elevated temperature for the condenser, if not fully open at all time, causing lower Performance Factor, especially at lower load operation, seen in Figure 7 and Figure 8. At the site visit the temperature increased rapidly over the condenser, causing compressor stops after five minutes. Repeated short compressor operating time can cause premature compressor failures and will lead to transient losses [1] that, especially in combination with elevated condenser temperature, will lead to poor performance. The reason for the short compressor operating time is likely that the three-port rotary control valve decreases the working fluid volume for the heat pump to a minimum, by effectively cutting of the heating systems large fluid volume.

This three-port rotary control valve solution is not to be used in a well-designed heat pump system, except for decreasing temperatures to sub heating systems with lower operating temperatures.

3.6 Discussion

The heat pump solution underperforms according to expected performance for a heat pump with an aquifer heat source, heating a state-of-the-art Swedish office building with a low temperature heating system. The unnecessary complexity of the system, with a DHW heat pump in series with the main heat pump and unintuitive circuit layout means it is very difficult to understand when in operation. This was clearly stated by the personnel met at the site visit.

Due to lack of temperature data no relevant uncertainty analysis for the performance factors could be calculated

4 Conclusions

The GSHP solution in this report is complex, with a control system that most likely would need improvements to perform well. The 0.3 MW total heating capacity is almost three-fold the maximum heating demand seen during the two-year measurement period 2012-2014, despite having very cold winter days these years. This means only two of the four compressors in the main heat pump will be used, most of the year there is surplus heating capacity with only one compressor.

The DHW heat pump is seen operating many hours in heating mode, despite its purpose is for DHW. With an unknown change to the control system the second year, made twice, the DHW heat pump heated the heating system significantly less, meaning an overall higher performance factor for the system. Due to system design the DHW heat pump has the ability to heat its own evaporator, it has been identified that it likely does that during the first year. Moreover, the DHW was at times heated by the condenser of the main heat pump, causing lower performance factor, instead of the intention of using the subcooler heat.

A three-port rotary control valve is restricting the flow to the heating system and thus likely elevating the condensing temperatures of the main heat pump. This causes lower performance factors, but also leads to shorter than necessary run time for the compressors, being observed during the site visit. This solution should be avoided in heat pump heating systems. The Seasonal Performance Factor, SPF_{H4} is as low as 2.5 the first year and 2.7 the second year.

The compressors of the heat pump system are not controlled to run actively at cooling operation, the aquifer is then passively supplying the cooling to the building. This means a good potential for high performance factors, but it deteriorated with lower load, suggesting pump management is poor. The pump power

consumption is significantly higher than needed at low cooling demand. The cooling system has regardless high Seasonal Performance Factor, SPF_{C4} was 5.7 the first year and 5.8 the second year.

No temperature data was available; thus no scientifically valid uncertainty analysis was possible to perform. All system boundaries used in the report are the IEA Annex 52 proposal.

Abstract

The need for retrofitting of residential buildings with energy efficient solutions requires for the development of a wide range of solutions, suitable for different climates and buildings. In the present paper, a concept based on a gas-driven sorption heat pump using geothermal source for evaporation is presented. A dynamic luped-parameter model was implemented in Dymola and used to verify the flexibility of the system in terms of response to variable load and comfort conditions. The outcomes of the activity will be used to propose an improved design of the system.

1. Introduction

The building heating and cooling sector is accounting for a relevant amount of primary energy consumption in Europe. So far, according to EU, less than 20% of heating and cooling is provided by renewable sources. Heat pumps represent an innovative solution to increase the share of renewables at the building scale, thus participating to the decarbonisation of the heating and cooling sector [1]. In order to make them suitable for different climates, keeping high performance in terms of COP/EER also in severe conditions, the exploitation of geothermal energy as ambient heat source/sink is considered of great interest [2]. In particular, advantages of geothermal heat pumps include high efficiencies (COPs of ground source heat pumps are in the range 3–5 while COPs of air source heat pumps are in the range 2.3–3.5) and low operating costs [2]. The application of ground-source heat pumps was investigated and proven in a wide variety of climates, including European Mediterranean and Continental [3,4], Turkey [5], Iran [6] and China [7], as well as in different building typologies, i.e. residential and commercial [4,8]. However, the exploitability of this resource in the built environment, for retrofitting applications, becomes quite challenging due to both, technical and regulatory constraints that limit the drilling procedures for the ground source heat exchangers (GSHEX) installation.

With this mind, the EU funded GEOFIT [9] project aims at the deployment of innovative geothermal heat pump solutions for retrofitting applications. Particularly, an innovative hybrid geothermal heat pump will be developed, tested and installed in two demo sites. Different hybrid geothermal heat pumps have been proposed, such as a solar-geothermal heat pump able to exploit alternatively the heat from vacuum collectors or the ground [10] or a hybrid configuration with the cooling tower and the ground loops connected together [11,12].

Instead, in the present work, the hybrid solution proposed consists of a hybrid gas-driven hybrid adsorption/electric heat pump Indeed, this combination of thermally and electrically driven HP, despite the lower thermal COP compared to an electrical vapour compression chiller, can be efficiently operated with a smaller size GSHEX. This will make the heat pump more suitable for applications with reduced space availability.

In order to assess the feasibility of such a hybrid solution, a detailed dynamic model was developed in Dymola environment. Adsorption heat pump and gas boiler were modelled by means of TIL Media Library, TIL Suite and self-developed components to match the specific characteristics of the hybrid unit developed. Particular focus was put on the control strategy for enhancing the comfort level achievable by the retrofit of existing systems with the hybrid solution proposed. A first prototype will be developed by Fahrenheit GmbH which will be tested at the CNR ITAE lab subsequently.

2. The GEOFIT sorption solution

The core of the hybrid sorption heat pump developed within GEOFIT is a gas-driven sorption heat pump, whose main components are shown in Figure 1. It is based on the two-modules layout from Fahrenheit GmbH commercial system. Each module consists of an adsorber/desorber and an evaporator/condenser. The desorber is connected through the HTF circuit to the gas boiler that allows the regeneration of the sorption material. At the same time, through the vacuum circuit, the refrigerant flows from the desorber to the condenser, that supplies heat at the temperature level requested for space heating. The adsorber is connected in parallel to the condenser through the HTF circuit. The vacuum circuit allows the flow of the refrigerant from the evaporator to the adsorber. The ground heat exchanger allows the use of the soil as heat source for evaporation. The useful effect delivered to the user is represented by the adsorption heat and condensation heat.

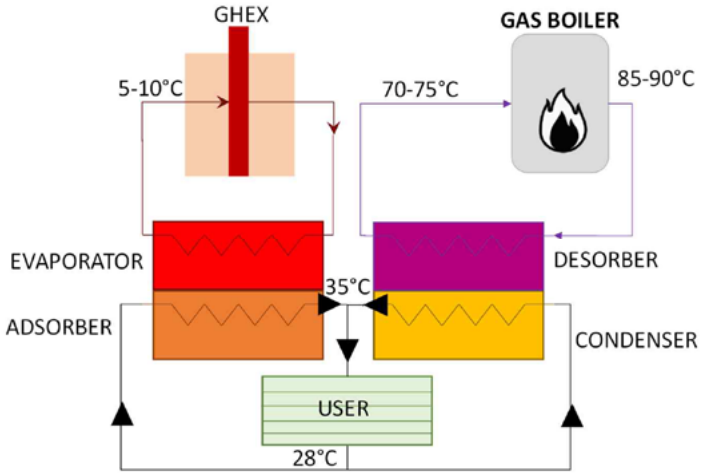

Figure 1: Main layout and thermal levels for GEOFIT hybrid gas-driven heat pump.

The main advantages in the utilization of such thermally-driven heat pumps as retrofitting solutions lies in the possibility of using shallow GSHEXs with a superficial area significantly lower than that needed when the heating system is represented by a vapour compression electrically-driven heat pump.

A schematic of a possible integration of the proposed gas-driven hybrid heat pump is depicted in Figure 2. It is clear that the gas boiler is exploited both to drive the desorption process and to provide domestic hot water (DHW) to the user. The typical distribution system used to increase the heat pump efficiency is a floor heating system, while GHEX is used to provide heat of evaporation in winter and to dump heat of condensation in summer.

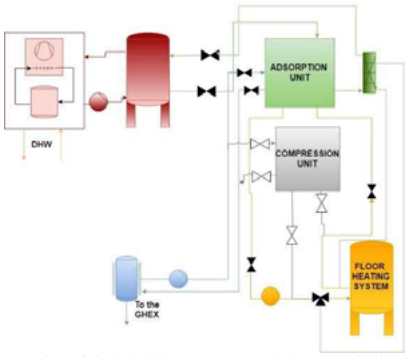

Figure 2: Schematic of the integration of the hybrid heat pump coupled to a gas boiler and the space heating system.

3. The modelling approach

The modelling approach used is schematically shown in Figure 3: Modelica language and Dymola commercial software were chosen as simulation environment. The main reasons for such a choice are the possibility of creating acausal and easily reusable models that, thanks to the FMU functionality of Dymola, can be easily exchanged and integrated in other simulation environments[13,14]. In order to model the refrigerant, the Heat Transfer Fluid (HTF) and the main components of the system, the commercial libraries included in TIL Suite were employed. Correspondently, the same structure as for components already included in the libraries, based on a cell level and a component level was employed also for the self-developed models. In particular, standard models based on liquid cells were employed to model the heat exchanger and heat transfer correlations, whereas self-developed model were used for the sorption equilibrium and the vapour/liquid control volume of the evaporator/condenser. The gas boiler was modelled considering a constant thermal power and an efficiency variable with part load and return temperature. All the components are properly managed thanks to specifically developed controls. The main equations of the model are presented in Table 1, while for a more detailed description of the Dymola model for the sorption unit, the reader is referred to [15].

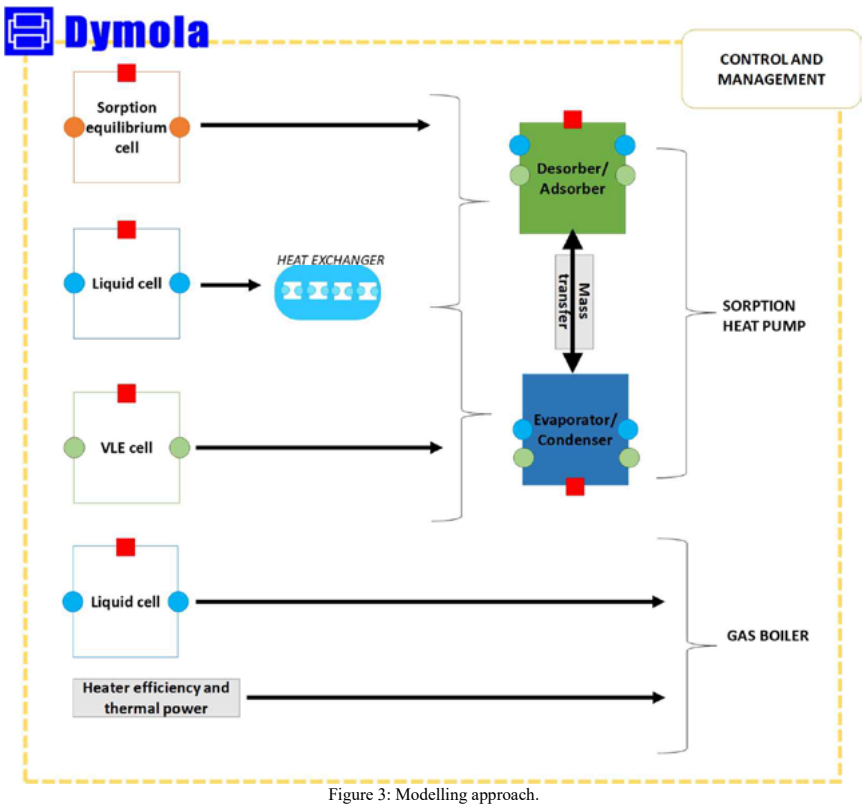

Figure 3: Modelling approach.

4. System control and management

In order to give indications on the best management strategy for the hybrid heat pumps and its integration in retrofitted systems, different controls were implemented and evaluated. In particular, three possible options for controlling the system were considered:

a. Variable flow rate of the pumps according to part load;
b. Step variation of the cycle time of the adsorption unit using the load requested by the user as target variable;
c. Step variation of the cycle time of the adsorption unit using the temperature in the user circuit as target variable.

The models for such components were developed in Dymola using existing components from Modelica Standard Library.

Since the main goal for the system under the GEOFIT activity here presented is the retrofitting of existing heating systems in different climates, two key elements play a particularly significant role:

1. the design of components, that must be as compact as possible;
2. the possibility of ensuring the same level of comfort and a flexible operation, in terms of adaptivity to the load of the building.

The first goal can be achieved thanks to the use of zeolite/water working pair, applying the patented crystallization technique developed by Fahrenheit [16], that has a significant higher power density when compared to standard silica gel/water systems on the market [17].

Instead, the second goal was the focus of the numerical activity here presented. Two key aspects were evaluated: the possibility of delivering a constant temperature to the user under different climatic conditions and the proper management of the sorption unit to be adaptable to user load.

Table 1: List of main equations used for the model implementation.

Component		Equation	
Adsorber	Mass balance sorbent cell	$\dot{m}_{ref} = \dot{m}_{evap} + \dot{m}_{cond}$	(1)
	Energy balance sorbent cell	$\left(m_{sorb}\, c_{p_{sorb}} + w \cdot m_{sorb}\, c_{p_{ref}}\right)\frac{dT_{sorb}}{dt} = \dot{Q}_{fbw} + \dot{m}_{ref}\, h_{ads} - m_{sorb}\, c_{p_{sorb}}\, T_{sorb}\, \frac{dw}{dt}$	(2)
	Mass balance adsorber HEX	$0 = \dot{m}_{in} + \dot{m}_{out}$	(3)
	Energy balance adsorber HEX	$m_{fluid}\, c_{p_{fluid}}\frac{dT_{fluid}}{dt} = \dot{m}_{fluid}\, c_{p_{fluid}}\left(T_{fluid_{in}} - T_{fluid_{out}}\right) + \dot{Q}_{fbw}$	(4)
	Heat transfer sorbent/HEX	$\dot{Q}_{fbw} = (\alpha S)_{ads}\,(T_{sorb} - T_{fluid})$	(5)
	Sorption equilibrium	$w = w_0 \exp(-bA)$	(6)
		$A = -RT_{sorb} \log\frac{p_{ads}}{p_{sat}}$	(7)
Vapor Liquid Equilibrium (VLE) volume evaporator/ condenser	Mass balance	$\frac{dm}{dt} = \dot{m}_v + \dot{m}_l$	(8)
	Energy balance	$\frac{dU}{dt} = \dot{H}_v + \dot{H}_l + Q_{fbw}$	(9)
	Mass balance HEX	$0 = \dot{m}_{in} + \dot{m}_{out}$	(10)
	Energy balance HEX	$m_{fluid}\, c_{p_{fluid}}\frac{dT_{fluid}}{dt} = \dot{m}_{fluid}\, c_{p_{fluid}}\left(T_{fluid_{in}} - T_{fluid_{out}}\right) + \dot{Q}_{fbw}$	(11)
	Heat transfer refrigerant/HEX	$\dot{Q}_{fbw} = (\alpha S)_{evap/cond}\,(T_{VLE} - T_{HEX})$	(12)
	Additional equations	$p_{VLE} = p_{sat}\,(T_{VLE})$	(13)
Mass transfer	Mass balance	$\dot{m}_{ref} = \dot{m}_{in} + \dot{m}_{out}$	(14)
	Linear Driving Force	$\dot{m}_{ref} = m_{sorb}\,\frac{dw}{dt} = m_{sorb}\,\beta(w_{eq} - w)$	(15)
	Mass transfer coefficient	$\beta = \frac{15D}{r_{sorb}^2}$	(16)
Gas boiler	Thermal power output	$\dot{Q}_{fbw} = \dot{Q}_{nominal}\,\eta$	(17)
	Efficiency	$\eta = a * T_{w_{in}} + b * T_{w_{in}}{}^2 + c * T_{w_{in}}{}^3 + d * T_{w_{in}}{}^4 - e * \mathrm{PL} + f * \left(T_{w_{in}} * \mathrm{PL}\right) - g * \left(T_{w_{in}}{}^2 * \mathrm{PL}\right) + h$	(18)

5. Results

To evaluate the adaptability of the heat pump to a variable user load, a signal with changing load (between 4 kW and 8 kW) was used, aiming at simulating a variable user demand. The first approach, based on varying the heat transfer fluid flow rate, resulted not robust enough to let the adsorption machine being properly operated. Accordingly, the control strategy based on the variation of adsorption cycle time as a function of user load was implemented. To this aim, a multi-switch control was used, able to switch between different cycle periods as a function of the expected requested power. Clearly, the higher is the power demand the lower is the cycle time, in order to enhance the average heating capacity provided by the adsorption module, whose behaviour is intrinsically discontinuous due to the physics of the adsorption process[18]. This control is not based on a linear variation of the cycle time, but rather a step variation is investigated. To demonstrate the effect of the variable cycle time on the average power, in Figure 4 the output power provided by the adsorption heat pump is showed. The adsorption/desorption cycle time variation is clearly visible. The average heating power provided increases from about 3 kW at 800 s cycle time up to 5 kW for 200 s cycle time.

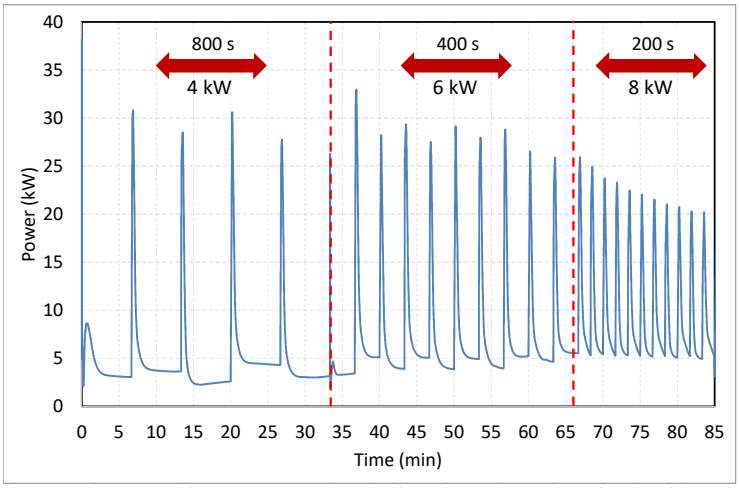

Figure 4: Adsorption machine output power (adsorption/desorption cycle control as a function of the load)

Analysing the temperature of water provided to the user Figure 5) it could be noted that the control works properly when the load is 3 kW and the cycle time is 800 s. Differently, it tends to deviate from the target when the power increases, most probably because the cycle time is reduced too much. This means that, to achieve a proper management, a continuous variation of cycle time according to the measured values of the temperature at each sampling time is needed.

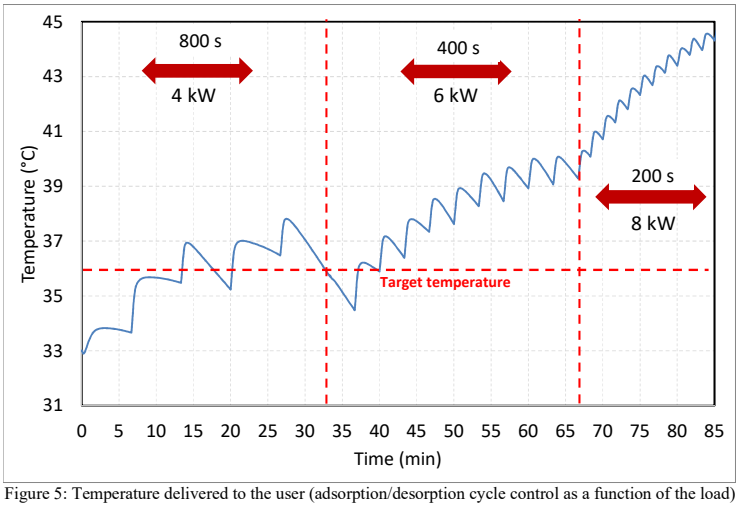

Figure 5: Temperature delivered to the user (adsorption/desorption cycle control as a function of the load)

From such results, it is clear that, to get comfort conditions, it is necessary to use a control that allows a finer tuning in terms of temperatures delivered to the user. Therefore, a second control was developed, that manages in real time the adsorption/desorption cycle time as a function of the temperature delivered to the user. The control compares the signal coming from the T_{user} sensor with the set point (e.g. 35°C); if the measured temperature is lower than the set point, this means that the heating load is higher than the one produced by the adsorption machine, therefore the adsorption/desorption cycle time is reduced. If the measured temperature is higher, than the cycle time is increased, because the requested heating power is decreasing. Compared to the previous case, the cycle time is not imposed a priori, i.e. there is not a predetermined cycle time as a function of the temperature, but rather a user-defined Δt is used for following the user heating demand:

- When the feedback signal $T_{user,measured}$-$T_{user,set}$ is <0, the cycle time is reduced of an amount Δt;

- When the feedback signal $T_{user,measured}$-$T_{user,set}$ is >0, the cycle time is increased of an amount Δt;

Threshold values for minimum and maximum cycle time are imposed as well, to avoid inefficient operation of the unit. Figure 6 reports the power delivered by the adsorption machine for a 30 min operation at variable load with the implemented control. The feedback loop operates changing the cycle time with a Δt of 50 s. The feedback signal is reported in Figure 6 as well. It is possible to notice that the average power output from the sorption heat pump during an overall can be adjusted with this strategy. Furthermore, as confirmed by Figure 7, the proposed approach is able to keep the temperature level delivered to the user close to the target, thus properly operating the adsorption machine. It will be then proposed for the implementation in the prototype to be tested in the lab and then in the demo sites for the GEOFIT project.

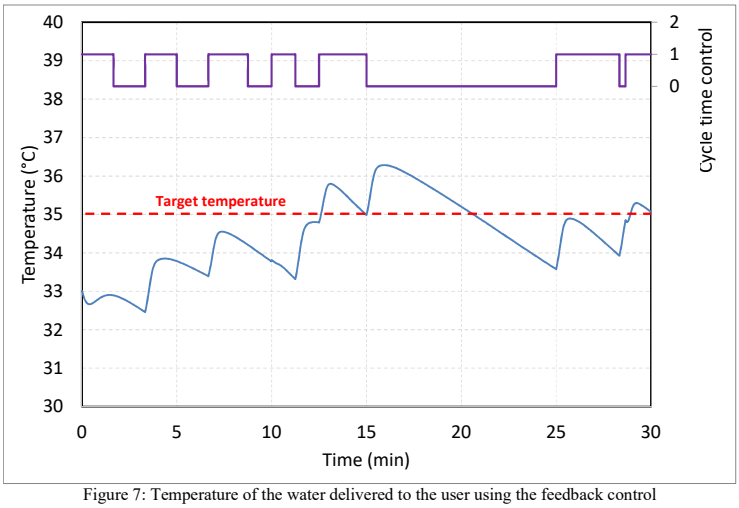

Figure 7: Temperature of the water delivered to the user using the feedback control

6. Conclusions and future activities

The present paper presents the modelling activity of a novel hybrid sorption concept for retrofitting of heating systems in existing buildings, using a gas-driven sorption heat pump and a ground-source HEX as heat

source for evaporation. A dynamic model in Dymola was implemented, including a black-box model of the gas boiler, as well as a detailed adsorption module which comprises heat and mass transfer mode as well as equilibrium data for the given zeolite/water working pair. Particular focus was put on control and management strategies for the system, evaluating the flexibility of the heat pump with variable load and temperature conditions. The best control strategy identified is based on the continuous variation of cycle time according to a feedback control on delivered temperature to the user. As shown in Figure 8, the next steps will include model validation thanks to results from laboratory activity, as well as the definition of an improved design and its adaptation to the pilot sites for the project.

Heat pump noise – Seasonal averaging and operation dependence

Ola Gustafsson[a], Henrik Hellgren[a], Caroline Haglund Stignor[a]

[a]RISE Research Institutes of Sweden, Box 857, Borås 50115, Sweden

Abstract

This study has developed an improved method for evaluation and new indicators for declaration of noise from heat pumps. The improvements may lead to better informed consumers and an Energy Labeling scheme that better reflect the actual use of the heat pump and thereby deployment of quieter and less disturbing heat pumps. And as a consequence, larger acceptance of this efficient technology.
17 heat pumps of the types; air/water and brine/water were evaluated through field and laboratory measurements to provided information of how the noise from heat pumps varies over time and at different operating conditions.
The results indicate that noise measurements should be performed at the operating conditions representing an outdoor temperature of 2°C according to the European standard EN14825 (alternatively 7°C for air/water heat pumps, but with the capacity of 2°C). The reason is that this operating condition is the one that best coincide with the seasonal averaged noise. In addition, the maximal noise of the heat pump should be measured to show the customer how the noise can vary and to be able to compare the noise from an on/off heat pump and an inverter-controlled heat pump.

Keywords: Heat pump; noise; sound power level; seasonal noise; SCOP; evaluation method;

1. Introduction

1.1. Background

Traditionally heat pumps have been controlled with fixed capacity (on/off), but variable capacity heat pumps (inverter) have become more common the latest years. The outcome is that the sound level varies with the change in capacity. Bessac showed that one single operating condition is not enough to evaluate the noise performance of variable capacity heat pump [1]. Gustafsson et al showed that the part load operation of a variable capacity air source heat pump has an important impact on the sound power level [2]. This project previously suggested that it might be necessary to use separate evaluation methods for air/water and brine/water, depending on the noise characteristics experienced in the field [3]. And it is of greatest importance, to identify methods that provide accurate and relevant information to customer and that also pushes the manufacturers to develop products that generates low noise in real operation. However, the aim should be to develop methods that ensure cost effective testing for the manufactures.

For labeling purposes, the sound power level is determined at one operating condition. In the current testing standard EN12102 [4], the heating capacity during the sound test should be within ± 5% according to test point C in EN14825 [5] (method for calculating SCOP). Still the sound power level is determined at a capacity in the lower region of the possible operating range. According to EN14825, test point C corresponds to 35% capacity at 7°C.

In the long-term studies should focus on investigations to identify the correlation of the SCOP and a seasonal noise average. Seasonal averaging of noise is however not that straight forward. It might be difficult to

understand what the average noise level would mean to the consumer, but a way to use it to identify to the best operating condition to perform the standard measurements.

1.2. Scope

The scope of this study was to:

- Define the noise of heat pumps at different state of operation
- Develop and suggest an improved method of evaluation and new indicators for declaration of noise from heat pumps. This would give consumers better guidance and also support the manufacturers in their product development.

1.3. Delimitations

The scope of this study has not been to identify methods that reduces the noise from a heat pump. The focus has instead been on how to develop methods used to measure and evaluate the noise.

2. Methodology

This paper presents results from 17 heat pumps that were investigated in laboratory measurements. The heat pumps included in the study were both on/off- and inverter-controlled heat pumps of type air/water (only monobloc type) and brine/water in heating capacity range up to 18kW. The sound power level was determined at several operating conditions according to standards EN12102, ISO3747 [6] and EN14825. The forward flow temperature was altered and for the heat pump with inverter-controlled compressors the sound power level of different compressor frequency was evaluated, ranging from minimum to maximum frequency. The sound power level depending on heating capacity and part load was compared for both heat pump types, to identify a general noise behavior. From this data a calculation method of seasonal noise averaging was proposed, to identify the most realistic operating condition for standard measurements. The proposed calculation method for seasonal noise average is generally using the same reasoning as the SCOP calculation method defined in EN14825. The noise level is assumed to vary linearly with the heating capacity of the heat pump. The lowest part load assumed to be 30% and the heat pump covers the maximum heating load down to -10°C. A bin-method with bins according to the “average climate” was used to provide a weighting factor for each outdoor condition. Hence, the seasonal noise average, denoted weighted sound power level was defined as the log-based average of the sound power level in each bin multiplied with the corresponding bin hours

The weighted sound power level combined with the linearized sound power level (describing the variation of sound power level depending on the outdoor temperature) gives an indication to what outdoor temperature and its correlated sound power level that best represent seasonal averaged noise. The method is showed graphically in figure 3.

3. Results and discussion

The sound power level for air-source heat pumps is generally higher than for ground source, depending on the fan noise. Hence, the control of the fan is an important factor for the generated noise of an air/water heat pump. For inverter heat pumps the A-weighted sound power level in relation to heating capacity is shown in figure 1, for both air/water and brine/water. The variation in sound power level has a strong connection to the heating capacity. Hence, the sound power level varies more for an inverter heat pump compared to an on/off heat pump. The fan noise of an air/water heat pump adds between 10 to 15 dBA for a corresponding heating capacity.

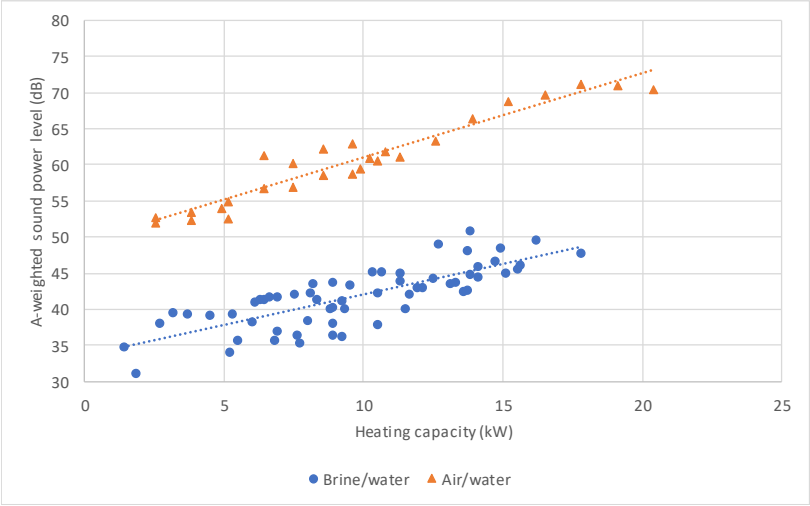

Figure 1. The A-weighted sound power level depending on the heating capacity for both air/water and brine/water. Results from several different heat pumps of each type is shown. The sound power level of air/water heat pumps is up to 15 dBA higher for a corresponding heating capacity of brine/water heat pumps.

The observed variation in sound power level for inverter brine/water heat pumps have both a part load and forward flow temperature effect, shown in figure 2. The part load effect is around 10 dBA between the lowest and highest part load and the flow temperature (condensation temperature) effect around 2 to 3 dBA. The observed increment of the sound power level for an on/off heat pump is around 2 to 3 dBA, when increasing the forward flow temperature from 35 to 55 °C. Hence, the forward flow temperature effect is in the same vicinity for both on/off and inverter heat pumps.

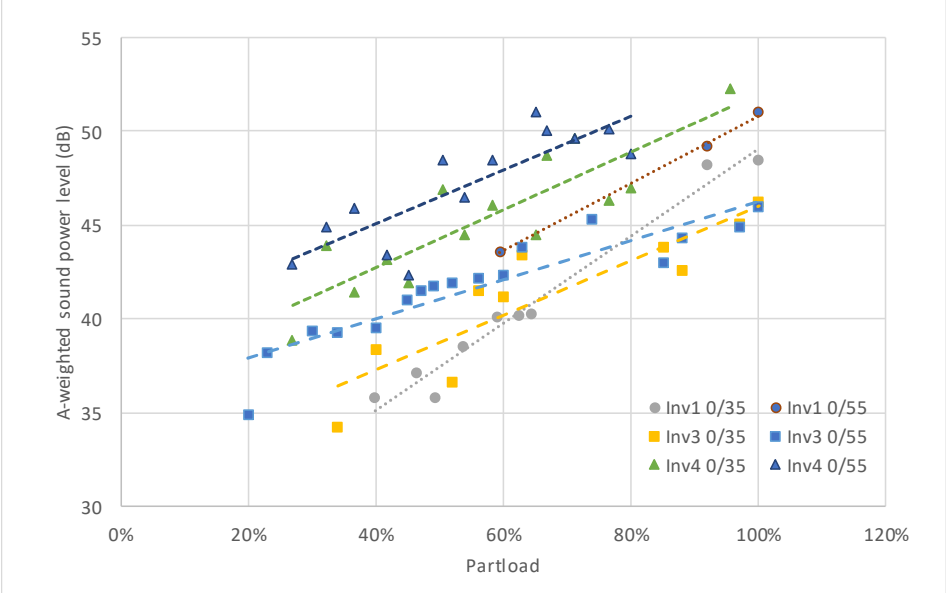

Figure 2. The A-weighted sound power level of inverter 3 brine/water heat pumps depending on part load. There is a part load effect of around 10 dBA and outlet temperature effect of around 2 to 3 dBA.

For labeling purposes, as an alternative to test the sound power level at a multitude of different operation conditions, it would be beneficial to identify a part load condition that correspond to a seasonal noise average. Also, due to the wide range in the observed sound power levels, the maximum sound power level should be stated to inform the consumer about the possible noise variation even though the maximum sound power level might not occur very often depending on the dimensioning of the heat pump. Still, a combination of both seasonal noise average and maximum sound power level would allow for better comparison between different heat pump and especially for differences between inverter and on/off heat pumps.

Based on the assumptions previously described, the lowest part load is set to 30% and given a value of 50 dBA and the maximum heating load at -10 °C is given a value 62 dBA. For the purpose of example is shown in figure 3. The total sound power level range is assumed to be 12 dBA, to account for both the observed part load and outlet temperature effect. To calculate the seasonal noise average, the sound power level is converted to energy levels before multiplying it with the bin hours for average climate according to EN14825. The calculated weighted sound power level (seasonal noise average) in figure 3 takes a value of 53 dBA. The lines of the theoretical and weighted sound power level intersect at a temperature of 2.5°C. Hence, determination of sound power level at test point B 2°C correspond quite well to the seasonal noise average.

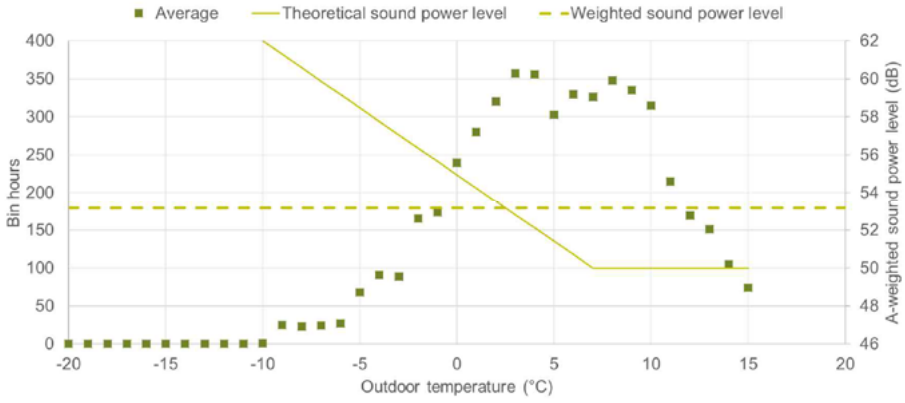

Figure 3. Basis of the calculation method for seasonal noise averaging. The average corresponding the bin hours at each temperature is multiplied with the energy levels of the theoretical sound power level to obtain the weighted sound power level (seasonal noise average). The lines of the weighted sound power level and the theoretical sound power level intersect at 2.5°C.

4. Conclusion

The test condition corresponding best to the calculated seasonal noise average is test point B according to EN14825. To avoid problems with defrosting of air-source heat pumps the determination of sound power level should be performed at 7 °C, but with the capacity of test point B. Determination of maximum sound power level for ground source should be performed at B0/W55 and maximum compressor speed. For air-source heat pumps the determination should be made at test point B and but with maximum compressor speed.

CHP-Waste Heat Utilization with Small-scaled Absorption-Resorption Chillers for Supermarket Refrigeration

O Ziegler[a*], U Hesse[a] and C Thomas[a]

[a]Technische Universität Dresden, Bitzer Chair of Refrigeration, Cryogenics and Compressor Technology, 01062, Dresden, Germany

Abstract

The IEA says in its World Energy Outlook 2012, "a key constraint on the deployment of CHP is the difficulty of distributing heat over long distances. Because of this, CHP units must be located close to demand, potentially increasing costs."[1] In the trade and commerce sector, especially the food retailing, it seems to be unfeasible to utilize the entire amount of heat while there is a permanent demand on electric energy provided by a CHP plant. In summer or transitional months there is nearly no demand on heating but the need for air conditioning (A/C) is increasing while the demand for normal refrigeration is almost constant throughout the year. A possible solution to the waste heat problem is the installation of a sorption refrigeration system to compensate the opposite demand for heating and cooling capacity providing both temperature levels of normal cooling and air conditioning. Especially for those applications small-scaled sorption chillers in the range <50 kW are currently not available on the market. In a pilot project a thermally driven refrigeration plant with a cooling capacity of <25 kW using the resorption principle was evolved and installed in a supermarket. Special focus is given to the operating costs, the amortization as well as the CO_2 emissions of the examined system.

1. Introduction

"The exergy consumption of the processes necessary for human life thus corresponds to the consumption of primary energy. In order to save primary energy, it is necessary to select exergetically favorable processes, i.e. those with a low exergy demand, and also to try to avoid exergy losses when converting primary energy into the effective energy required." [2]

Supermarkets are structurally complex objects with regard to the supply of effective energy. Electricity and fossil fuels are used to supply the applications for heating, for cooling at different temperature levels, for lighting and for ventilation. The structures of industrial providers of supply technology that have grown over the decades show a highly specialized equipment portfolio. Suppliers can manufacture and install a product specialized on the boundary conditions specified by the customer like ventilation unit, deep freezing- and normal cooling-chillers, gas boiler, etc. The unavoidable problem for the customer is the interface management of these highly specialized systems. If systems, e.g. for room temperature regulation are not coordinated with each other, the resulting losses due to unfavorable controlling are higher than the savings achieved by increasing the efficiency of the single systems.

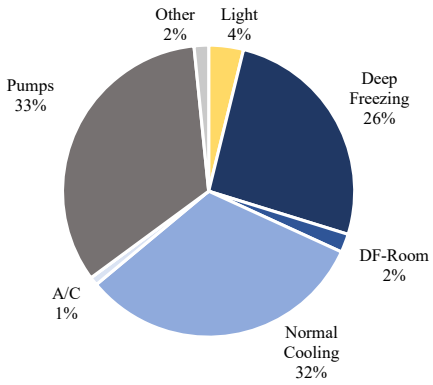

Figure 1: Percentages of electrical energy at the examined supermarket (regarding Table 2)

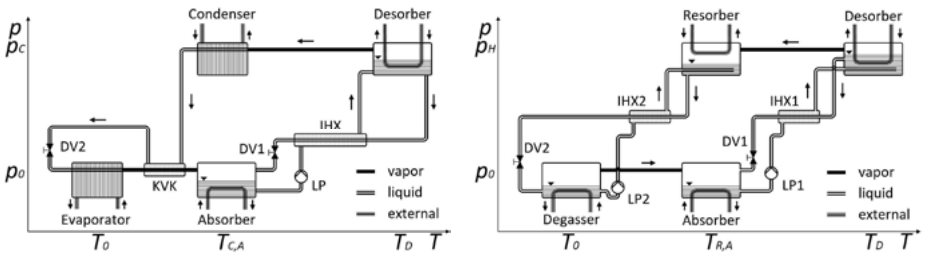
Table 1: Final and effective energy types in supermarkets

Type of Final Energy	Type of Effective Energy	Specification
Natural gas	Heating heat	Room heating
		DHW
Electricity	Light	Light
	Cooling	Deep freezing
		Normal cooling
		A/C
		Pumps (Brine etc.)
	Others	Ventilation
		Heating

However, since efficiency increases represent one of the implicit actions for global primary energy savings, it is necessary to consider the overall supply system, especially with increasingly complex systems, such as in supermarkets, to control interfaces and to use synergy effects with regard to energy and exergy flows. Looking at a supermarket as an overall system, it is primarily the final energy consumption entering the system that can be identified and can be broken down according to its utilization (see Figure 1 and Table 1).



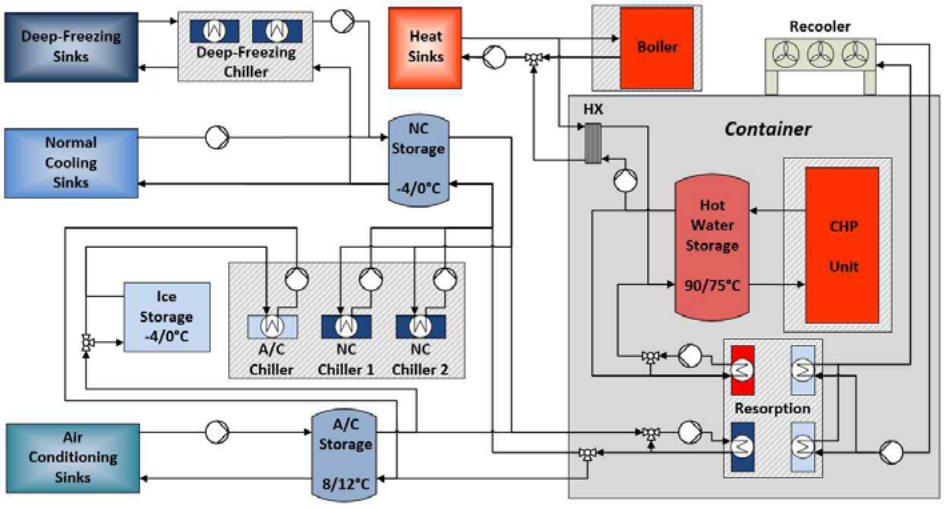
It is obvious that refrigeration and distribution (pumps) account for the major part of the electrical energy consumption (> 90%), which is almost constant throughout the year. Contrary to electrical energy, thermal energy for heating is only required in the colder season, therefore cogeneration plants for supermarkets have not been considered so far. Thermally driven refrigeration systems using the excess heat generated by cogeneration units and providing refrigeration at the normal cooling level could be an acceptable option. As part of a pilot project, such a system was installed in a supermarket in southern Germany and monitored over a period of 1.5 years.

2. Heating and Cooling Technologies for Supermarkets

2.1. Resorption Refrigeration System

Sorption refrigeration systems were developed in the middle of the 19th century with the necessity of industrial cooling. In a much quoted basic work from Altenkirch [3] on continuously operated sorption chillers, the so far very rarely used – and therefore almost unknown – configuration of the *resorption refrigeration system* is presented. Altenkirch describes its essential components and work processes in *p-T*-diagrams (cf. Figure 2). The significant difference in resorption compared to absorption is the second solution cycle with an additional absorber (resorber) instead of a condenser and an additional desorber (degasser) instead of the evaporator. Both absorption and resorption systems are continuously operating systems and are equally suitable for the utilization of waste heat. The decisive factor for the selection is the focus on the respective task to be fulfilled, taking the quality and availability of the driving energy as well as other boundary conditions into account. To select the appropriate system, temperature levels should be considered foremost.

As shown in Figure 2, three temperature levels are required to operate a sorption system – the heating temperature T_D, the recooling temperature $T_{C,A}$ resp. $T_{R,A}$ and the refrigeration temperature T_0. If cooling temperature values above 4 °C are targeted, *Water-LiBr-Absorption* and *Water-Silicagel-Adsorption* systems are available which can achieve higher coefficients of performance (*COP*) than ammonia-water systems. Therefore, they are mainly used for cold water generation in the process industry or for air conditioning, e.g. in office buildings or for server cooling. The use of water as the refrigerant is not suitable for providing a cooling capacity below 0 °C due to its triple point of $T_{TP} = 0.01$ °C, as it would freeze and block the evaporator and eventually also the expansion device in conventional absorption systems. For this case of application, other working fluid pairs are suitable. Usually ammonia-water *absorption refrigeration systems* are used for this purpose. However, due to their high technical and safety requirements, they were almost exclusively implemented for large-scale systems with cooling capacities of $\dot{Q}_0 >> 100$ kW.



SP…solution pump; TV…throttle valve; IHX…internal heat exchanger; CPC…condensate precooler

Figure 2: Comparison of an absorption refrigeration system without rectification (left) and a resorption refrigeration system (right) according to [3], [4]

The so far almost forgotten technology of the *resorption refrigeration system* (RRS) is the focus of a currently running project. A system for the utilization of waste heat with a small cooling capacity ($\dot{Q}_0$ = 25 kW) and the working fluid pair ammonia-water is investigated. This system has a wide range of operation with regard to part load operation and temperature ranges. The equipment requirements and thus the system costs are significantly reduced. On the one hand, this is due to the fact that rectification and the dephlegmation of the ammonia vapor is no longer necessary. Furthermore, the system pressure is reduced to p_H < 0.6 MPa due to the presence of the ammonia only in aqueous solution. With regard to the thermal boundary conditions, the range of operation is considerably more flexible, even though the temperature of the decoupled cooling capacity is limited to $T_0 \approx$ -10 °C. Current operational experiences also demonstrate that, in particular, operation under short-term varying boundary conditions with regard to temperatures has only minimal effects on the plant performance, which can cause problems with conventional absorption systems. [5]

2.2. Heating and Cooling Network of the examined Supermarket

A supermarket was restructured as a part of a project funded by the German Federal Ministry of Economics and Energy. This includes the installation of a CHP-unit (nominal electrical power of P_{CHP} = 48 kW_{el} and a heating capacity of $\dot{Q}_{CHP}$ = 80 kW_{th}), a brine circuit with connected deep-freezing chillers, propane chillers (3 times $\dot{Q}_{0,PC}$ = 25 kW_{th}) and a resorption refrigeration system ($\dot{Q}_{0,RRS,max}$ = 25 kW_{th}) using waste heat to provide A/C and normal cooling. The network of heating, cooling and electrical energy generators resulting from the retrofitting is illustrated in Figure 3.

NC…normal cooling; A/C…air conditioning; HX…heating heat exchanger; CHP unit…combined heat and power unit

Figure 3: Heating and Cooling Network of the examined supermarket [5]

A special requirement was to assemble the system as a compact unit in the external area of the supermarket. Therefore, the implementation of the CHP unit and the resorption system was realized as a container-solution. In addition, the A/C and NC propane chillers were installed in another nearby container, and the resorption system was coupled into the piping network of these chillers. It can also be seen that a condensing boiler is installed in addition to the CHP unit. This existing unit has been preserved and now serves as failure redundancy for the CHP unit for the heating supply of the supermarket. A special aspect and sub-task of the project was the installation of a latent energy storage tank (ice storage) and the investigation of its influence on the flexibilization of cooling load and cooling generation. Furthermore, various sensitive storage tanks (hot water, A/C and NC) can be seen, which are necessary for the operation of the resorption plant, but also for the temporal decoupling of thermal energy load and generation.

3. Energy cost analysis

3.1. Database

In order to be able to answer the economically interesting question of current energy costs and payback period, it is necessary to have a sufficient database. Comprehensive monitoring of the entire supermarket enables consumption data to be displayed. Figure 4 shows an example of the electrical energy consumption of the supermarket over a period of one month as the sum of the electrical energy generated by the CHP unit and the electrical energy obtained from the grid. In addition, the excess electrical energy generated by the CHP unit and not consumed by the supermarket which is fed into the grid. Especially on Sundays when the market is closed, is shown.

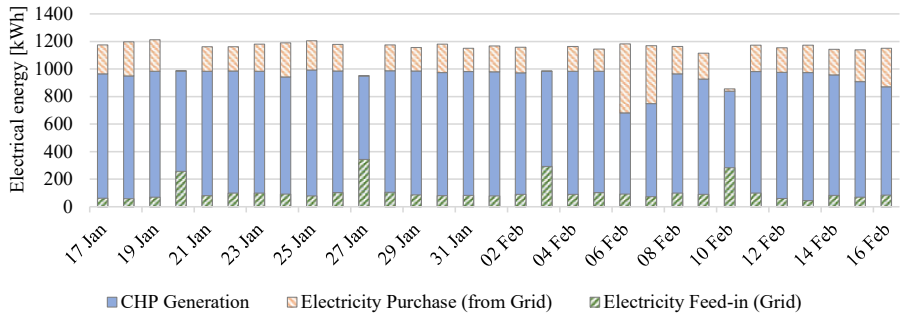


Figure 4: Daily electrical energy generation (CHP unit), purchase and feed-in (grid) for one month (winter period 2019) at the examined supermarket

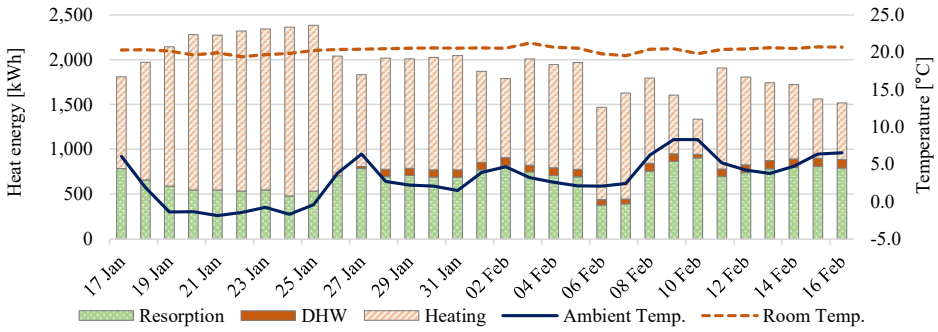

Figure 5: Distribution of heat in the examined supermarket for one month (winter period 2019) at the examined supermarket

The CHP unit is not managed according to electricity consumption, but according to heat consumption. Thus, it is only active if the hot water storage tank to be supplied by it does not exceed a temperature limit. If there is insufficient consumption of thermal energy by the heating system or the resorption system, the

temperature in the storage tank increases and the CHP unit switches off. It is therefore interesting to see how the heat provided by the CHP unit is distributed among the consumers depending on the ambient temperature (cf. Figure 5). It can be clearly seen that with decreasing ambient temperatures the necessary heat demand of the supermarket increases and the available heat for the resorption plant decreases. If the resorption system would consume a continuous heat flow, the hot water storage tank would cool down and the necessary temperature for room heating would no longer be reached. It is therefore necessary to operate the resorption plant at partial load, especially in the winter months, with very low ambient temperatures.

Based on the measurement data, the annual quantities and percentages of the individual electrical energy consumers can be summarized, as shown in Table 2. Particular importance is attached to the distribution of the consumption of electrical energy for the provision of cooling. The reason for this is that the resorption system partially covers the load of normal cooling and air conditioning, whereas the consumption values for lighting, deep-freezing (DF) and others remain constant. Due to the installed brine system, a considerable amount of energy is used to generate pumping power. This proportion can also be reduced by running the resorption system, as the brine pumps of the normal cooling chillers can be operated at partial load during the operation of the resorption system.

Table 2: Annual consumption values in MWh and the distribution in % of electrical energy in the examined supermarket with and without the CHP unit and Resorption system

	Light	*Deep Freezing*	*LT-Storage Room*	*Normal Cooling*	*A/C*	*Resorption*	*Pumps/ Recooler*	*Others*	*Total*
Grid Electricity + Condensing Boiler	14,0 MWh	94,5 MWh	7,5 MWh	117,0 MWh	3,4 MWh	0,0 MWh	122,1 MWh	5,8 MWh	364,3 MWh
	3,8%	25,9%	2,1%	32,1%	0,9%	0,0%	33,5%	1,6%	100,0%
CHP Unit + Resorption Refr. System	14,0 MWh	94,5 MWh	7,5 MWh	58,5 MWh	0,7 MWh	18,6 MWh	108,1 MWh	5,8 MWh	307,6 MWh
	4,6%	30,7%	2,4%	19,0%	0,2%	6,0%	35,1%	1,9%	100,0%

In order to carry out a comparison between the original (condensing boiler and grid electricity) and the new (CHP and resorption system) configuration, the measured values of several representative weeks were extrapolated to the period of one entire year. This was necessary because the CHP plant was not in continuous operation during the entire monitoring period and the originally installed systems thus fulfilled their task not only as additional but also as redundant systems.

3.2. Final energy costs

For an economic analysis it is necessary to know the expenses for the energy consumption of the supermarket. **오류! 참조 원본을 찾을 수 없습니다.** shows the average electricity and natural gas costs per kWh for industrial customers in selected countries of the European Union in the first semester of 2019.

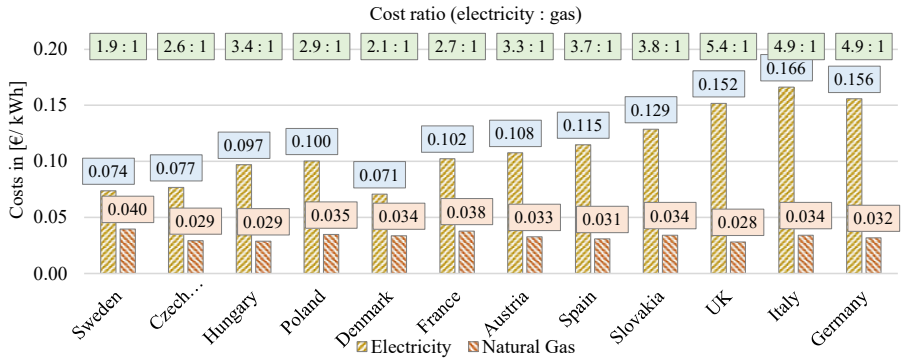

Figure 6: Electricity and natural gas prizes for industrial customers in European countries (excluding VAT and other recoverable taxes and levies), 2019 [6],[7]

It can be seen that the prices for electricity differ strongly, while the price for natural gas is almost constant. It should be noted that the given values exclude VAT and other recoverable taxes and levies, but national additional charges such as the EEG levy (German Renewable Energy Act) are included. This leads to significant price differences between the countries. The decisive factor for the profitability of a CHP unit is the ratio of natural gas price to electricity price, which is highlighted in green in the upper part of **오류! 참조 원본을 찾을 수 없습니다.**. As a result, before calculating the operating costs (chapter 3.3), it becomes clear that the system proposed in this paper is not suitable from an economic point of view in all countries.

3.3. Operating costs

In addition to the energy consumption data shown in Table 2 and the effective energy costs shown in **오류! 참조 원본을 찾을 수 없습니다.**, the efficiencies of the individual systems are also relevant for the calculation of operating costs. The thermal efficiency of the condensing boiler is $\eta_{th,CB} = 0.95$. The electrical efficiency of the CHP is $\eta_{el,CHP} = 0.38$ and the thermal efficiency is only $\eta_{th,CHP} = 0.55$. Nevertheless, the entire thermal energy required by the supermarket for heating and hot water supply is covered by the CHP unit and also provides the input heat for the resorption refrigeration system.

오류! 참조 원본을 찾을 수 없습니다. shows the annual operating costs for electricity and natural gas for the standard system (blue) and the system with CHP + resorption (orange) for the European countries mentioned above. In addition, the green highlighted annual operating cost savings are shown as a percentage. It becomes clear that there is a significant correlation between the price ratio (natural gas to electrical energy) and the annual cost savings. Due to the high effective energy price ratio in countries such as Germany, Italy and the UK almost or even more than half of the annual costs can be saved.

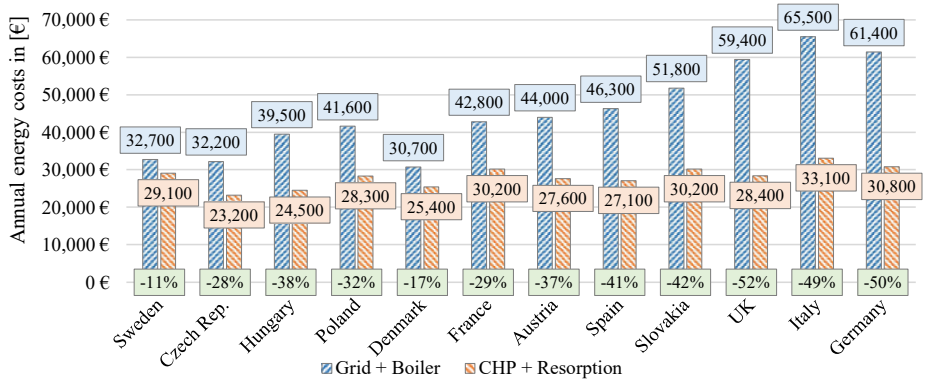

Figure 7: Annual energy costs with and without CHP + Resorption system

4. Amortization

In addition to the consideration of running costs, the necessary investment costs for the installation of such a system are also decisive. Table 3 shows the necessary costs for the various components, based on the investment costs for the pilot project in Germany. In particular, the costs for the resorption system are hypothetical, as there is no supplier for this yet.

Table 3: Investment costs of the CHP + Resorption system

CHP unit	Resorption System	Container, Recooler, Storages, etc.	Other	Engineering	Total
60.000 €	25.000 €	50.000 €	15.000 €	50.000 €	200.000 €

Figure 8 shows the amortization period based on these investment costs. Due to the very low operating cost savings for the operation in Sweden and Denmark, the system will only amortize after more than 25 years, which is not a realistic investment. Considering the previously mentioned countries Germany, Italy and the

UK, the system represents an alternative to existing solutions, as the lifetime of about 10-15 years is longer than the amortization period of the system.

Considering the values in Table 3, it is obvious that the engineering of the plant accounts for 25% of the total investment. Therefore, within the framework of the investigations of the overall system, the idea of a modular design was developed, which should be scalable with regard to electrical energy generation, heating and cooling capacities for each customer. This could significantly reduce engineering costs and shorten amortization periods, thereby opening up new markets.

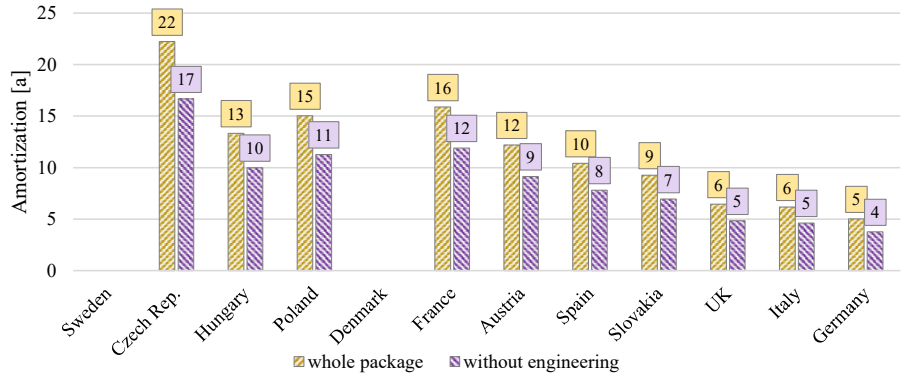

Figure 8: Amortization period of the CHP + Resorption system with and without engineering costs

5. CO_2 emissions

5.1. CO_2 emission factors

In addition to economic considerations, the impact on the environment is also decisive. In this context, the amount of fossil fuels used in the electricity generation chain must be considered first and foremost. As for natural gas and electrical energy prices, also statistics on the CO_2 equivalents of electricity generation can be found as shown in Figure 9. Depending on the main type of generation, the situation in the European countries varies considerably. Countries such as Sweden or France, where electricity is mainly generated from renewable sources or from nuclear power plants, have a significantly lower CO_2 emission factor than countries such as Germany, the Czech Republic or Poland, where a large amount of electricity is generated by fossil-fired steam power plants.

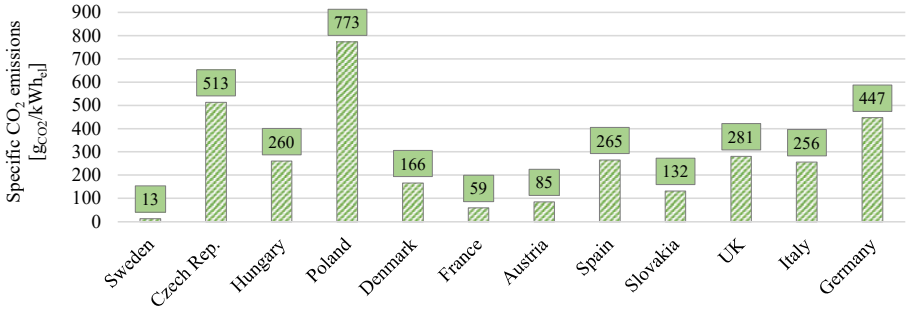

Figure 9: Specific CO_2 emissions for electricity generation in European countries [8]

When generating electrical and thermal energy from a CHP plant natural gas is used. Due to its high specific calorific value at the lowest amount of carbon of all fossil energy sources, natural gas, which consists mainly

of methane (CH_4), has a low emission factor of only ε_{CH4} = 202 g_{CO2}/kWh_{th}, which is however significantly higher than that from regenerative sources such as wind or solar power plants.

5.2. Annual CO_2 emissions

The specific annual emission values of the two system configurations (with and without CHP + resorption) can be calculated using the consumption values from Table 2 and the emission values of the electricity generation shown in Figure 9. Figure 10 shows that in the countries with a threshold value of < 315 g_{CO2}/kWh_{el} the annual emission values with the system solution of CHP + resorption system are above those of the initial configuration. Therefore, they do not represent a sustainable alternative. Key factors to improve the system and to decrease this threshold value are the percentage coverage of the cooling load by the resorption system and the electrical efficiency ratio of the CHP unit.

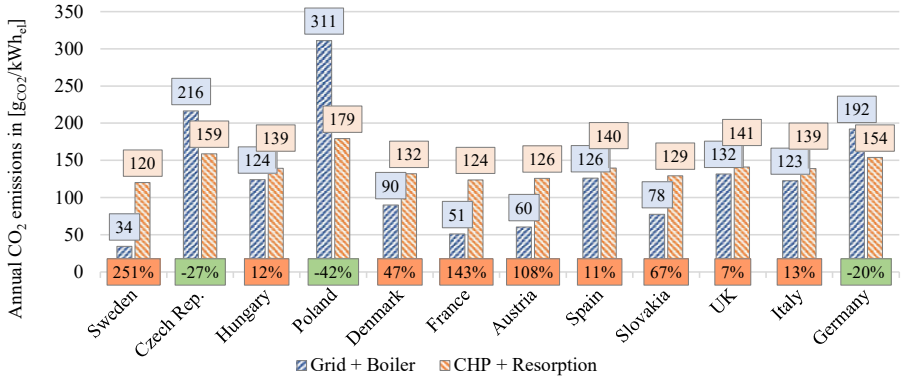

Figure 10: Annual CO_2 emissions with and without CHP + Resorption system

6. Conclusion and Outlook

As part of a pilot project, a supermarket was retrofitted in such a way that a combined heat and power unit (CHP) was installed to supply electricity and heating energy. Especially in the transition and summer months from March to November, only a small amount of thermal energy is needed for heating and domestic hot water supply. In order not to dissipate the co-generated heat to the environment, a thermally driven resorption refrigeration system was additionally installed. This system uses the waste heat from the CHP unit to provide cooling capacity for normal refrigeration and air conditioning of the supermarket, thus reducing the power consumption of the conventional vapor compression refrigeration systems.

The monitoring of the supermarket and the calculations based on it show that a considerable amount of up to 52 % of the annual operating costs could be saved. Based on these values, it was possible to determine an amortization calculation that proves the cost-effectiveness of the technology. In an European comparison, a partly lower economic efficiency can be observed, since the prices for electrical energy differ significantly and thus lead to unfavorable gas/electricity cost ratios, which are reflected in the achievable annual savings.

In addition, the system of a CHP + resorption unit in the supermarket network was investigated with regard to the CO_2 balance. It can be stated that the internationally varying generation strategies for electrical energy have a decisive influence on this. The combined CHP + resorption system emits a lower amount of CO_2 only if the local production of electrical energy has an emission factor of > 315 g_{CO2}/kWh_{el}, which in the future will decrease internationally as production from renewable sources increases.

Finally, it can be said that the use of systems that are individually uneconomical (resorption system) or environmentally harmful with regard to CO_2 emissions (CHP) overcome both disadvantages when they are used in combination. Technologies such as power-to-gas, which convert excess electrical energy, e.g. into synthetically produced methane, will enable the economic and climate-friendly operation of decentralized combustion-based electrical energy generation (e.g. CHP units) using the existing natural gas infrastructure. This shows the advantages of a cross-system approach in the design of energy systems.

Abstract

To minimize noise immissions in urban areas, methods of sound measurement combined with augmented reality have been developed that enable simple and intuitive access to noise emissions and possibilities to their reduction. These methods allow a virtual representation of a sound emitting device and the resulting sound dispersion in a real environment.
In this work, the methods of sound measurement, to obtain transient directional and frequency-dependent sound emission behavior of a device in addition to the sound power level under different operating conditions, are shown. The focus lies on the development of an application for mobile devices, which visualizes the sound emitting apparatus with direction-dependent sound propagation virtually in a real environment. Using augmented reality this apparatus can be freely positioned and moved to find the acoustically optimal position. The sound pressure level can be determined at any position by the observer. In the future, the technology should facilitate the planning and installation of heating and air conditioning units regarding noise pollution, increase the acceptance of heat pumps and thus lead to a higher proportion of renewable energy.

Keywords: augmented reality; acoustics; air heat pumps; sound propagation

1. Introduction

Noise causes stress and thus triggers reactions such as cardiovascular diseases, sleep and concentration disorders and mental illnesses and has an influence on social behavior (aggression) [1]. In urban areas in particular, people are severely affected by noise pollution. In addition to traffic and commercial noise, heating and cooling equipment is particularly important here. Air-conditioning systems, heat pump external units (source) or even noisy control cabinets or fast-charge stations of batteries often lead to conflicts. In addition, noise pollution has increased again in recent years and about 40% of Austrians are affected [2]. In view of the steady expansion of renewable energy sources, the number of air heat pumps in particular will increase strongly in the urban area. Nowadays, sound emissions are usually determined from a single number, the direction- and location-independent sound power level and converted into a location-dependent sound pressure level by simple mathematical methods. This does not take into account the frequency dependence, direction dependency, operating state or the influence of the environment. It is therefore urgently necessary to develop a more intuitive, simpler but at the same time more accurate and more complete approach to the sound issue in order to make cities 100% renewable and at the same time quieter. This approach is based on Augmented Reality (AR) and represents a unique approach to date.

The aim of this work is to make sound emissions from noise sources visible and audible in real time before they are installed. This shall be done by means of "Augmented Reality" on site, depending on frequency, direction, operating condition and environment. Noise sources such as recirculating chillers, evaporators, fans, etc. in/around the building as well as noise-insulating measures should be able to be placed virtually before the units are installed on site. Their sound emissions are visualized on the surrounding surfaces in real time and made acoustically perceptible. For the calculations, the automatically detected environment is taken into account in terms of its acoustical properties. With the unique methodology developed, different installation locations, noise reduction measures and facades which are yet to be built can be taken into account, thus virtually optimizing the noise level of the heating and cooling units to be installed in the future, even before the units are ordered.

Several works regarding augmented reality acoustics and acoustic augmented reality have been published so far. However, the approach presented in this work is new to date. Most recently Green and Murphy [3] published a study of an intuitive environmental sound monitoring system that can be used on-site and return meaningful measurements beyond the standard L_{Aeq}. The created iOS-app returns readings indicating the human, natural and mechanical sound content of the local acoustic scene and implements four virtual sound objects which the user can place in the scene to observe their effect on the readings. Other existing concepts in this area of development refer to assigning a sound source to real objects in the environment and making them perceptible with e.g. headphones. The Japanese technology group *NEC*, for example, is pursuing such a concept [4].The system is similarly called "Acoustic augmented reality" and is to be used, for example, for marketing purposes, guidance systems, information for tourists or speaking advertising pillars. The French company *Augmented Acoustics* strives to use the same functional principle for concerts. A similar approach has also been followed at the *Finnish University of Aalto* together with *Nokia* under "acoustic-hear-through" and "microphone-hear-through" approaches [5]. *Microsoft* also follows this approach to help visually impaired people find their way [6]. A different approach is being pursued in the automotive sector. In the future, vehicles will be able to warn drivers of hidden dangers before they are visible [7].

The work presented here includes sound data acquisition, software/hardware selection and app development.

2. Methods

2.1. Experimental setup for acoustic measurements

A large part of the components in the heating & cooling sector, but also switch cabinets, transformers and similar apparatus like charging stations, emit sound waves which are caused by vibrating surfaces or flow effects. Methods are available for the characterization of sound emissions in different depths, e.g. ISO 3741, ISO 3741-1 / ISO 3741-2, ISO 3744, ISO 3745, ISO 3746, ISO 3747. Usually, the sound power level is specified for a sound emitting object, which is determined using an enveloping surface method with standard microphones or intensity probes, using different test environments, e.g. EN 12102-1 for heating and cooling or prNE 12102-2 for heat pumps. In this method, the acoustic information is reduced to a single number - the sound power level. Directional and time-dependent emissions are not taken into account. Tonal components in the signal are only taken into account as a lump sum by the addition of a "penalty surcharge" in some countries [8]. With the help of this sound power level, simple mathematical models can be used to calculate the sound pressure level at observer positions. In Austria, the association *Wärmepumpe Austria* provides a sound propagation calculator for this purpose [9]. In the current variant, a direction factor or the existence of sound insulation measures can also be taken into account. The sound propagation visualization of the *Danish Energy Agency* calculates a sound map based on the sound power level, which is superimposed on Google-Maps [10] (see Figure 1).

In order to characterize the directional dependence of sound propagation and the long-term behavior of components even under different climatic conditions, measurement with a large number of microphones over a large time range is necessary. This can be done with an acoustic dome (Figure 2).

The dome used in this work consists of up to 64 microphones with a 64 channel simultaneous data acquisition system and a sampling rate of up to 192 kHz. This allows measurements for time-dependent sound power determination, but also frequency, location and time-dependent analyses.

For this work an AIT-built heat pump, the SilentAirHP (Figure 3), was put into a climate chamber surrounded by the acoustic dome. The heat pump was measured at several different operating conditions. For the further work a data set was selected, where the evaporator of the heat pump was iced up.

Figure 1: Visualization of the expected sound propagation through the installation of a heat pump on a house wall (stoejberegner.ens.dk) [10]

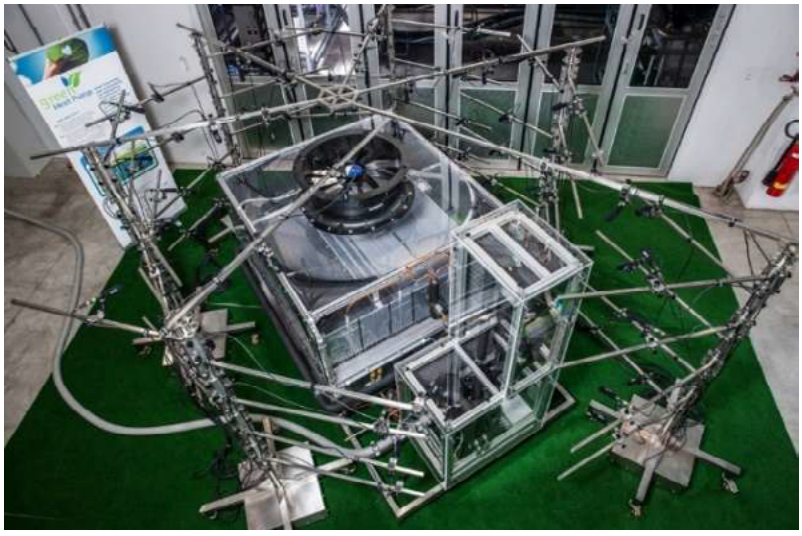

Figure 2: Acoustic dome placed around the *GreenHP [11]* (image by AIT)

Figure 3: SilentAirHP in the AIT climate chambers. The acoustic dome has been setup around the heat pump. In the background the white bags allowing for a very uniform quit inflow air distribution into the climate chamber can be seen.

2.2. Selected hardware and software for augmented reality acoustics

There are a number of SDKs (Software Development Kits) and environments used for the development of augmented reality applications, ranging from vendor-specific solutions only working on their native platforms, like SDKs from BOSE [12] or Apple [13] or Microsoft's MixedRealityToolkit for HoloLense [14], to more general approaches like Vuforia [15], DeepAR [16] or Kudan [17], and from open-source or free projects to commercial offers to new and upcoming solutions still existing as a beta version. They can be further categorized based on their overlaying capability or their tracking, as discussed in [18]. For iOS, Apple's own framework, ARKit, which was released in 2017, is mostly used. Google's Tango was discontinued in 2018 after only three years, shifting the focus to the new project, ARCore [19], for android devices [20] while Facebook's Spark AR public beta was launched in Summer this year [21]. Most SDKs rely on third party 3D engines such as Unity [22], UnrealEngine [23] or SceneKit [24] as development environment [25].

For this project Apples ARKit and Unity were used to create an app running on all devices that support ARKit.

2.3. Methods for sound propagation calculations

There are various methods for calculating sound propagation, which are briefly described in the following.

I) **Ray tracing**: The different methods of ray tracing have proven to be useful for interior problems. The effort is less than with the finite and boundary element method (FEM and BEM, respectively). Therefore, also sound propagation in large spaces with many borders can be calculated [26]. However, the diffraction is

normally not recorded. This is why this method is not suitable for the calculation of the sound propagation in the open air in particular behind sound screens without further corrections.

II) **Methods of noise mapping**: Simplified methods are used for noise mapping which are limited to direct sound and first and second reflections. The direct sound paths (i.e. also deflected by diffraction) are determined according to ÖNORM ISO 9613-2. Diffractions at single or multiple edges are considered only approximately on the basis of experiments and analytical solutions. Due to the relatively simple calculation, these methods can be used on a large scale, whereby the efficiency of the analytical approaches is also limited here [27]. Within the RELSKG program, frequency-dependent correction factors for noise barriers on roads and railways with and without absorbing material have already been determined [28]. However, these values have to be adjusted for the low heights, short distances and shorter lengths, which are usual for the situations considered in this project.

III) **Finite Element Methods**: The calculation of the sound distribution using the FEM [29, 30] is only possible for small rooms, whereas semi-infinite elements or Perfectly Matched Layers (PMLs) also allow the consideration of radiation. This method can therefore only be used to determine correction factors for diffraction behind noise barriers. This is essentially limited to the 2D case.

IV) **Boundary Element Method**: For noise barriers, mainly 2D calculations or 2.5D calculations are performed for the BEM. It is assumed that the geometry is constant in the third dimension, but the source can also be a point source [31]. This method was further developed in terms of efficiency at the Acoustic Research Institute [32]. Nevertheless, the computational effort required for this does not allow an ad-hoc calculation. Thus, this method is also only suitable for the determination of correction factors. 3D-BEM can only be used for small geometries and/or low frequencies due to the much higher effort, and therefore can only be used for special problems in this project.

V) **Further methods**: Beside the mentioned methods there is also the Finite Difference Method, which is unsuitable for external space problems, the Wave Based Method [33], which is also rather used for internal space problems, and transformation methods, which are only used for single bordered areas.

In this work a frequency dependent sound propagation was derived from the measurements. For this purpose, the entire frequency space was divided into third octave bands. For each band, the sound pressure was calculated as a function of the distance.

3. Results & Discussion

3.1. Data processing

For this work the raw data-files of 64 channels were split into ~1.3 seconds wavelets and were further processed using Fast Fourier Transform technique. After applying the A-weighting the data was stored as third octave band transient sets. Integration over the acoustic dome surface per third octave yields the time dependent A-weighted third octave sound power P (see equation 1), where $\overline{p^2}$ is the mean squared sound pressure, ρ the air density, c the sound velocity and dA an area element of the surrounding surface [34].

$$P = \int \frac{\overline{p^2}}{\rho \cdot c} dA \tag{1}$$

The sound power level LwA is calculated with equation 2.

$$LwA = 10 \cdot \log\left(\frac{P}{P_0}\right) \tag{2}$$

Where P_0 is 10^{-12} Watts. The third octave band sound power levels were used for the *SilentAirHP-App*. An additional app, *HVAC Positioner*, was compiled using the sound power level over all frequencies. To calculate the sound power level over all frequencies the third octave sound powers levels are logarithmically summed up.

3.2. App-assembling

3.2.1. SilentAirHP-App

For the *SilentAirHP-App* the resulting sound pressure levels of the different third octave bands were calculated via equation 3, where LpA is the sound pressure level, Q is a geometry factor [35] an r is the distance

from the sound source. The geometry factor Q is 1 for a sound source in mid-air, 2 for a sound source placed on plane surface, 4 near a wall, 8 in a corner. The different geometry factors are shown in Figure 4. For the version of the app at time of writing fixed value of Q was hard coded into the software. This will be changed to allow for user selection or automatic detection. Sound pressure values were assigned to colors for visualization.

$$LpA = LwA - \left|10 \cdot \log\left(\frac{Q}{4\pi \cdot r^2}\right)\right| \quad (3)$$

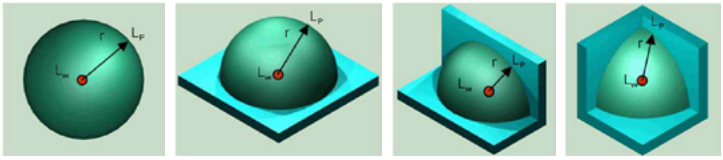

Figure 4: Full sphere $Q = 1$, half sphere $Q = 2$, quarter sphere $Q = 4$, eighth sphere $Q = 8$ (http://www.sengpielaudio.com/calculator-soundpower.htm) [35]

A photorealistic model of the SilentAirHP was created by a third party, i.e. Wunderwerk GmbH. Eventually the app included the following features: i) positioning of the SilentAirHP, ii) switching it on/off, iii) switch to choose either hearing and visualizing all frequencies or a third octave band around a certain frequency, iv) a slider to choose the third octave band frequency, v) a display of the actual dB-value and distance, and vi) audio output. All these features are visible in Figure 5, where the AR-SilentAirHP was positioned in front of a building in Austria. The observer can freely move and change position and has also the possibility to change the position of the heat pump in order to find a more suitable spot with regard to acoustic emissions.

Figure 5: Augmented Reality Acoustics at AIT - current state of development, a laboratory heat pump (SilentAirHP) placed using AR in a real environment with frequency-dependent sound propagation of a point source (without directional characteristic, diffraction or reflection)

3.2.2. HVAC Positioner

The second app that was built includes nearly all heat pumps that can be bought in Austria, but only refers to the overall sound power level for calculating dB(A) values and has no audio output. The data of the heat pumps is stores in an external data base to keep safe storage on the mobile device, requiring an internet connection. This app can be downloaded from the *Apple App Store* and *Google Play Store* [36]. For this app the sound power levels are calculated in real time.

Figure 6 shows a chiller put on the lawn via augmented reality with the corresponding sound power level indicated on the right-hand side of the image. The color code corresponds to guidelines regarding allowed maximal sound power levels for positioning the air heat pump.

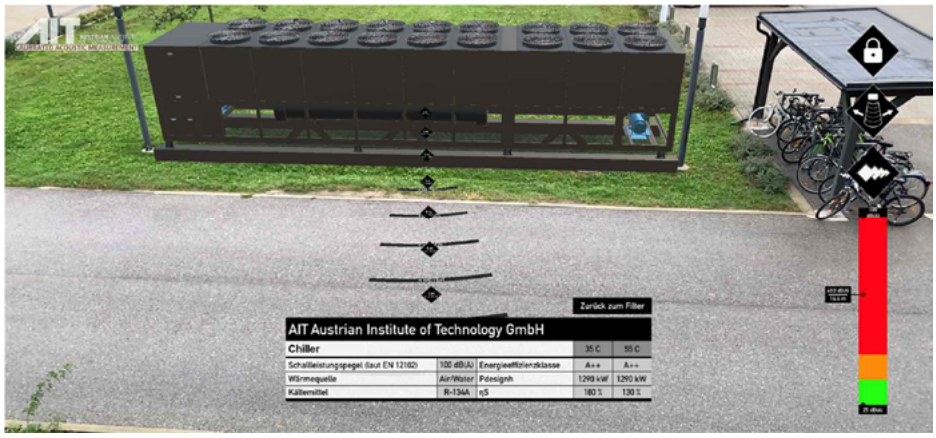

Figure 6: HVAC Positioner

4. Conclusion & Outlook

The base for an intuitive approach to acoustic problems with air heat pumps and chillers was created. This was done by building an app, which made it possible not only to visualize air heat pumps and chillers via augmented reality, but also to make the sound of these machines visible and thus much easier to comprehend. The sound pressure level is calculated from the sound power levels. Guidelines regarding allowed maximal sound pressure levels for positioning the air heat pump are intrinsically included in the via the color code on the right-hand side of the app. A database including nearly all available air heat pumps in Austria was generated and will be extended in the future. Next steps in the projects will be i) a faster raw-data handling algorithm and conversion of noise source measurements into suitable sound profiles, ii) an automatic sound physical detection of the environment (near and far range), iii) calculation of sound propagation based on sound profiles and environmental data, iv) implementation of sound absorption and reflection, and v) an interactive visual and acoustic representation of the calculations using AR, i.e. virtual noise source with virtual sound in real environments.

5. Acknowledgements

The Austrian Research Promotion Agency (FFG) and the Austrian Climate and Energy Fund (KLIEN) is gratefully acknowledged for funding this work under Grant No. 848891 (program line 'Energieforschung e!Mission 1st call', project 'SilentAirHP') and Grant No 873588 (program line 'Stadt der Zukunft 2nd call, project 'RAARA'). We also want to thank the Federal Ministry of the Republic of Austria for Transport, Innovation and Technology for supporting IEA HPT Annex 51 in Austria in the framework of the IEA Research Cooperation.

Analysis of a directly gas-fired absorption heat pump with an improved condensing boiler technology

Philipp Wagner[a*], Rene Rieberer[a]

[a]Graz University of Technology, Institute of Thermal Engineering, Inffeldgasse 25/B, 8010 Graz, Austria

Abstract

Residential heating is one of the most important factors for the reduction of fossil energy consumption and CO_2 emissions. A relevant contribution can be expected from directly gas-fired ammonia/water absorption heat pumps (GAHP) when it comes to the replacement of traditional condensing boilers in cold and moderate climatic regions (e.g. Europe). Especially in old buildings, the return flow temperature of the heat distribution system is above the dew point of the flue gas, thus water vapor condensation of the flue gas cannot take place in the flue gas heat exchanger. To ensure water vapor condensation under all operating conditions the flue gas can be cooled by the refrigerant in a refrigerant cooled flue gas heat exchanger, installed between the evaporator and the absorber. A GAHP with a nominal heating capacity of 18 kW was equipped with a water cooled and a novel refrigerant cooled flue gas heat exchanger to experimentally investigate the achievable increase in efficiency by means of the refrigerant cooled flue gas heat exchanger. The GAHP was operated at different heat source temperatures and different cycle configurations.

1. Introduction

In order to reach the ambitious targets of the European Unions climate and energy framework the share of renewable energies as well as the energy efficiency of all processes - especially for heating processes - have to be significantly increased. In 2030 the greenhouse gas emissions shall be reduced by at least 40 % below the levels of 1990. Renewables shall be increased by at least 32 % and the energy efficiency shall be increased by at least 32.5 %. [1]

As the energy consumption used for residential heating has a significant share on the total energy consumption - around 26 % of the Europeans total energy consumption [2] - this sector can contribute significantly to reach the climate targets. Especially, the heating demand of buildings has to be reduced and the efficiency of heating technologies has to be increased. Currently the heating demand is mainly covered by condensing gas boilers. E.g. in Germany gas and oil boilers had a market share of 75 % in the year 2017, whereas electrically driven heat pumps only had a market share of 11 % [3].

State-of-the-art condensing boilers provide the heating demand by burning fossil fuels (e.g. gas, oil) and cooling the combustion gas by the return flow of the hydronic heat distribution system. If the return flow temperature is below the dew point of the combustion gas, latent heat can be utilized by water vapor condensation. In this way, with state-of-the-art condensing gas boilers in combination with a low temperature heating system (e.g. floor heating system) an efficiency of up to 109 % (based on the lower calorific value) - which is already the limit - can be achieved [4].

To achieve a 40 % decrease in greenhouse gas emissions a more efficient technology is necessary to replace state-of-the-art condensing boilers. Especially in old buildings it is not realistic to replace all oil and gas fired boilers with electrically driven compression heat pumps due to the high temperature of the hydronic heat distribution system which leads to a low efficiency and a peak demand especially at low ambient temperatures. In this context, it is not meaningful to only use electrically driven heating systems as there is already an existing natural gas network which can be used. According to the current state-of-the-art the storage of natural gas is easier than the storage of electrical energy. It has also taken into account, that in some countries electrical energy is still produced in fossil-fired power stations at low efficiencies.

For old buildings a worthwhile contribution can be expected from directly gas-fired absorption heat pumps (GAHPs). Recently, a lot of research has been carried out in this field to increase the efficiency and/or to reduce the size and/or the complexity and/or the costs [5–9]. A GAHP is driven by a high temperature heat source (combustion of natural gas) and utilizes low temperature heat from the ambient (e.g. air, ground, water) and releases the sum of both heat flows to the hydronic heat distribution system at a medium temperature. Due to the utilization of ambient heat which is “free of charge”, with this promising technology an efficiency of up to 180 % (based on the lower calorific value) is possible [9]. Therefore a reduction of the energy consumption and greenhouse gas emissions of more than 40 % compared to state-of-the-art condensing boilers is possible. To further reduce the environmental impact of GAHPs in the future there are already suggestions to increase the amount of hydrogen in the natural gas network and to supply the natural gas network with renewable gas.

It has to be noted, that such high efficiencies are only possible in combination with a low temperature heating system (e.g. floor heating system) and if the low temperature heat from the ambient is supplied at a rather high level. If the return flow temperature of the hydronic heat distribution system is above the dew point of the flue gas the latent heat of the flue gas cannot be used and dissipates into the environment. This issue can impede the future market penetration of GAHPs as e.g. in Germany around three quarters of the residential buildings were built more than 30 years ago. Under typical operating conditions the return flow temperature is around 55 °C in the heating system of these buildings [10]. With a combustion-air ratio of λ=1.3 the dew point of the flue gas of a natural gas combustion is around 55 °C, which means in most applications the condensing boiler technology cannot be used because water vapor condensation in the combustion gas does not take place.

With a modified cycle GAHPs offer a great possibility to cool the combustion gas with a low temperature fluid to use the condensing boiler technology under all operating conditions. The lowest temperature in a GAHP occurs at the evaporator which results in the possibility of cooling the combustion gas with the refrigerant. As it is not advantageous to (partially) replace the evaporator with a refrigerant cooled flue gas heat exchanger, it makes sense to install it after the evaporator or depending on the cycle design after a refrigerant heat exchanger (internal heat exchanger). Generally, after the evaporator or the refrigerant heat exchanger the temperature is around -15 °C to +20 °C, which is lower and independent from the temperature of the hydronic heat distribution system, which ensures water vapor condensation under all operating conditions. Wagner and Rieberer [5] have shown a simulation study of a GAHP with a conventional water cooled flue gas heat exchanger (cooled by the hydronic heat distribution system) compared to a GAHP with a refrigerant cooled flue gas heat exchanger (cooled by the refrigerant). This study has shown the possibility to

increase the efficiency of a GAHP by up to 12 % depending on the operating conditions and the cycle configuration by installing a refrigerant cooled flue gas heat exchanger.

First measurement results of a GAHP prototype with a novel refrigerant cooled flue gas heat exchanger were recently published by Wagner and Rieberer [6]. An increase in efficiency of around 3 %, which was lower than expected based on the previous work [5], was achieved. Based on this sub-optimal results a first optimization of the integration of the refrigerant cooled flue gas heat exchanger was done.

Currently there are two working pairs used in absorption heat pumps. As heat source temperatures below 0 °C (e.g. air) are usual for heating applications the working pair ammonia/water has been used in the investigated prototype. Ammonia is a natural refrigerant and has the advantage of no ozone depletion potential and no global warming potential. It is classified as hardly inflammable and toxic. Therefore, national standards and regulations have to be observed if ammonia/water absorption heat pumps are operated in residential buildings (e.g. outdoor installation, installation with a ventilated housing, …). The ammonia charge in GAHPs is quite low and mainly dissolved in water, nevertheless it should be kept as low as possible.

Within this work a GAHP prototype with a nominal heating capacity of 18 kW was equipped with a refrigerant cooled flue gas heat exchanger between the evaporator and the absorber. Compared to the previous work by Wagner and Rieberer [6] first results with a modified flue gas flow direction are shown. Different cycle configurations were experimentally investigated and a comparison between a GAHP with a refrigerant cooled flue gas heat exchanger and a GAHP with a water cooled flue gas heat exchanger was performed.

2. System Description

Fig. 1 shows a schematic flow chart of the analyzed GAHP cycle, Fig. 2 shows the laboratory prototype. Rich solution (rso) with a relatively high ammonia mass fraction is brought to the high pressure (condensation pressure p_{CON}) by means of an electrical solution pump (PUMP). The rich solution is used to cool the dephlegmator (DEP) to produce the required reflux for the rectification column (REC) and to achieve a higher ammonia mass fraction in the refrigerant (ref). A bypass (V_{nDEP}) at the dephlegmator gives the opportunity to investigate the influence of the dephlegmator on the ammonia mass fraction and the overall efficiency. Via valve V_{REC}, a part of the rich solution can be fed into the rectification column and be used as an additional reflux. An optimum of the valve settings of V_{REC} and V_{ABS-3} was experimentally determined and kept constant for all investigations. The rich solution that is not fed into the rectification column is preheated in the solution cooled absorber (ABS-3) before it enters the generator (GEN). In the generator the rich solution is partly evaporated by the heat supplied by a natural gas combustion (Q_{GEN}). Ammonia vapor rises upwards in the rectification column, where it is brought into contact with the liquid solution (reflux) flowing downwards.

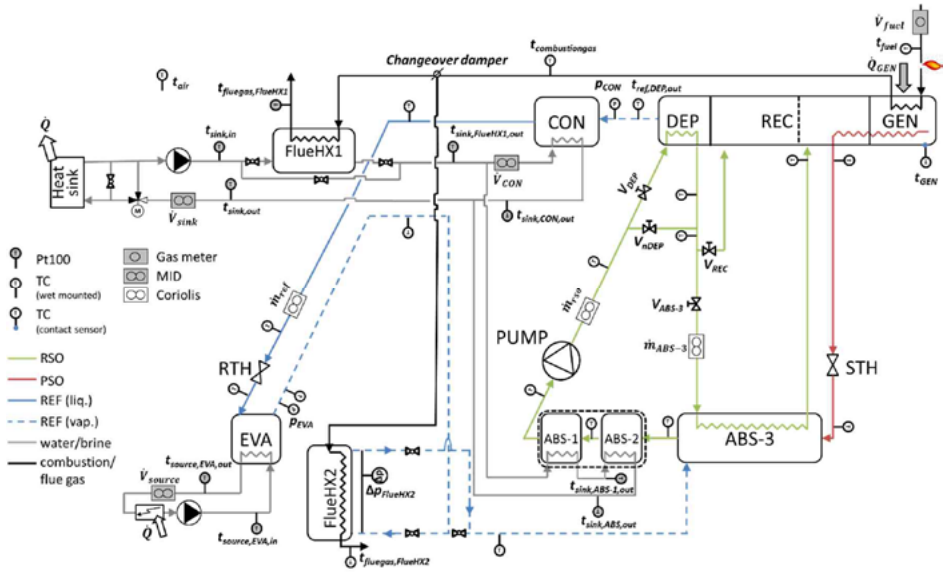

Fig. 1. Schematic flow chart of the analyzed absorption heat pump cycle

The refrigerant vapor leaving the dephlegmator enters the condenser (CON) where it is liquefied by releasing heat to the heat sink. After being expanded in the refrigerant throttle (RTH) to the low pressure (evaporation pressure p_{EVA}), the refrigerant enters the evaporator (EVA) and evaporates by extracting heat from the heat source. If the GAHP cycle is analyzed with a refrigerant cooled flue gas heat exchanger the refrigerant can be further heated by the combustion gas, before it enters the solution cooled absorber.

To further increase the overall efficiency of the GAHP and the transferrable heat in the evaporator a refrigerant heat exchanger can be installed on the warm side between the condenser and the refrigerant throttle and on the cold side between the evaporator and the refrigerant cooled flue gas heat exchanger / solution cooled absorber. Wagner and Rieberer [6] have previously investigated the influence of the refrigerant heat exchanger on the overall efficiency. It was found that the refrigerant heat exchanger had only a minor effect (within the measurement uncertainties) on the overall efficiency of the GAHP and is therefore not investigated within this work.

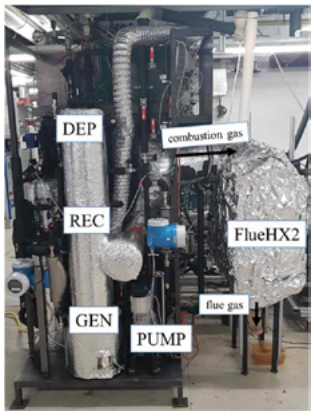

Fig. 2. Laboratory prototype

After partly evaporation of the solution in the generator, the poor solution (pso) with a relatively low ammonia mass fraction (x_{pso}) is taken from the bottom of the generator and cooled by a solution recirculation pipe. After being expanded in the solution throttle (STH), the poor solution enters the solution cooled absorber (ABS-3), where it absorbs the refrigerant. A complete absorption of the refrigerant by the poor solution takes place in the water cooled absorbers (ABS-1 & ABS-2).

The combustion gas which leaves the generator at around 130 °C to 150 °C (depending on the operating condition) can be either cooled by the return flow of the hydronic heat distribution system in a water cooled flue gas heat exchanger (FlueHX1) or by the refrigerant in a refrigerant cooled flue gas heat exchanger (FlueHX2) to reduce the energy losses. By analyzing the GAHP cycle with the water cooled flue gas heat exchanger the return flow of the hydronic heat distribution system is preheated (from $t_{sink,in}$ to $t_{sink,FlueHX1,out}$) before entering the condenser and the water cooled absorbers. If the GAHP cycle is analyzed with a refrigerant cooled flue gas heat exchanger the refrigerant can be further heated by the combustion gas, before it enters the solution cooled absorber.

The refrigerant cooled flue gas heat exchanger prototype is designed like a counterflow fin and tube heat exchanger with a heat transfer area of approx. 16 m² on the flue gas side. The cold refrigerant enters the flue gas heat exchanger at the bottom and the hot combustion gas (leaving the generator) enters at the top. On each level the refrigerant flows through two to three parallel pipes in series before it flows up to the next level. After 24 levels the refrigerant exits the flue gas heat exchanger at the top at a high temperature. The hot combustion gas flows downwards while getting cooled and exits at the bottom of the flue gas heat exchanger as flue gas. Compared to the results shown in Wagner and Rieberer [6] the flow direction of the flue gas and the refrigerant was changed, because it turned out that the condensate which was flowing downwards (against the combustion gas) created an additional layer for the heat transfer and was partially evaporated by the hot combustion gas which entered the refrigerant cooled flue gas heat exchanger at the bottom. Therefore the heat transfer was negatively influenced and reduced by the additional layer and a partial evaporation of the condensate. In addition to these issues, the combustion gas side connection between the generator and the refrigerant cooled flue gas heat exchanger was too long and insufficient insulated which caused non-negligible heat losses. These issues were solved before the experimental investigations with the optimized integration of the refrigerant cooled flue gas heat exchanger were continued.

The standard water cooled flue gas heat exchanger is designed like a finned heat exchanger with a heat transfer area of approx. 0.5 m². The difference in the heat transfer area of the novel refrigerant cooled flue gas heat exchanger is caused by the limited convective heat transfer of superheated refrigerant, which is substantially lower than the one of liquid water.

3. Measurements

Measurements with a GAHP have been conducted. Different cycle configurations with and without the dephlegmator and different flue gas heat exchangers as well as different operating conditions have been investigated. The mass flow rate of the refrigerant (m_{ref}), the rich solution (m_{rso}) and through the solution cooled

absorber (m_{ABS-3}) were measured using Coriolis flow meters. The mass flow rate of the poor solution (m_{pso}) was calculated by applying a mass balance ($m_{ref} + m_{pso} - m_{rso} = 0$) at the solution cooled absorber. The condensation pressure (p_{CON}) was measured at the condenser inlet and the evaporation pressure (p_{EVA}) was measured at the evaporator outlet. The pressure loss of the refrigerant cooled flue gas heat exchanger ($\Delta p_{FlueHX2}$) was determined using a differential pressure transmitter.

The "internal temperatures" (refrigerant & solution, except the temperature at the generator bottom - t_{GEN}) and the combustion gas temperature ($t_{combustiongas}$) were measured by means of wet mounted thermocouples. The temperature at the generator bottom (t_{GEN}) was calculated as an average of the temperatures measured using three contact sensors (thermocouples) mounted at the outer wall where the poor solution enters the solution recirculation pipe. The "external" temperatures, i.e. the heat sink (t_{sink}) and heat source (t_{source}) and the flue gas ($t_{fluegas}$) temperature, were measured using wet mounted Pt100 sensors. The volume flow rates of the heat sink (V_{sink}, V_{CON}) and the heat source (V_{source}) were measured using MID flow meters. The volume flow rate through the water cooled absorbers (V_{ABS}) was calculated by applying a mass balance ($V_{CON} \bullet \rho(t_{sink,FlueHX1,out}) + V_{ABS} \bullet \rho(t_{sink,FlueHX1,out}) - V_{sink} \bullet \rho(t_{sink,out}) = 0$) at the confluence of the condenser and the absorber. The fuels' volume flow rate (V_{fuel}) was measured using a gas meter.

3.1. Methodology

In order to compare the different cycle configurations and flue gas heat exchanger types, measurements were taken at a constant natural gas flow rate. For the experimental investigation different heat source temperatures were combined with a constant heat sink temperature. The ammonia mass fraction of the refrigerant was influenced by the dephlegmator. Investigations were performed with (DEP) and without (nDEP) the dephlegmator. Table 1 shows an overview of the varied parameters during the experimental investigation.

Table 1. Overview of the varied parameters

Parameter	Values
Natural gas flow rate ($V_{fuel,norm}$) in m³/h	0.75
Heat source in/outlet temperature ($t_{source,EVA,in/out}$) in °C	+10/+7, -5/-8
Heat sink in/outlet temperature ($t_{sink,in/out}$) in °C	45/55
Dephlegmator	with (DEP), without (nDEP)
Flue gas heat exchanger	FlueHX1 (water cooled), FlueHX2 (refrigerant cooled)

The evaluation of the measured data was performed with the software Engineering Equation Solver (EES) [11]. The substance data of ammonia/water was taken from the equation of state formulated by Ibrahim and Klein [12], which is implemented in EES as a predefined function. All measurement uncertainties were calculated by means of Gaussion error propagation rule implemented in EES and are indicated by error bars in the figures in chapter 3.2 and chapter 3.3.

The following assumptions were made within the evaluation:

- The ammonia concentration of the refrigerant (x_{ref}) at the dephlegmator outlet was determined by assuming saturated conditions according to Eq. (1).

$$x_{ref} = f(p_{CON}, t_{ref,DEP,out}, q = 1) \quad (1)$$

- The heat flow rates at the condenser and the absorbers were determined using the measured values at the external circuits due to the smaller measurement uncertainty. Eq. (2) shows the calculation of the heat flow rate at the condenser and Eq. (3) and Eq. (4) are showing the calculation of the heat flow rates at the water cooled absorbers.

$$\dot{Q}_{CON} = \dot{V}_{CON} \cdot \rho(t_{sink,FlueHX1,out}) \cdot (h_{sink,CON,out} - h_{sink,FlueHX1,out}) \quad (2)$$

$$\dot{Q}_{ABS-1} = (\dot{V}_{sink} \cdot \rho(t_{sink,out}) - \dot{V}_{CON} \cdot \rho(t_{sink,FlueHX1,out})) \cdot (h_{sink,ABS-1,out} - h_{sink,FlueHX1,out}) \quad (3)$$

$$\dot{Q}_{ABS-2} = (\dot{V}_{sink} \cdot \rho(t_{sink,out}) - \dot{V}_{CON} \cdot \rho(t_{sink,FlueHX1,out})) \cdot (h_{sink,ABS-2,out} - h_{sink,ABS-1,out}) \quad (4)$$

- The mean refrigerant flow velocity at the refrigerant cooled flue gas heat exchanger was estimated according to Eq. (5) as an average of the measured refrigerant side inlet and outlet conditions taking the transferred heat flow rate from the flue gas to the refrigerant into account.

$$w_{ref,mean,sin} = \frac{\dot{m}_{ref}}{A_{pipe}} \cdot \frac{(v_{ref,FlueHX2,in} + v_{ref,FlueHX2,out})}{2} = \frac{\dot{m}_{ref} \cdot 4}{d_{pipe}^2 \pi} \cdot \frac{(v_{ref,FlueHX2,in} + v_{ref,FlueHX2,out})}{2} \quad (5)$$

- Pressure losses were neglected, except the refrigerant side pressure loss in the refrigerant cooled flue gas heat exchanger as well as when determining the theoretically achievable efficiency ($GUE_{FlueHX2,\Delta pFlueHX2\approx0}$, see Fig. 10).
- Heat losses were neglected.

For the assessment of the heat pump process the ratio of the total heating capacity and the fuel input based on the calorific value is relevant according to DIN EN 12309-1 [13]. In this consideration the energy consumption of the solution pump is neglected. Eq. (6) shows the Gas Utilization Efficiency (GUE) according to DIN EN 12309-1 [13], where the calorific value (H_s) is taken as the reference value. Conversely, Eq. (7) shows the calculation of the Gas Utilization Efficiency (GUE) according to DIN EN 12309-4 [14] where the lower calorific value (H_i) is taken as the reference value. Due to the inconsistency in the standard, two ordinates are plotted in the figures that show the efficiency of the GAHP determined with Eq. (6) and Eq. (7). The achievable efficiency $GUE_{FlueHX2,\Delta pFlueHX2\approx0}$ (shown in Fig. 10) was estimated according to the measurements performed and published by Wagner and Rieberer [6]. These results should show the efficiency which could be achieved with an optimized geometry if the refrigerant side pressure loss in the refrigerant cooled flue gas heat exchanger could be omitted.

$$GUE_{Hs} = \frac{\dot{Q}_{sink}}{\dot{Q}_{fuel,norm,H_s}} = \frac{\dot{Q}_{sink}}{\dot{V}_{fuel,norm} \cdot H_{s,norm}} \quad (6)$$

$$GUE_{Hi} = \frac{\dot{Q}_{sink}}{\dot{Q}_{fuel,norm,H_i}} = \frac{\dot{Q}_{sink}}{\dot{V}_{fuel,norm} \cdot H_{i,norm}} \quad (7)$$

3.2. Results

In Fig. 3 - Fig. 8 the measurement results regarding the ammonia mass fraction in the refrigerant (x_{ref}), the refrigerant mass flow rate (m_{ref}), the flue gas temperature at the outlet of the flue gas heat exchanger ($t_{fluegas}$), the Gas Utilization Efficiency (GUE), the heat flow rates in the water cooled absorbers (Q_{ABS-1}, Q_{ABS-2}) and the heat flow rate in the condenser (Q_{CON}) with different cycle configurations (with/without DEP) and different operating conditions (t_{source}) are shown. The heat source in/outlet temperature ($t_{source,in}/t_{source,out}$) is abbreviated with SRC in the following figures (e.g. $t_{source,in}/t_{source,out}$ = +10/+7 °C is abbreviated as SRC 10/7). In Fig. 9 the refrigerant side pressure loss in the refrigerant cooled flue gas heat exchanger and in Fig. 10 the achievable Gas Utilization Efficiency ($GUE_{FlueHX2,\Delta pFlueHX2\approx0}$) if the refrigerant side pressure loss could be omitted are shown.

Fig. 3 shows the ammonia mass fraction in the refrigerant vapor with (DEP) and without (nDEP) the dephlegmator. It can be seen that the ammonia mass fraction is independent of the flue gas heat exchanger type, but dependent on the presence of a dephlegmator. If a dephlegmator is used, the ammonia mass fraction could be increased from 0,964 to 0,994, i.e. by around 3 % (compare “SRC 10/7 DEP” and “SRC 10/7 nDEP” in Fig. 3).

The decrease of the refrigerant mass flow rate shown in Fig. 4 is mainly based on two effects. Firstly, the absorption process is influenced by the superheated ammonia vapor entering the absorber which basically causes an increase of the evaporating pressure due to a worse absorption behavior which has to be considered by the control of the refrigerant and the solution throttle. Secondly, the additional refrigerant side pressure loss had a negative effect on the absorption pressure and therefore on the refrigerant mass flow rate which can be absorbed by the poor solution. The decrease in the refrigerant mass flow rate becomes higher if the refrigerant mass flow rate is higher, which is the case at a higher heat source temperature. These two effects caused a decrease in the refrigerant mass flow rate of up to 11 % (see “SRC 10/7 DEP” in Fig. 4).

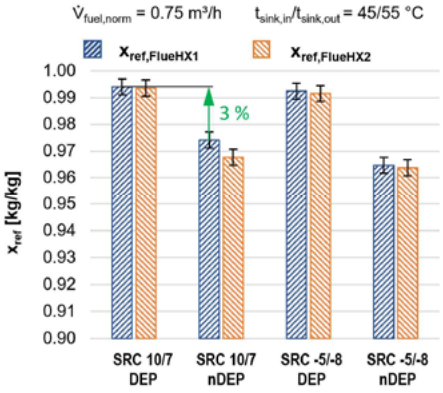

Fig. 3. Ammonia mass fraction depending on the cycle configuration

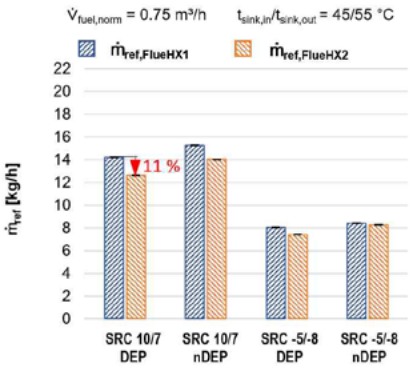

Fig. 4. Refrigerant mass flow rate depending on the cycle configuration

Fig. 5 shows the flue gas temperature at the outlet of the flue gas heat exchanger. The flue gas temperature at the water cooled flue gas heat exchanger ($t_{fluegas,FlueHX1}$) shows only minor changes due to the independence of the flue gas temperature on the cycle configuration and the heat source temperature. The flue gas temperature at the refrigerant cooled flue gas heat exchanger shows a noticeable dependence on the cycle configuration and the heat source temperature. A lower flue gas temperature ($t_{fluegas,FlueHX2}$) could be achieved at a lower ammonia mass fraction in the refrigerant (compare "SRC 10/7 DEP" and "SRC 10/7 nDEP" or "SRC -5/-8 DEP" and "SRC -5/-8 nDEP"). This is caused by a higher temperature glide during the evaporation and therefore a lower vapor quality after the evaporator. Due to a lower ammonia mass fraction a higher heat flow rate can be transferred in the refrigerant cooled flue gas heat exchanger, which – in general – leads to a lower flue gas temperature. I.e., a flue gas temperature of 2 °C instead of 49 °C (see "SRC -5/-8 nDEP" in Fig. 5) could be achieved with the refrigerant cooled flue gas heat exchanger which led to a significant increase in the recovered heat flow rate from the flue gas.

It also turned out that the flue gas temperature for "SRC -5/-8 DEP" ($t_{Fluegas,FlueHX2}$ = 43 °C) is higher than the one at "SRC 10/7 DEP" ($t_{Fluegas,FlueHX2}$ = 11 °C) even though the heat source temperature and therefore the refrigerant inlet temperature of the refrigerant cooled flue gas heat exchanger is lower. This is caused by the high ammonia mass fraction in the refrigerant (see Fig. 3) and the low refrigerant mass flow rate (see Fig. 4) at "SRC -5/-8 DEP".

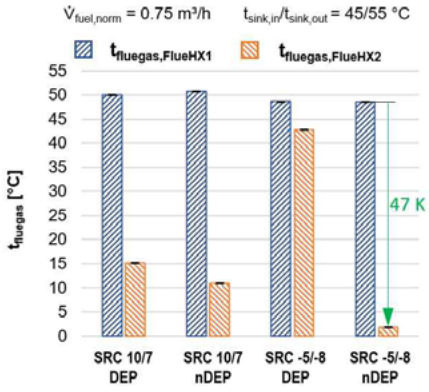

Fig. 5. Flue gas outlet temperatures depending on the cycle configuration

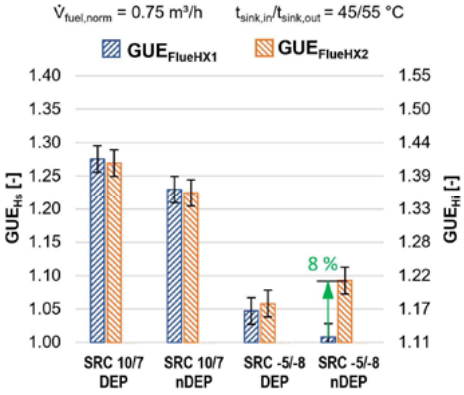

Fig. 6. GUE depending on the cycle configuration

The achieved GUEs at different heat source temperatures and different cycle configurations are shown in Fig. 6. At a heat source temperature of $t_{source,in/out}$ = +10/+7 °C the GAHP with a refrigerant cooled flue gas heat exchanger and the GAHP with the water cooled flue gas heat exchanger are showing nearly the same Gas Utilization Efficiencies. The higher recovered heat flow rate from the flue gas due to the lower flue gas outlet temperature gets compensated by the lower refrigerant mass flow rate and the negative effect of the refrigerant side pressure loss in the refrigerant cooled flue gas heat exchanger. At a heat source temperature of $t_{source,in/out}$ = -5/-8 °C the GAHP with a refrigerant cooled flue gas heat exchanger shows an increase of the GUE with as well as without the dephlegmator. The highest increase of the GUE_{Hs} from 1.01 ($GUE_{FlueHX1}$) to 1.09 ($GUE_{FlueHX2}$), i.e. by around 8 % can be achieved at "SRC -5/-8 nDEP" (see Fig. 6).

In Fig. 7 the heat flow rates at the water cooled absorbers (ABS-1 & ABS-2) are shown. The heat flow at the absorber results from cooling the refrigerant to the saturation state, liquefying the refrigerant, the released heat during the absorption of the refrigerant by the poor solution, and cooling the solution dependent on the heat sink inlet temperature. Fig. 7 should show the change of the heat flow rates in the water cooled absorbers (Q_{ABS-1} & Q_{ABS-2}) if the flue gas is cooled by the refrigerant. The measurements have shown that the temperature of the rich solution at the outlet of the solution cooled absorber does not significantly change if the refrigerant enters the solution cooled absorber at a higher temperature due to the limitation of the heat flow rate (pinch-point) which can be transferred to the rich solution. As the temperature of the rich solution at the water cooled absorber outlet also does not significantly change, the heat flow transferred to the refrigerant in the refrigerant cooled flue gas heat exchanger is rejected to the heat sink in the water cooled absorbers. It can also be seen that the heat flow rate transferred in ABS-1 is much lower compared to the one in ABS-2. The change in the heat flow rate mainly occurred in ABS-2, which means that the heat flow rate supplied in the refrigerant cooled flue gas heat exchanger is mainly rejected in ABS-2. E.g., within the operating condition "SRC -5/-8 nDEP" (see Fig. 7) the total heat transferred to the heat sink in the absorbers increased from 5.3 kW to 6.5 kW, i.e. by around 23 %. Due to the decreased mass flow rate of the refrigerant with the refrigerant cooled flue gas heat exchanger the heat flow rate to liquefy and to absorb the refrigerant is lower compared to the configuration with the water cooled flue gas heat exchanger. Only the capacity to cool the refrigerant from a superheated state to the saturation state increases. Therefore, the increase of the rejected heat flow rate in the absorbers is lower than the recovered heat flow rate in the refrigerant cooled flue gas heat exchanger.

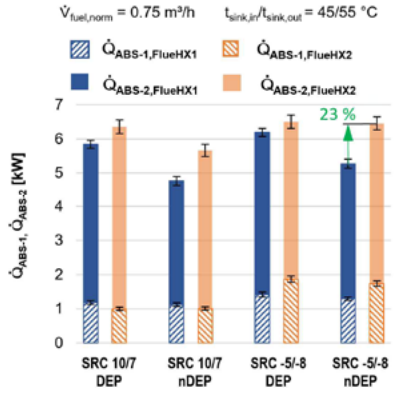

Fig. 7. Comparison of the heat flow rate in the water cooled absorbers

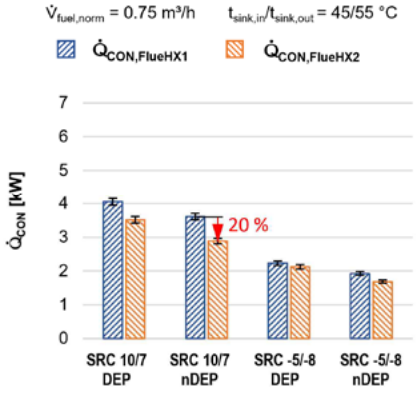

Fig. 8. Comparison of the heat flow rate in the condenser

Fig. 8 shows exemplarily the impact of the reduced refrigerant mass flow rate on the condenser capacity. The impact on the evaporator capacity is similar to the one described at the condenser. In principle the decrease of the condenser capacity is higher if the decrease of the refrigerant mass flow rate is higher, which is the case at a higher heat source temperature (see Fig. 4). For example at the operating condition "SRC 10/7 nDEP" the condenser capacity was reduced from 3.6 kW to 2.9 kW, i.e. by 20 % (see Fig. 8). Basically the reduction of the condenser capacity and the increase of the absorber capacity balance each other at "SRC 10/7" which does not cause an advantage for the refrigerant cooled flue gas heat exchanger in the overall efficiency as explained in context to Fig. 6. At a lower heat source temperature, e.g. "SRC -5/-8 nDEP", the increase of the absorber capacity (from 5.3 kW to 6.5 kW) outperforms the decrease of the condenser capacity (from 1.9 kW to 1.7 kW) which leads to a higher heat flow rate transferred to the heat sink (+1 kW) and therefore to a higher GUE.

3.3. Further optimization potential

As mentioned in chapter 3.2 the refrigerant side pressure loss in the refrigerant cooled flue gas heat exchanger (see Fig. 9) had a negative effect on the GUE. The influence of the pressure loss in the refrigerant cooled flue gas heat exchanger on the GUE was previously experimentally determined by Wagner and Rieberer [6]. In general the pressure loss in the refrigerant cooled flue gas heat exchanger is higher if the ammonia mass flow rate is higher, due to a higher volume flow rate and therefore a higher flow velocity of the refrigerant. In the case of the working pair ammonia/water the ammonia mass fraction has also an influence on the density of the refrigerant and therefore an influence on the volume flow rate and the flow velocity. The mean refrigerant flow velocity in the refrigerant cooled flue gas heat exchanger is shown in Fig. 9 and was calculated according to Eq. (5). Even though the refrigerant mass flow rate at "SRC 10/7 nDEP" is higher than at "SRC 10/7 DEP" (see Fig. 4) the refrigerant velocity is lower at "SRC 10/7 nDEP" due to the higher refrigerant density caused by the lower ammonia mass fraction in the refrigerant (see Fig. 3). Due to the lower refrigerant velocity the pressure loss at "SRC 10/7 nDEP" is slightly lower compared to the pressure loss at "SRC 10/7 DEP". The pressure loss showed a maximum of 0.023 MPa at "SRC 10/7 DEP". At a heat source temperature of "SRC -5/-8" the pressure loss was less than half of the pressure loss at "SRC 10/7" (see Fig. 9), mainly due to the lower refrigerant mass flow rate.

Fig. 10 shows the GUE of the GAHP with the water cooled ($GUE_{FlueHX1}$) and the GUE of the GAHP with the refrigerant cooled flue gas heat exchanger ($GUE_{FlueHX2}$) as shown in Fig. 6. In addition to these values a theoretically determined GUE of the GAHP with the refrigerant cooled flue gas heat exchanger ($GUE_{FlueHX2,\Delta pFlueHX2\approx0}$) is shown if the refrigerant side pressure loss can be omitted. The pressure loss in the refrigerant cooled flue gas heat exchanger caused a decrease of the GUE_{Hs} between 2.5 % ("SRC -5/-8") and 4 % ("SRC 10/7"). Without the pressure loss the highest increase of the GUE_{Hs} from 1.01 ($GUE_{FlueHX1}$) to 1.12 ($GUE_{FlueHX2,\Delta pFlueHX2\approx0}$), i.e. by around 11 % can be achieved at "SRC -5/-8 nDEP" (see Fig. 10).

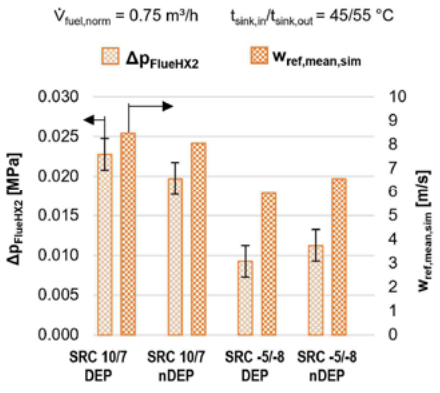

Fig. 9. Refrigerant side pressure loss ($\Delta p_{FlueHX2}$) and mean refrigerant velocity ($w_{ref,mean,sim}$) in FlueHX2

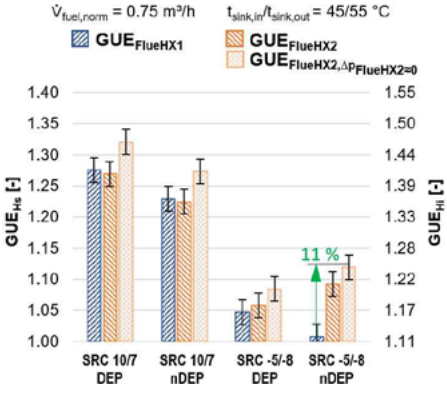

Fig. 10. Effect of the pressure loss in FlueHX2 on the GUE

4. Conclusion

A gas-fired absorption heat pump (GAHP) with a conventional, i.e. water cooled, flue gas heat exchanger was compared to a GAHP with a novel refrigerant cooled flue gas heat exchanger. The influence of the dephlegmator on the ammonia mass fraction in the refrigerant as well as the flue gas exit temperature were analyzed. Furthermore, the Gas Utilization Efficiency (GUE) and the heat flow rates in the condenser and the water cooled absorbers were compared.

The measurements with the refrigerant cooled flue gas heat exchanger have shown that a lower flue gas temperature at the flue gas heat exchanger outlet could be achieved and thus the dissipation of latent heat into the environment was significantly reduced. The highest benefits could be achieved at a lower ammonia mass fraction in the refrigerant, i.e. if no dephlegmator was in use. This means in a GAHP with a refrigerant cooled flue gas heat exchanger components of the desorber, such as the dephlegmator or the rectification column can be smaller or omitted. An increase in efficiency of the GAHP with a refrigerant cooled flue gas heat exchanger

compared to the GAHP with a water cooled flue gas heat exchanger of up to 8 % within the first tests could be achieved. The refrigerant side pressure loss has hindered a higher increase in efficiency. If the pressure loss could be significantly reduced an increase in efficiency of up to 11 % is possible. At an even higher return flow temperature of the hydronic heat distribution system (e.g. 55 °C) the advantage in efficiency can be further increased.

Hence further efforts are required to reduce the size and the refrigerant side pressure loss of the refrigerant cooled flue gas heat exchanger. The know-how gathered from this experimental analysis will be considered in a simulation model of the GAHP. Furthermore, an economical and ecological analysis will be performed to show the advantage of a refrigerant cooled flue gas heat exchanger and to determine the most suitable cycle configuration.

Abstract

Variable Refrigerant Flow (VRF) system is widely known for its flexibility and energy efficiency. Nevertheless, most of the research has focused on experiments in laboratory. Limited papers discussed the field test case. To enhance operational efficiency, we investigated details of cooling operational behavior through field testing and developed a machine learning-based model for a better control algorithm. We conducted the test in a university office building. The power consumption under cooling mode was investigated. In addition, a Support Vector Regression algorithm-based model has been built to predict the power consumption of the VRF system. The penalty parameters in the SVR model have been optimized to decrease the generalization error of the model. We found that the compressor frequency and condensing temperature are the two most important parameters for the accurate. The mean relative error of the model was 7% for outdoor unit power consumption when we compared experimental data and modeling results. The modeling results showed that if the compressor frequency, outdoor fan speed, and condensing temperature were the same, the power consumption should be the same.

1. Introduction

Variable refrigerant flow (VRF) systems have been introduced to the U.S. at around 2002 and are widely used in commercial and office buildings [1]. VRF system is known for its flexibility and energy-efficiency. Some researchers studied the VRF system in the laboratory. For example, Yun et al. [2] conducted a series of experiments in the multi-calorimeter consisting of one outdoor unit chamber and two indoor unit chambers, as part of their work to develop a load responsive control of the evaporating temperature in a VRF system under cooling operations. The results indicate that increasing the evaporating temperature can reduce the energy consumption of the system by up to 35%. However, the system performance in the field test is sometimes different from that in the laboratory due to the following reasons. First, a steady-state condition is hard to achieve in the field test, since the compressor frequency is typically low in this mode, and thus the system is open under cycling. Second, the ambient condition is uncontrolled, which causes the control logic different from that applied in the laboratory. Thus, more study is needed in the field test.

To fill this gap, we conducted field tests of the VRF system under cooling mode (from April to May 2019) in an office building in MD, US, as shown below in Fig. 1. Seven same indoor units were installed in five rooms. The users controlled the indoor units. The system schematic diagram is given in Fig. 2. This figure shows the system operation status when seven indoor units are in cooling mode as an example. We measured

* Corresponding author. Tel.: +1-301-405-5247.
E-mail address: yhwang@umd.edu.

the pressure, temperature, mass flow rate, and power consumption. The sensors' positions are also shown in this figure. We used DAQ system and made the measurement every two seconds. In this research, we mainly measured and compared the outdoor unit power consumption under cooling only mode. To analyze the data under the same ambient and operation conditions, we also set up a machine learning-based data-driven model.

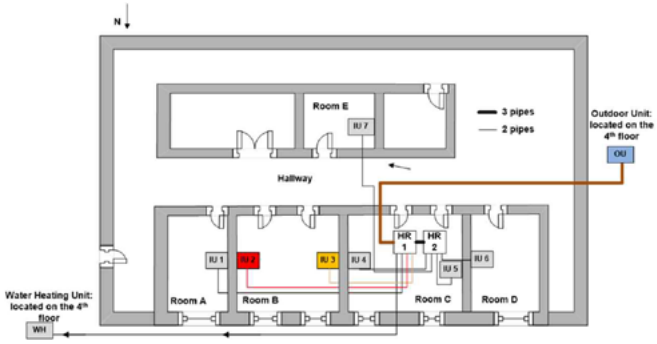

Fig. 1. Room Layout (third floor)

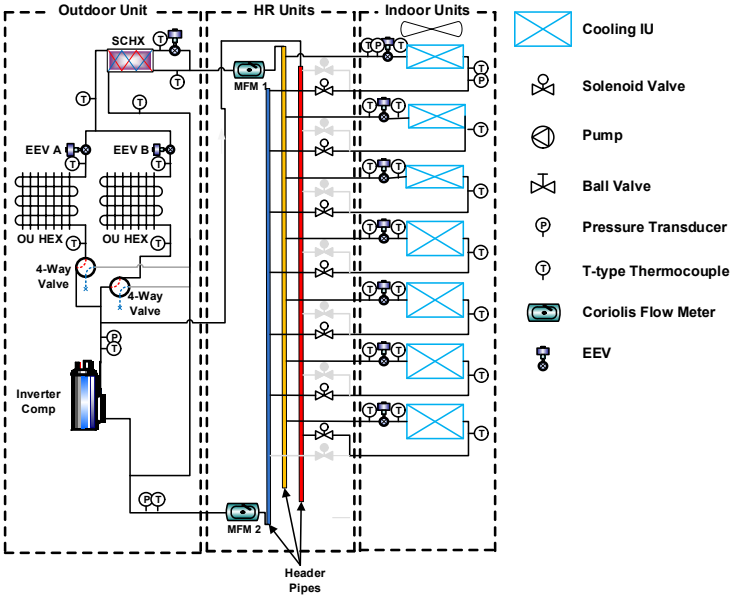

Fig. 2. System Diagram

Recently, the machine learning based model is a hot topic in refrigeration system modeling and fault detection. Kang et al. proposed a Neural Network-based model using weather data including outside temperature, relative humidity, solar radiation, cloudiness, wind speed, and rainfall events as input data to predict the energy consumption [3]. Applying the same algorithm, Chung et al. [4] used ambient temperature, outside humidity, cooling load, saturated temperature, condensate temperature, and condense pressure as input neurons to predict energy consumptions. Shi et al. [5] combined the Bayesian neural network with the ReliefF classifier to detect low refrigerant charge. Yu et al. [6] proposed a VRF charge fault method based on expert modification C5.0 decision tree, and the overall error rate could be decreased by 4%. As a linear regression method, Support Vector Regression (SVR) algorithm is able to build a simple structured model and can be

well explained. According to our literature review survey, Sun et al. [7] proposed a new method based on SVR, which resulted in a decrease in error rate by 2.1%. Li et al. [8] found the various virtual refrigerant charge sensors combined with the SVR could reduce the error rate to 5.5%. Only limited researchers used this algorithm in refrigerant charge fault detection. The SVR algorithm has not been used to predict the system power consumption and COP. In addition, no one discussed the process in penalty parameter optimization of this algorithm in VRF data analysis.

2. Methodology

As mentioned in the introduction part, the first challenge of field test data analysis is searching for semi-steady-state data. A steady-state filter was introduced by some researchers [9]. However, in our field test, this requirement for steady state was so strong that limited data points could be accessed. Thus, we considered the semi-steady state of the data points. The conditions in our study were for the standard deviation of the total mass flow rate to be smaller than 5 g/s in a ten-second time window while the compressor frequency and all the electric expansion valve (EEV) opening degrees kept unchanged. We finally secured 23,323 data points. We defined a two-digit number M. The digit of M means the number of indoor units operating in cooling mode. As an example, “M=3” means that three cooling units operated. Table 1 shows the distribution of the M value of our database. We ignored the group with the count number smaller than 100.

Table 1 Tabulated Data

M Value	Count	Percentage
1	1,167	5.0%
2	6,182	26.5%
3	7,425	31.8%
4	3,191	13.7%
5	371	1.6%

In the field test, the ambient conditions were not controlled. It was challenging to make the system working under the same condition. Thus, modeling work was needed to simulate each working model of the system to compare their performance under the same conditions. In the model, SVR was applied. SVR was a regression algorithm based on a classification algorithm called Support Vector Machine. The objective of support vector machine algorithm is to find a hyperplane in a space that distinctly classifies the data points [10]. For the details of this algorithm, interested readers could read the reference [11]. In a simple two-dimension case, the algorithm was used to solve the following optimization problem:

$$M\dot{n}\left(\frac{1}{2}\|w\|^2 + C\sum_{i=1}^{N}(\xi_i + \xi_i^*)\right) \quad (1)$$

subject to

$$y_i - wx_i - b \le \varepsilon + \xi_i \quad (2)$$

$$wx_i + b - y_i \le \varepsilon + \xi_i^* \quad (3)$$

$$\xi_i, \xi_i^* \ge 0 \quad (4)$$

where symbols, w, and b, are weighting factor and bias, respectively. C and ε are two crucial parameters that would affect the performance of the algorithm. In this study, we conducted a parametric study to optimize the two parameters to build a robust and accurate model. We used Python to conduct this study. Ambient temperature range was from 20 °C to 40 °C.

3. Discussion and results

3.1. Field test

The field test result of the power consumption is shown in Fig. 3. Different rows indicate a different number of cooling units. For example, the first row means that there is only one cooling unit operating. As can be found in Fig. 3, the slope of the data points increases with the number of cooling units. It is because the cooling load is increased with the ambient temperature. In this situation, the system control logic would apply a higher frequency of the compressor. Therefore, the power consumption of the compressor was increased with the

compressor frequency. According to **오류! 참조 원본을 찾을 수 없습니다.**, it is hard to conclude the energy efficiency of different cases. Thus, we conducted a machine learning-based model using the two data sets. The goal was to predict the power consumption under the same ambient and operating conditions.

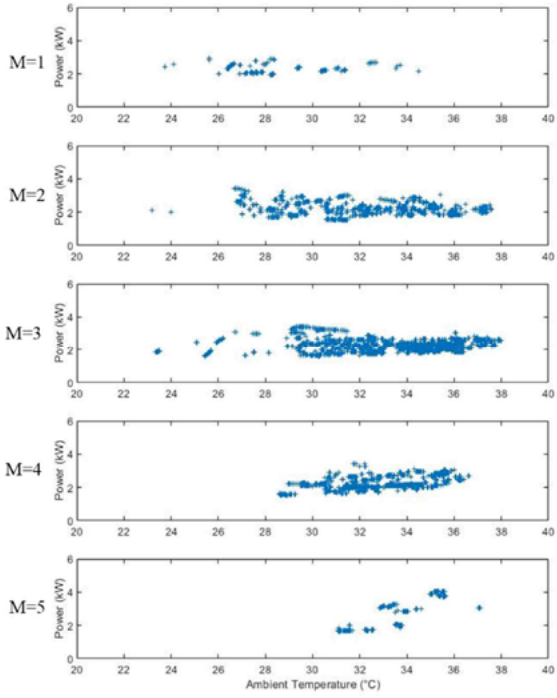

Fig. 3. Power Consumption versus Ambient Temperature

3.2. Modeling results

Typically, the compressor map, which is developed under the steady-state operation at a given ambient condition, is used in VRF system models. However, in the field test, the steady-state point is difficult to find, and the ambient temperature is not controlled so that the compressor map cannot be used. Therefore, we propose the machine learning-based modeling work, which only requires hundreds of field test data points. For this, we conducted data-based modeling work to simulate the power consumption of the system based on the SVR algorithm. This model could be used as a substitution of the compressor map. However, before the modeling work, we need to decide which input parameters should be used. We draw a so-called heatmap to see the effect of seven possible parameters that might affect the outdoor unit power consumption. The parameters selected are outdoor power consumption, compressor frequency, condensing temperature, suction temperature, outdoor fan speed, evaporating temperature, and ambient temperature, respectively. The heatmap shows the covariance between each pair of these parameters. The covariance means the relation between the two parameters. The absolute value of the covariance equals to one means the two parameters are the same, while if the covariance equals to zero, the two parameters had no relationship. In Fig. 4, we used the light color to show a positive relationship, while the dark color to show a negative relationship. We sorted the parameters according to the absolute value of their covariance with the outdoor unit power consumption. The frequency of the compressor was the most significant factor which might affect power consumption. The ambient temperature was nearly not related to outdoor power consumption, at least in certain control logics. It was possible since the significant part of the outdoor unit power consumption is from the compressor. Moreover, the frequency was the essential parameter affecting the compressor power consumption.

The performance of the model was evaluated by Mean Squared Error (MSE), which was defined by the following equation:

$$MSE = \frac{1}{N}\sum_{i=1}^{N}\left(y_{train\ ,i} - y_{pred\ ,i}\right)^2 \quad (5)$$

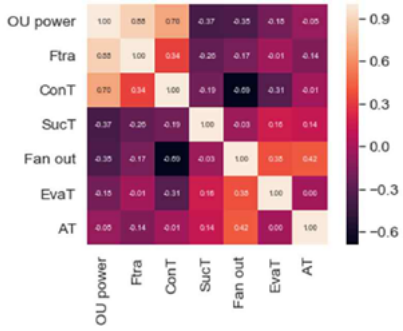

Fig. 4. Covariance Heatmap

It was also known as the loss function in SVR modeling. We built SVR models based on the data sets. All the data were normalized before the modeling. We first used "*C*=1 and *ε*=0.08". The result validation was shown in Fig. 5. The two dash lines in these figures represented "±10%" deviation. The denormalized result is shown in Fig. 5 on the left side. The measured value and the predicted value did not match very well before parameter study. Then we continued to optimize the parameters, C and ε, in the model. We separated the data set into training and testing data set. The training data set has 60% data points, and the testing data set has 40% data points, respectively. The MSE, C, and ε listed here are dimensionless since all the parameters are normalized. From **오류! 참조 원본을 찾을 수 없습니다.**, we could see that for training data set, C should be as large as possible, while for testing data set, the MSE decreased first and then increased as C increased. Thus, C should not be too large. Furthermore, as the right-side figure shows, epsilon should be as small as possible. In this case, *ε* should be small, and C should not be too large. We used "*C*=20 and *ε*=0". The mean relative error, which represented the average percentage error of the prediction, of this case was 7%.

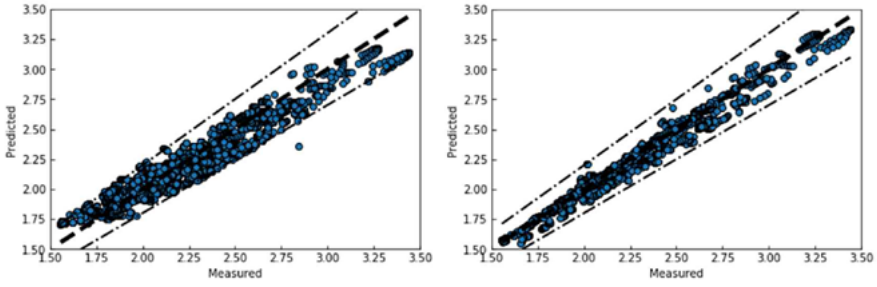

Fig. 5. Model Validation (left: before parametric study; right: after parametric study)

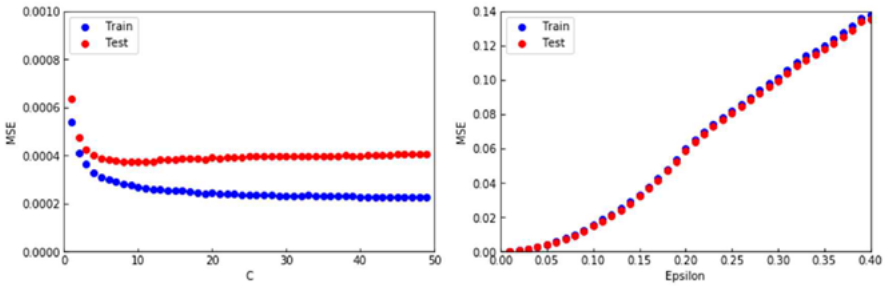

Fig. 6. Parametric study

The final validation result is shown in Fig. 5. As mentioned above, we applied the three operating conditions for the model to predict power consumption. Table 2 shows the modeling results. The columns meant suction temperature, condensing temperature, evaporating temperature, compressor frequency, outdoor fan speed, and outdoor power consumption, respectively. However, the conclusion could not be made without the uncertainty analysis.

Table 2 Modeling results

SucT (°C)	ConT (°C)	EvaT (°C)	Ftra (Hz)	Fan out (RPM)	OU Power (kW)
9.8	45.3	4.5	30	200	2.02
10.2	42.4	6.3	40	200	2.39
12.4	45.4	8.7	50	200	3.18

3.3. Uncertainty analysis and parametric study

We used the method introduced by Lecompte et al. [9] and Koçyigit and Bulgurcu [12] to conduct uncertainty analysis. The uncertainty on the variable y was calculated as a function of uncertainties U_{xi} on each measured variable x_i, as shown in Equation (6).

$$U_y = \sqrt{\sum_i \left(\frac{\partial y}{\partial xi}\right)^2 {U_{xi}}^2} \tag{6}$$

The accuracy of the measurement equipment used was given in Table 3. Since the correlation obtained from the model is complicated, the value of the partial derivative was derived by numerical differentiation. The uncertainty of the modeling power consumption varied when the input values varied. Thus, we only gave the uncertainty of one point, when the suction temperature was 10.2 °C, condensing temperature was 42.4 °C, the compressor frequency was 40 Hz, and the outdoor fan speed was 200 RPM, respectively. We applied a 1% variation to each input parameter, excluding compressor frequency and outdoor fan speed. The condensing temperature and evaporating temperature were calculated by the high pressure and low pressure. Thus, the instrument uncertainty was calculated based on the uncertainty of the pressure sensor.

Table 3 Instrument Uncertainty

Measurement	**Range**	**Uncertainty**
T-type Thermocouples	-200~350 °C	± 0.5 K
Pressure Transducer (High pressure side)	0~6,770 kPa	± 6.34 kPa
Pressure Transducer (Low pressure side)	0~3,339 kPa	± 4.21 kPa
Wattmeter (Outdoor unit)	0~40 kW	± 0.5% FS

Table 4 Uncertainty Analysis

	Instrument uncertainty (℃)	1% Deviation (℃)	OU Power deviation (-)	Uy (-)
SucT	0.5	0.1	0.01%	1.54E-06
ConT	0.1	0.4	0.71%	1.82E-05
EvaT	0.03	0.06	0.06%	6.99E-07
	Uncertainty of the model (B type)			0.5%
	Power meter uncertainty (A type)			0.5%
	Total Uncertainty			0.7%

According to the calculation, the total uncertainty of power consumption should be 0.7%, as shown in **오류! 참조 원본을 찾을 수 없습니다.**. We could further find that the condensing temperature, which also meant the high pressure had the most critical impact on the outdoor power consumption when frequency and outdoor fan speed were fixed. This result was consistent with our result shown in the heatmap.

3.4. Energy efficiency analysis

Fig.7 shows the Coefficient of Performance (COP). Similarly to what we show in Fig.3, the trend of the COP is not apparent when M is small. When M equals 4 or 5, as the ambient temperature increases, the COP of the system decreases. The reason might be that when only 1 or 2 indoor units operated, the cooling load was not high. Thus, the compressor was working under low frequency, which caused the efficiency of the compressor was low. This would make a complicated result for the COP. However, when the compressor frequency was high, the efficiency of the heat exchanger would be a significant factor. When ambient temperature decreased, the heat transfer efficiency of the outdoor unit heat exchanger increased, and the COP of the system should also increase.

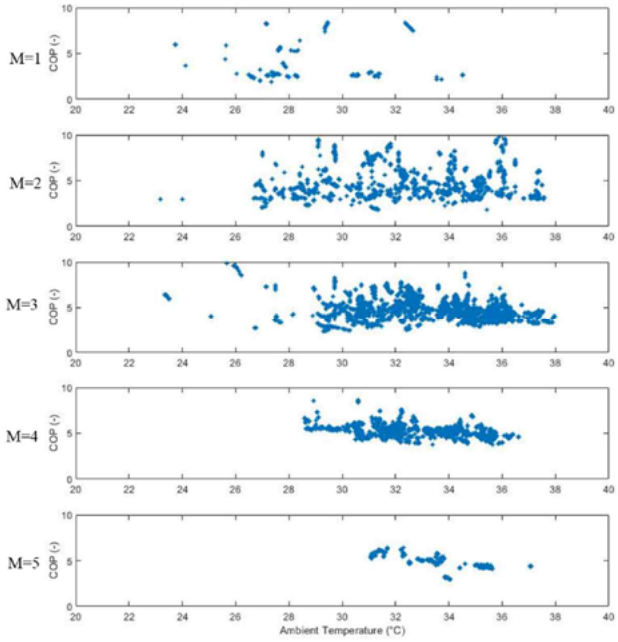

Fig. 7. COP versus Ambient Temperature

4. Conclusions

To enhance the operational efficiency of VRF system, we investigated details of cooling operational behavior through field testing and developed a machine learning-based model for better control logic development. In the test conducted in a university office building, the power consumption under cooling mode was investigated while the number of indoor units operating varied. As the number of indoor units operating increased, the positive linear relationship between power consumption and ambient temperature was increasingly evident for cooling-only mode. Moreover, an SVR algorithm-based model was built to predict the power consumption of the VRF system by five groups of inputs. The penalty parameters in the SVR model were optimized to decrease the generalization error of the model. According to the study, when C is equal to 20, and ε is equal to 0, the model had the best performance. We also found that the compressor frequency and condensing temperature were the two most important parameters for the accurate prediction of outdoor unit power consumption. The mean relative error, which means the average prediction error, of the model was 7% for outdoor unit power consumption when we compared experimental data and modeling results. Based on the field test and modeling work conducted, we found that the power consumptions of cooling only mode were the same if the five groups' inputs were fixed. Future work could be conducted to study heat recovery mode of the VRF system.

Nomenclature

C	penalty parameter
ConT	condensing temperature (°C)
COP	coefficient of performance
EEV	electric expansion valve
EvaT	evaporating temperature (°C)
Ftra	compressor frequency (Hz)

Abstract

Climate change concerns have driven the development of lower Global Warming Potential (GWP) fluorocarbon refrigerants and transition away from incumbent HFC refrigerants is already in progress in multiple applications. In this paper, R-516A, a ternary azeotropic refrigerant with GWP of 131 (AR5) and essentially a near drop-in of R-134a, is evaluated as a refrigerant for air-to-water chiller and heat pump applications. Performance and application map of R-516A are compared to the R-134a baseline as well as other HFO solutions.

Keywords: Low GWP refrigerant ; R-516A ; R-134a ; Oil-free compressor ; Low ambient heat pump

1. Introduction

The HVAC&R industry continues to strive to meet stringent energy regulations while transitioning to environmentally friendly refrigerants with lower global warming potential (GWP) in an effort to minimize the carbon footprint. Global regulations such as F-gas Regulation and Kigali Amendment to the Montreal Protocol are also forcing the adoption of refrigerants that lead to lower CO_2 direct emission indicated by the GWP values.

In a typical office building, heating and comfort cooling accounts for approximately 40% of the total energy consumption [1]. Therefore, there is a constant demand in search of more efficient systems. For that reason, there are emerging opportunities for oil-free compressors to be further utilized due to their superior efficiency and lower energy and maintenance cost throughout the life of the compressor. One potential application would be low ambient heat pump systems where typically today, positive displacement compressors are being used with high density refrigerants such as R-410A with relatively high GWP of 1924 (AR5) [2]. In this paper, the potential of using low GWP refrigerant R-516A in low ambient heat pumps will be evaluated.

2. Refrigerant properties

R-516A

R-516A is a mildly flammable (A2L) refrigerant with a low GWP of 131 (AR5) [2]. This fluid and early versions of this fluid (same components of slightly different compositions) have been extensively studied for the possibility of replacing R-134a in medium pressure chillers [3-4]. Results were promising where R-516A was shown to be essentially a drop-in like fluid to R-134a in terms of system design. In this work, we will focus on evaluation of R-516A in low ambient heat pumps as a replacement solution to R-134a.

2.1. Compatibility and stability

R-134a is used with polyol ester (POE) type lubricating oils. The miscibility of R-516A was tested with typical POE lubricants over a wide range of concentrations and temperatures that covers the operating ranges typically encountered in commercial refrigeration and air-conditioning; the operating range of R-516A was found to be comparable to that of R-134a.

The stability of R-516A in the presence of materials that it would likely encounter in practical use was evaluated in sealed tube tests according to the ASHRAE Standard 97-2007. At the evaluated test conditions, R-516A and R-516A/POE blends in the presence of steel, copper, and aluminum showed thermal stability similar to that of R-134a.

2.2. Flammability

R-516A's A2L safety classification indicates that it is a lower toxicity and lower flammability refrigerant. The flammability properties of R-516A are shown in Table 1. The burning velocity was measured using the worst case of formulation for flammability (WCF) as defined by ASHRAE 34.

Table 1. Flammability characteristics of R-516A

Flammability parameters	
LFL (%v/v) @ 23°C	5
UFL (%v/v) @ 23°C	14
Burning velocity (cm/s) @ 23°C	4.8
Heat of combustion (MJ/kg)	11.2

2.3. Thermodynamic properties

The fluid and thermodynamic properties of R-516A are presented in Table 2 and compared to R-134a as well as other lower GWP R-134a replacements. The vapor pressure of R-516A is very close to R-134a for a wide range of temperatures with only minor differences observed at temperatures above 60°C [4].

Table 2. Fluid and thermodynamic properties of R-134a and replacement refrigerants

	R-134a	R-516A	R-513A	R-1234ze(E)
GWP_{100} (AR5) [2]	1300	131	573	<1
Flammability Class	1	2L	1	2L
Bubble point (°C) at 1atm*	-26.3	-29.6	-29.6	-19.0
Dew point (°C) at 1atm*	-26.3	-29.6	-29.5	-19.0
Critical Temperature (°C)*	101.1	96.8	94.9	109.4
Critical Pressure (MPa)*	4.0	3.6	3.6	3.6
Liquid Density at 25°C (kg/m^3)*	1206.7	1069.2	1134.2	1163.1
Vapor Density at 25°C (kg/m^3)*	32.4	34.5	37.6	26.3

*R-134a, R-513A and R-1234ze(E) properties were obtained from REFPROP [5]. R-516A properties were obtained through proprietary measurements and models.

3. Results

In order to be utilized in a low ambient heat pump, the evaporating temperature must be below -25°C, which makes R-516A a suitable refrigerant for this application. R-516A and R-513A were compared to R-134a based on an oil-free R-1234ze(E) optimized compressor model with same electricity power input inside the aero map. This small capacity compressor utilizes a plate heat exchanger economizer.

The performance of the refrigerants were calculated at the following conditions:

Cooling
Evaporation Temperature = 7.2°C
Condensation Temperature = 54.4°C
Temperature approach of economizer = 3K
Evaporator Superheat = 11.1K
Condenser Subcooling = 8.3K

Heating
Evaporation Temperature = -7°C
Condensation Temperature = 50°C
Temperature approach of economizer = 5K
Evaporator Superheat = 5K
Condenser Subcooling = 5K

When the compressor performance of R-516A was compared to that of R-134a and R-513A with same motor design, both capacity and COP for cooling and heating of R-516A and R-513A were found to be slightly lower than R-134a, Figure 1 and 2. R-516A showed very similar performance to R-513A, but with significantly lower GWP. In terms of compressor operation speed, R-516A needs slightly lower speed than R-134a but slightly higher speed than R-513A.

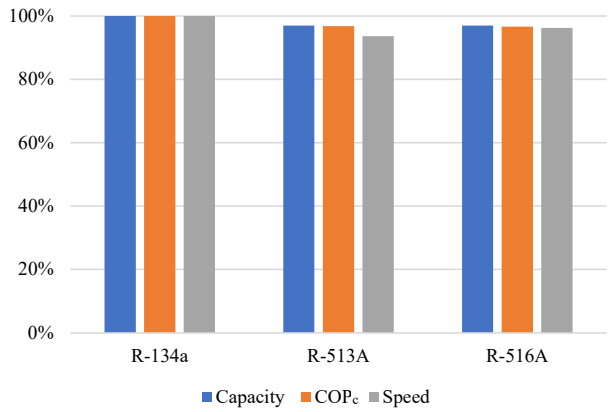

Fig. 1. Cooling mode compressor performance prediction of R-134a, R-513A, and R-516A in a R-1234ze(E) optimized compressor

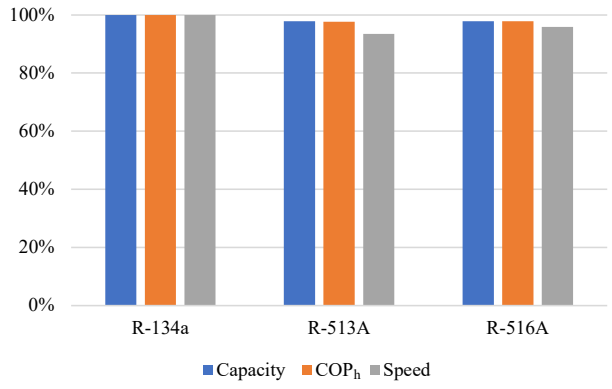

Fig. 2. Heating mode compressor performance prediction of R-134a, R-513A, and R-516A in a R-1234ze(E) optimized compressor

In terms of discharge temperature, both R-513A and R-516A showed similar values that were lower than R-134a by approximately 6K lower at the cooling condition and 8K lower at specific heating condition (Fig. 3).

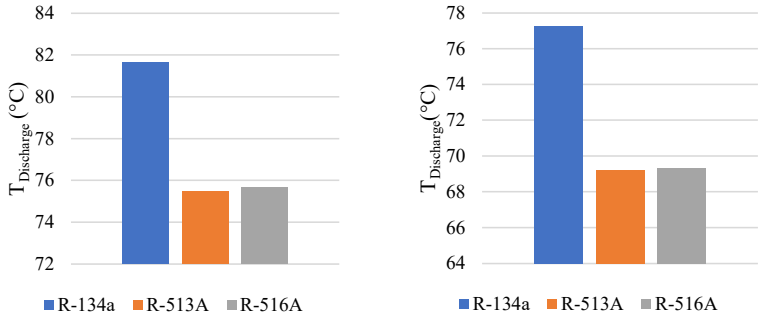

Fig. 3. Cooling (left) and heating (right) mode discharge temperature calculation of R-134a, R-513A, and R-516A in a R-1234ze(E) optimized compressor

The usage of R-516A was also evaluated in a larger capacity oil-free compressor optimized for R-134a and utilizing a flash tank economizer. In general, the trends are similar regardless of whether the compressor was optimized for R-1234ze(E) or R-134a, but the exact values are slightly different.

The capacity/efficiency comparison provides a couple of interesting highlights (Fig. 4 and 5); R-516A is closer to R-134a for heating than cooling with the efficiency within 1% of R-134a in the large capacity compressor. However, cooling with large capacity model was approximately 1.5% lower than with small capacity model, which was optimized for R-1234ze(E).

The closer capacity and efficiency performance of R-516A to R-134a in heating mode becomes critical when optimizing product designs to either cooling or heating, depending on the primary application driver.

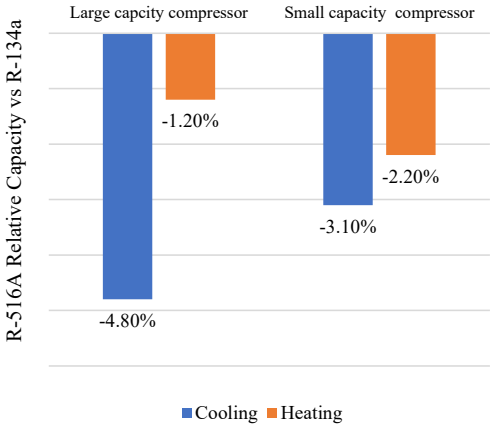

Fig. 4. Relative capacity of R-516A compared to R-134a in a R-134a compressor (left) and R-1234ze(E) compressor (right) in cooling and heating mode

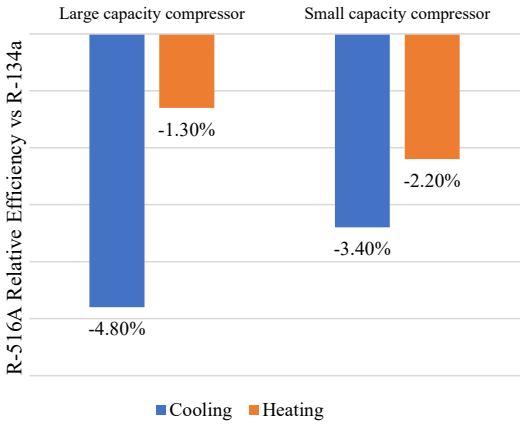

Fig. 5. Relative efficiency of R-516A compared to R-134a in a R-134a compressor (left) and R-1234ze(E) compressor (right) in cooling and heating mode

4. Conclusions

R-516A is a good drop-in alternative directly to R-134a/R-513A compressors with material compatibility qualification and consideration of the mildly flammable nature. R-516A showed matching capacity and efficiency to R-134a both in cooling and heating mode when evaluated in a R-134a optimized oil-free compressor while providing a 90% reduction in CO_2 direct emission. Heating performance of R-516A was closer to R-134a than in cooling mode. Similar stability, compatibility, and oil miscibility of R-516A to R-134a will also allow easy adoption of R-516A as a replacement fluid.

Abstract

Thermally driven chemical adsorption (chemisorption) systems have recently seen increased research and development for their potential in novel energy applications such as solar-driven refrigeration and cold-climate heat pumping. The sorbent-containing adsorber is the core of a chemisorption system where the reversible chemical reaction occurs between the sorbent and the refrigerant, generating useful heat and the desired pressure level. Therefore, properly designed adsorbers with enhanced chemical reaction and heat and mass transfer are critical to overcoming the key limitation of chemisorption technology of low power density and energy efficiency.
In this study, a dynamic model using the finite difference method is developed to simulate the heat/mass transfer and chemical reaction in a chemisorption adsorber using stacked heat pipe plates. The model is first used to simulate and analyze the transient desorption and adsorption performance of a baseline design. Then parametric analysis reveals the impact of key design parameters such as the heat pipe spacing and sorbent plate geometry and identifies optimal design for two different expanded graphite composite sorbents.

1. Introduction

Thermally driven chemical adsorption (chemisorption) systems have recently seen increased research and development for their unique potential in various novel energy applications, including solar-driven refrigeration [1], high-density thermal energy storage [2], and efficient cold-climate heat pumping [3]. The sorbent-containing adsorber is the most important component in a chemisorption system where the reversible chemical reaction occurs between the sorbent and the refrigerant, generating useful heat and desired pressure level. Therefore, properly designed adsorbers with enhanced chemical reaction and heat and mass transfer are critical to overcoming the key limitation of chemisorption technology of low power density and energy efficiency.

Typical adsorber designs use finned tubes [4] and annular tubes [5-6] to exchange heat between the external heat source and the sorbent. The considerable temperature gradient observed leads to a "reaction front" to propagate across the adsorber during the desorption and adsorption phases and reduce the power density of the system [5]. Heat pipe was applied in several studies in finned tube configurations [4,7] to enhance the heat transfer towards the sorbent without a pump.

An innovative design with an integrated heat pipe was recently proposed for high-performance chemisorption adsorber [8]. The new design uses stacks of heat pipe plates to significantly enhance the heat transfer between the sorbent and the external heat source/sink. On the other hand, there is a trade-off between the heat transfer improvement with larger heat transfer surfaces and energy efficiency loss due to increased thermal mass and reduced sorbent charge. Moreover, the heat and mass transfer in the sorbent is also affected by the height/radius ratio and inner/outer radius ratio of the heat pipe and sorbent assembly. The existing dynamic models of chemisorption adsorbers are dominantly based on annular [5-6] and finned-tube [4] configurations, which have very different heat and mass transfer characteristics compared with the new heat pipe plate design. Therefore, a detailed model for the adsorber is needed to analyze the influence of these design parameters and identify the optimal design for the highest performance.

This study develops such a dynamic model using the finite difference method to simulate the heat/mass transfer and chemical reaction in the heat-pipe-integrated adsorber. The model is first used to simulate and analyze the transient desorption and adsorption performance of a baseline design. Then parametric analysis reveals the impact of key design parameters such as the heat pipe density and sorbent plate geometry using different sorbents and identified the optimal design for the sorbents.

2. Dynamic Model of the Heat-pipe-integrated Adsorber

The adsorber is a cylindrical pressure vessel housing a heat exchanger made up of disc-shaped steel plates engineered in such a way as to allow a heat transfer fluid (steam or pumped water) to flow within the discs. There is a hollow center through all the salt and heat pipe plates from top to bottom, providing extra passage for ammonia vapor to flow in and out of the salt in the center of the plate. The heat exchanger of the adsorber provides thermal energy to or removes thermal energy from a matrix material infused with a salt such as $CaCl_2$ that reversibly adsorbs ammonia vapor. The matrix is hosted in between the heat exchanger discs and in good contact with the heat exchanger surfaces. The adsorber has an opening at the top to allow ammonia vapor to flow to the condenser or back from the evaporator, depending on the operating mode.

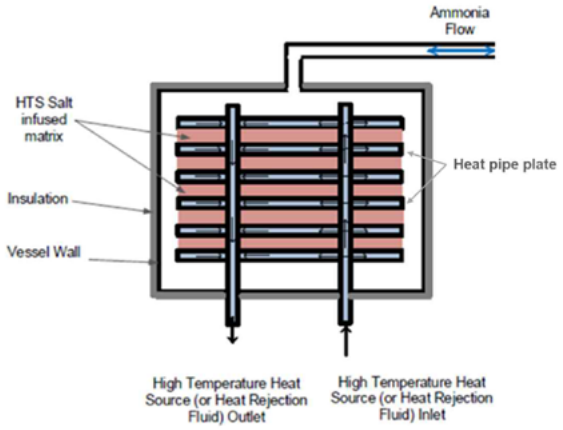

Fig. 1. Schematic of the heat-pipe-integrated adsorber [8]

During operation, the heat pipe discs conduct heat to or from the sorbent plates, leading to the endo- or exothermic chemical reaction between the salt and ammonia vapor to occur. With the proceeding of the reaction, the ammonia molar concentration around the salt grain changes, creating a driving force for the ammonia vapor to diffuse towards the low-concentration region. During desorption, the ammonia vapor accumulated in the interior of the salt plate eventually arrives at the inner or external perimeter of the sorbent plate and gets released into the adsorber chamber. During adsorption, ammonia vapor from the evaporator diffuses into the sorbent plates from the perimeter to get adsorbed by the "dry" salts.

Based on the geometry and operation of the heat-pipe-integrated adsorber, the coupled heat-and-mass transfer and chemical reaction inside the sorbent plates can be described in detail with a system of differential equations. The heat-and-mass transfer differential equations are established on a representative differential control volume (c.v.) as shown in Fig. 2. The salt plate is a typical cylindrical geometry that can be divided into differential "rings." The cross-section of the ring is rectangular, and by using cylindrical coordination $z - r$ the differential c.v. can be described as c.v. P is a representative c.v., with the adjacent c.v. termed east/west/north/south. The distance between the center of adjacent c.v. in the radial direction is defined as dr, and in the vertical direction as dz. The dimensions of the c.v. are determined by the number of c.v., created as well as the absolute radius from the c.v. center to the centerline of the cylinder.

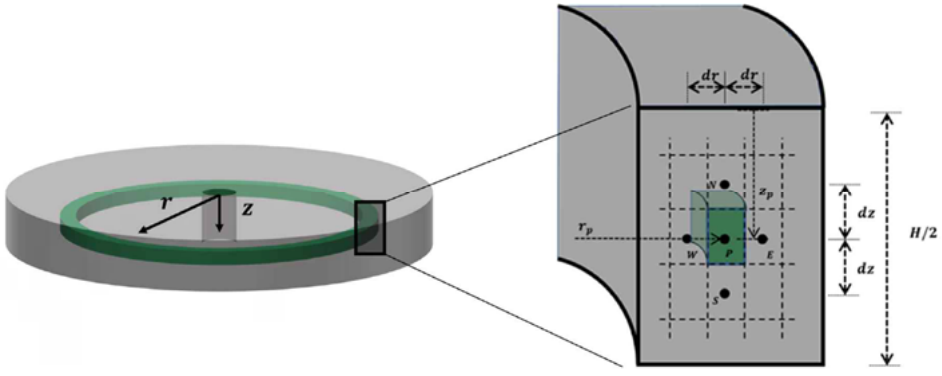

Fig. 2. Schematic of the differential control volume ring

The governing equations to describe the heat and mass transfer process are established based on the following assumptions:

1. The temperature of heat pipe discs is uniform across the entire heat pipe stack;

2. Heat exchanger metal temperature is the same as the steam/water inside;
3. The radiative, convective, and conductive heat transfer between ammonia vapor with the heat exchanger metal and sorbent is neglected;
4. The thermal mass of the adsorber vessel shell is neglected;
5. Uniform pressure around heat pipe/sorbent stack;
6. Ammonia vapor travels inside the sorbent plate only through diffusion;
7. The heating/cooling power through the adsorber heat exchanger during heating-desorption and cooling-adsorption is assumed to be constant, i.e. the temperature difference between the heat transfer medium in the heat exchanger and the adjacent sorbent is constant.

Since the sorbent plates are vertically symmetrical, the model only needs to describe the upper half of the entire plate. The overall energy balance equation for a control volume can be expressed as in equation (1):

$$\Delta Q_{int} = \dot{Q}_z + \dot{Q}_r + \dot{S}_{chem} \tag{1}$$

Where ΔQ_{int} is the change of internal energy, $\dot{Q}_z$ is the net heat inflow in the vertical direction, $\dot{Q}_r$ is the net heat inflow in the radial direction, and $\dot{S}_{chem}$ is the reaction heat. Applying Fourier's law for heat transfer between adjacent c.v., the vertical conduction can be calculated as equation (2):

$$\dot{Q}_z = \dot{Q}_n - \dot{Q}_s = K_T \cdot \frac{\partial^2 T}{\partial z^2} \cdot dr \cdot r \cdot 2\pi \cdot dz \tag{2}$$

Where K_T is the thermal conductivity, and $\dot{Q}_n$ and $\dot{Q}_s$ are heat conduction with the two vertically adjacent c.v. Similarly, for heat conduction in the radial direction can be calculated as in equation (3):

$$\dot{Q}_r = \dot{Q}_e - \dot{Q}_w = K_T \cdot \frac{\partial^2 T}{\partial r^2} \cdot dz \cdot r \cdot 2\pi \cdot dr + K_T \cdot \frac{\partial T}{\partial r} \cdot dz \cdot 2\pi \cdot dr \tag{3}$$

And finally, equation (4) calculates the chemical reaction heat in the c.v., with $N_{NH3,i}$ the ammonia change associated with the reaction, $\Delta H_{r,i}$ the reaction heat, and n_{salt} the volumetric mole density of salt in the c.v.

$$\dot{S}_{chem} = S_{vol} \cdot V = \Sigma \frac{dN_{NH3,i} \cdot \Delta H_{r,i}}{dt} \cdot n_{salt} \cdot dz \cdot dr \cdot r \cdot 2\pi \tag{4}$$

By defining the thermal diffusivity as in equation (5), the energy balance equation (1) can be re-written as equation (6) by inserting equation (1)-(5):

$$\alpha = \frac{K_T}{\rho \cdot Cp} \tag{5}$$

$$\frac{1}{\alpha} \cdot \frac{\partial T}{\partial t} = \frac{\partial^2 T}{\partial z^2} + \frac{\partial^2 T}{\partial r^2} + \frac{1}{r} \cdot \frac{\partial T}{\partial r} + \frac{1}{K} \cdot S_{vol} \tag{6}$$

Similar to heat conduction between adjacent c.v., ammonia vapor in the interconnected pores flows across the boundary of c.v. through diffusion driven by the molar concentration difference. The mass balance can be expressed as in equation (7)

$$\Delta N = J_z + J_r + J_{chem} \tag{7}$$

Where N is the total amount of ammonia vapor in the pores of the c.v., J_z is net mass inflow flux in the vertical direction, J_r for radial direction, and J_{chem} is the ammonia vapor change due to chemical reaction. By assuming Darcy flow, the diffusivity of the sorbent plate can be calculated from its permeability in equation (8):

$$D = -\frac{K_D}{\mu} \cdot P_p \cdot \varphi \tag{8}$$

Applying Fick's first law the diffusion mass flux can be calculated between vertically and horizontally adjacent c.v. as in equation (9) and (10):

$$J_z = J_n - J_s = D \cdot \frac{\partial^2 n}{\partial z^2} \cdot dr \cdot r \cdot 2\pi \cdot dz \tag{9}$$

$$J_r = J_e - J_w = D \cdot (\frac{\partial^2 n}{\partial r^2} \cdot r \cdot 1 \cdot dz + \frac{\partial n}{\partial r} \cdot dz \cdot 2\pi) \cdot dr \tag{10}$$

With the ammonia vapor flux generated from the chemical reaction as in equation (11), the ammonia vapor mass balance equation (7) can be expressed as in equation (12):

$$J_{chem} = S_{v,n} \cdot V = \Sigma \frac{dN_{NH3,i}}{dt} \cdot n_{sat} \cdot dz \cdot dr \cdot r \cdot 2\pi \tag{11}$$

$$\frac{\partial n}{\partial t} = D \cdot \left(\frac{\partial^2 n}{\partial z^2} + \frac{\partial^2 n}{\partial r^2} + \frac{1}{r} \cdot \frac{\partial n}{\partial r}\right) + S_{v,q} \tag{12}$$

The equilibrium of ammonia-based chemisorption reactions can be expressed by the van't Hoff equation as equation (13), and the chemical reaction kinetics can be described by the semi-empirical equation first proposed by Tykodi et al. [9] and used in various chemisorption reaction simulation studies [3-4]:

$$h\left(P_{eq}\right) = -\frac{\Delta H_r}{RT_{sat}} + \frac{\Delta S_r}{R} \tag{13}$$

$$\frac{dX}{dt} = (1 - X)^n \cdot Ar \cdot h\left(\frac{P_{eq}(T_{sat})}{P_{bcal}}\right) \tag{14}$$

For the upper half-plate, the top boundary is the heat pipe heat exchanger, and therefore the boundary condition for the c.v. on the top layer is the heat exchanger temperature. The bottom of the plate is assumed to be isothermal since the plate is symmetrical. These two boundaries are also assumed to allow no ammonia vapor flow. Around the outer perimeter and inner perimeter (around the center vapor channel) of the plate, the sorbent directly contacts with the ammonia vapor in the adsorber chamber. The heat transfer boundary conditions for the c.v. on the perimeter layer is isothermal since the heat transfer between ammonia vapor and solid sorbent is assumed to be negligible. However, the ammonia vapor next to the boundary sorbent is assumed to be at the sorbent temperature and the chamber pressure.

In a typical chemisorption heat pump cycle as in Fig. 3, the adsorber is connected with a condenser to draw and condense the ammonia vapor from the adsorber during the desorption phase, and an evaporator to supply ammonia vapor to the adsorber during the adsorption phase. In the current study, the condenser and evaporator are assumed to provide constant ammonia pressure based on the saturation temperature instantly. The condensing and evaporating heat is calculated directly from the latent heat of ammonia vapor to and from the adsorber.

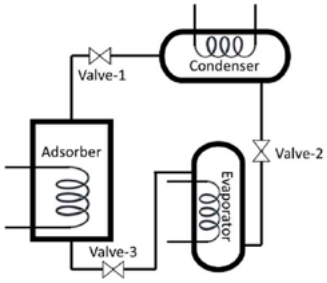

Fig. 3. Schematic of a chemisorption heat pump with one adsorber

A cycle starts with heating and desorbing the sorbent by the high-temperature heat source. At the end of the desorption phase, the heat flux from high-temperature source is stopped and the fluids in the adsorber heat exchanger start to cool the sorbent. Once the condensation is sufficiently reduced, the connection to the

condenser is cut off. The cool and dry salt continuously adsorbs the remainder ammonia vapor in the adsorber chamber until the adsorber chamber pressure reaches the evaporating pressure and the evaporator valve is opened. The operating procedure of a desorption-adsorption cycle of the adsorber is listed in Table 1.

Table 1. operating procedure of desorption-adsorption cycle

Stage	Endpoint	Adsorber heat flow	Valve positions
Desorption	Reached half-cycle time	Heating the sorbent	Valve-1 open, valve-2 and valve -3 closed
Cooldown -1	Condensation stops	Cooling the sorbent	Valve-1 open, valve-2 and valve -3 closed
Cooldown -2	Adsorber chamber reaches evaporating pressure	Cooling the sorbent	Valve-2 open, valve-1 and valve-3 closed
Adsorption	Reached cycle time	Cooling the sorbent	Valve-3 open, valve-2 and valve -1 closed

The performance of the adsorber is evaluated with three parameters: the cooling coefficient of performance (COP), the specific cooling capacity (SCP), and the cooling power density (CPD). The COP is calculated in equation (15) as the ratio of the evaporating heat over the heat transferred from the heat pipe to the sorbent during the desorption phase. The SCP in equation (16) is based on the mass of the sorbent material. The CPD in equation (17) is based on the volume of the heat pipe-sorbent stack enclosure.

$$COP = \frac{Q_{evap}}{Q_{input}} = \frac{\Delta H_{fg} \cdot m_{NH3}}{Q_{input}} \quad (15)$$

$$SCP = \frac{Q_{evap}}{\tau_{cycle}} \cdot \frac{1}{m_{sorbent}} \quad (16)$$

$$CPD = \frac{Q_{evap}}{\tau_{cycle}} \cdot \frac{1}{V_{stack}} \quad (17)$$

3. Modeling Results

In this study, a dynamic model was first developed in MATLAB for a baseline adsorber using the governing equations in the previous section. $CaCl_2$ has been a popular choice in ammonia-based chemisorption systems, and it is selected as the sorbent salt in this study. There are two ammoniate reactions under the assumed refrigeration working condition of evaporating at 0°C and rejecting condensation and adsorption heat at 45°C as listed below. The chemical equilibrium data of $CaCl_2$/ammonia reactions from Neveu et al. [10] and the kinetic coefficients from Wang et al. [11] are listed in Table 2.

$$CaCl_2 \cdot 8NH_3(s) \rightarrow CaCl_2 \cdot 4NH_3(s) + 4NH_3(g)$$

$$CaCl_2 \cdot 4NH_3(s) \rightarrow CaCl_2 \cdot 2NH_3(s) + 2NH_3(g)$$

Table 2. equilibrium and kinetic coefficients for $CaCl_2$ ammoniate reactions

	Parameter	$CaCl_2$-8/4	$CaCl_2$-4/2
Equilibrium	Reaction enthalpy (ΔH_r) [J/mol]	41013	42268
	Reaction entropy (ΔS_r) [J/mol-K]	230.3	229.92
Kinetics	Desorption: Order of reaction (n)	1.005	0.468
	Desorption: Arrhenius term (Ar)	0.0195	0.0045
	Adsorption: Order of reaction (n)	2.104	1.78
	Adsorption: Arrhenius term (Ar)	0.0125	0.0287

To enhance the heat and mass transfer and avoid agglomeration during reactions, the $CaCl_2$ salt is combined with two different porous matrix materials: expanded graphite (EG) and expanded natural graphite treated with sulfuric acid (ENGTSA). Compared with EG, ENGTSA further improves the heat transfer performance at the expense of lower permeability. The physical properties of the composite $CaCl_2$/EG and $CaCl_2$/ENGTSA are

taken from Tian et al. [12] and Jiang et al. [13]. The key parameters of the baseline adsorber and the sorbent materials are listed in Table 3.

Table 3. key parameters of the baseline adsorber and the sorbent materials

Item	Value	Unit
Total height of heat pipe stack	0.6	m
Sorbent plate thickness	0.01	m
Outer diameter of heat pipe and sorbent plates	0.2	m
Inner diameter of heat pipe and sorbent plates	0.01	m
Outer thickness of one heat pipe disc	0.01	m
Density of composite sorbent	450	kg/m3
Porosity of composite sorbent	0.5	-
Salt mass fraction in the composite sorbent	50	%
Thermal conductivity of $CaCl_2$/EG composite	1.	W/m-K
Permeability of $CaCl_2$/EG composite	1×10^{-11}	m^2
Thermal conductivity of $CaCl_2$/ENGTSA composite	40	W/m-K
Permeability of $CaCl_2$/ ENGTSA composite	1×10^{-14}	m^2

The performance of the adsorber is evaluated in one complete desorption-adsorption cycle with a full-cycle time of 40 min, a steam temperature limit of 140°C during desorption, cooling water temperature of 45°C in the adsorber during adsorption. At the start of the desorption phase, all sorbents are at 45°C and $CaCl_2$-$8NH_3$ state. The adsorber contained 40 sorbent plates and 41 heat pipe discs. The sorbent plates consist of 5.63 kg of $CaCl_2$/EG composite, 2.8 kg of which is $CaCl_2$ salt. The desorption lasted the first 1200 seconds of the cycle, followed by 71 seconds of continued condensation in cool down -1 phase, and 200 seconds of standalone cooling down before the final 924 seconds of adsorption. 6989 kJ heat was supplied through the adsorber heat exchanger to the sorbent during the desorption phase to heat the sorbent and support the decomposition of ammoniate salts. During the adsorption phase, 2.1 kg liquid ammonia evaporated, producing 2812.8 kJ cooling. The cooling COP of this baseline setup is 0.402, the SCP is 415.8 W/kg sorbent, and the CPD is 62.2 kW/m^3 based on the heat pipe-sorbent stack volume.

Fig. 4 illustrates the progression of salt state change in the control volume close to the heat pipe through the cycle. Initially, all the salt was in $CaCl_2$-$8NH_3$ state. The salt was heated up to the equilibrium temperature of about 95°C when it started to decompose into $CaCl_2$-$4NH_3$, which later further released ammonia and becomes $CaCl_2$-$2NH_3$ at even higher temperatures. Once the cooling-adsorption starts, the $CaCl_2$-$2NH_3$ compound absorbs ammonia and becomes $CaCl_2$-$4NH_3$ and then $CaCl_2$-$8NH_3$ as the temperature of the salt decreases. The fraction of the $CaCl_2$-$4NH_3$ and $CaCl_2$-$8NH_3$ gradually increases after the desorption-adsorption mode switch in Fig. 4.

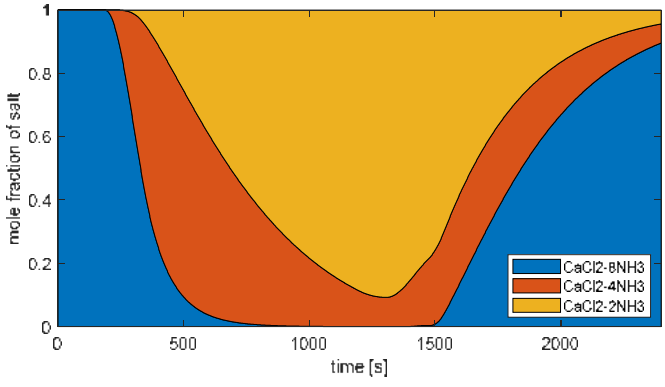

Fig. 4. Different ammoniate salts in control volume at sorbent plate top inner rim

Therefore, the mole fraction of $CaCl_2$-$8NH_3$ in Figure 4 drops quickly after about 300s into initial heating towards the decomposition temperature of the $CaCl_2$-$8NH_3$; then the mole fraction of $CaCl_2$-$4NH_3$ rises due to the 8→4 reaction; its share starts to decline when the 4→2 reaction starts at a higher temperature. The mole fraction of salt in different ammoniate states reverses once the adsorber switched to cool down and adsorption stages.

4. Design optimization

In this section, the performance of adsorbers using different geometries based on the baseline design is evaluated using the dynamic model to identify optimal design for composite sorbents with different heat and mass transfer characteristics and under different cycle times.

Fig. 5. Shows the COP and SCP of adsorbers using the baseline geometry but under cycle time of 20-60 minutes. Generally, the COP increases with cycle time as the reactions have more time to approach completeness, leading to more ammonia evaporation and higher efficiency. On the other hand, the increase of cycle time reduces the averaged cooling power of the EG adsorber as chemical reactions slow down when approaching completeness. In contrast, the SCP of ENGTSA adsorber slightly increases with longer cycle time. It is due to the low reaction completeness constrained by the low permeability of the ENGTSA matrix. Thus, the mass-transfer impeded ENGTSA adsorber requires longer cycle time to reach high reaction completeness under the baseline thin-plate geometry.

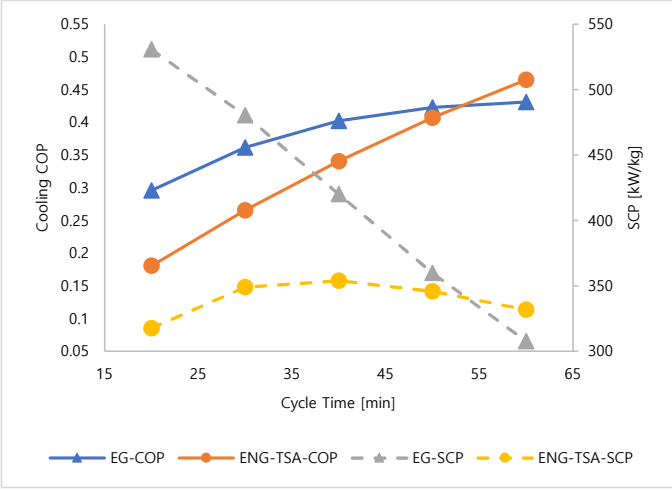

Fig. 5. COP and SCP of the adsorber with baseline geometry under different cycle time

Fig. 6 shows the influence of the sorbent plate thickness on the COP and SCP. Thicker plates contain more adsorbents in the same adsorber, but it also reduces the number of heat pipe discs and thus the heat transfer surface area between the external heat source and the sorbent. Therefore, adsorbers using both types of sorbent demonstrate an optimal sorbent plate thickness about COP and SCP. The performance of the adsorbers with plates thicker than 20mm are limited due to insufficient heat transfer area.

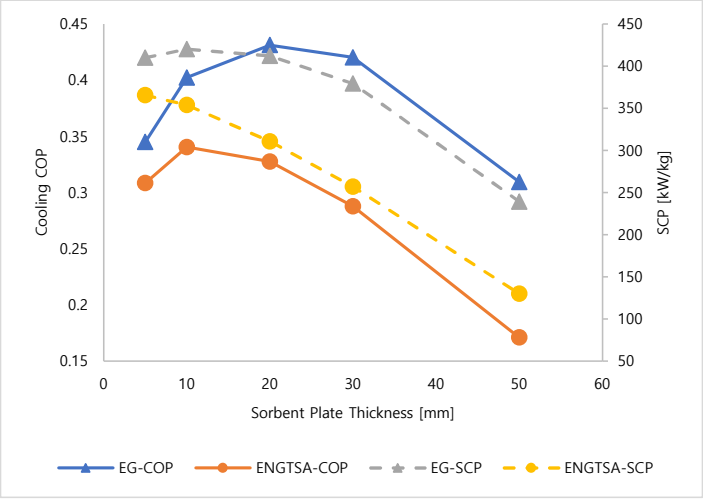

Fig. 6. Different ammoniate salts in control volume at sorbent plate top inner rim

The ENGTSA matrix offers significantly higher thermal conductivity compared with EG at the expense of much lower permeability. Therefore, mass transfer of the ammonia vapor from inside the sorbent to the adsorber chamber could be a limiting factor. Fig. 7 illustrates the influence of the center vent diameter on the adsorber performance. A wider vent leads to more sorbent exposure to the adsorber chamber and therefore better mass transfer. It is manifested by the significant increase of COP for ENGTSA adsorber shown in the left chart in Fig. 7 compared with the flat COP curve of EG. Meanwhile, increasing the vent size reduces the total amount of sorbent in the adsorber, as the outer diameter of the sorbent plate is fixed. Therefore, the power density, as shown in the right chart in Fig. 7 decreases quickly for EG adsorber with little benefit from the improved mass transfer. In contrast, the ENGTSA adsorber sees a peak PD in the trade-off of better mass transfer and less sorbent.

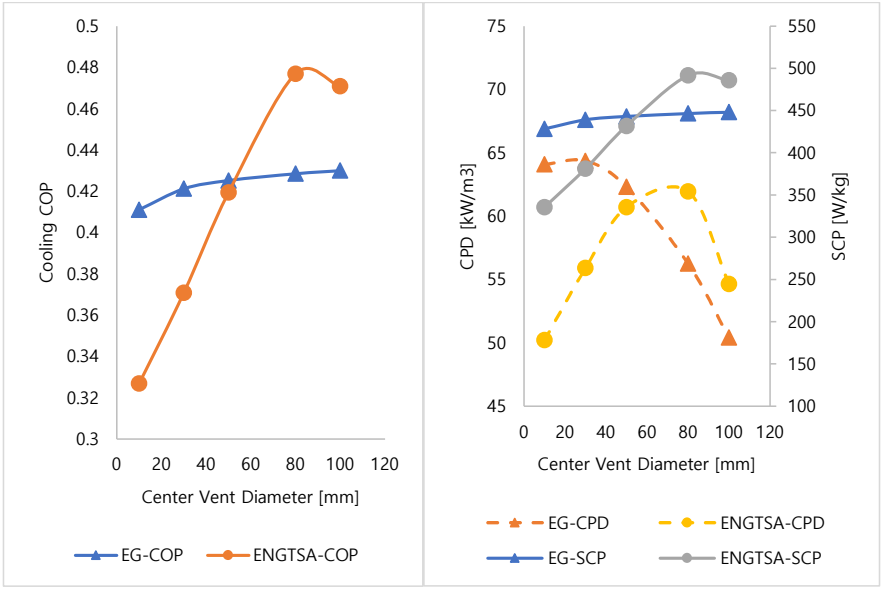

Fig. 7. Different ammoniate salts in control volume at sorbent plate top inner rim

5. Conclusions

This study develops a dynamic model using the finite difference method to simulate the heat/mass transfer and chemical reaction in the heat-pipe-integrated chemisorption adsorber. The model is first used to simulate and analyze the transient desorption and adsorption performance of a baseline design. The dynamic modeling predicts the system performance under different designs, and the effect of each design parameter is examined and the optimal design identified. The sorbent plate thickness affects both the amount of sorbent in the adsorber as well as the available heat transfer surface between the sorbent and the external heat source. Under the overall adsorber geometry constraint, the optimal sorbent plate thickness for EG sorbent is about 20 mm and ENGTSA is about 10 mm. The diameter of the vapor vent at the plate center affects the mass transfer area as well as the amount of sorbent in the adsorber. Since the EG matrix provides sufficient permeability, the widening of the vent doesn't improve the COP noticeably but rather decreases the power density. For ENGTSA with lower permeability, the increase of the mass transfer area by a larger vent significantly improves the COP and the power density of the adsorber, and the optimal vent diameter is found to be 80 mm.

The dynamic model demonstrated its capability of capturing the transient heat mass transfer and chemisorption reaction progression during the adsorber operation for predicting the energy efficiency and power density of the component. The model, once validated with experimental data, can be used for optimizing the design of similar plate-type adsorbers using various sorbent salt and matrix materials of different thermophysical properties.

Evaluation of a low charge heat pump circuit using propane

Clemens Dankwerth, Timo Methler, Simon Braungardt, Christian Sonner, Thore Oltersdorf, Marek Miara, Peter Schossig, Lena Schnabel*

Fraunhofer Institute for Solar Energy System - ISE, Department of Heating and Cooling Technologies, Heidenhofstr. 2, 79115 Freiburg, Germany

Abstract

A low refrigerant charge brine-to-water heat pump circuit was evaluated addressing a heating capacity of 5 – 10 kW and using propane as refrigerant. Propane is a natural refrigerant, has a low global warming potential (GWP) of three and attractive thermodynamic properties. No regulations, except for safety, are expected to apply for this refrigerant. Therefore it was chosen as refrigerant for this evaluation, the refrigerant charge of propane was limited to 150g, resulting in 0.45kg of CO_2 equivalent. The reduction of charge was achieved with different design approaches and techniques: The main goal was to minimize the internal volume on the refrigerant side in all components and tubes. The two heat exchangers and the liquid line are the components impacting the charge the most. To reduce the internal volume, different design aspects were taken into account: The condenser and evaporator are designed with an asymmetric plate profile and a long thermal length, the liquid line was designed as short and thin as possible, and the filter dryer in the liquid line was shifted to the suction line. Also, the refrigerant absorption in the oil has a large impact on the refrigerant charge. The majority of the oil is in the compressor sump and the rest in the refrigerant circuit. To reduce the quantity of refrigerant in the oil, the amount of oil was minimized and the arrangement of components in the refrigerant circuit was chosen carefully to prevent oil retention. The charge reduced heat pump circuit was tested with two different inverter-driven compressors (suction gas-cooled scroll compressor and a hot gas-cooled twin rotary compressor) at various points of operation. This paper presents the results of the experimental evaluation and discusses the safety issues and potential for further optimization.

1. Introduction

The installation and use of heat pumps is increasing worldwide. In parts of Europe, the heat pump has become the dominant heating solution in new buildings. Due to the increasing awareness towards global warming and the need to reduce the use of fossil fuels and environmentally harmful gases, the market share of heat pumps is expected to rise steeply. Heat pumps use electricity for heating purposes with significantly higher efficiency than purely electrical resistance heaters. Combined with electricity from renewable sources, heat pumps can provide building heating without using any fossil fuels. Currently most heat pump systems employ refrigerants with high global warming potential (GWP) refrigerants due to security advantages regarding flammability and toxicity. The global community unanimously banned refrigerants with ODP by the Montreal protocol [13] and is now gradually restricting the maximum GWP for refrigerants. In Europe the F-gas Regulation [9] is implemented to phase out the use of refrigerants with a high GWP. Such regulations encourage and force the shift towards refrigerants with very low GWP, such as natural refrigerants, in a timely

manner. Propane is a well-known refrigerant with excellent thermal dynamic properties and a minimal impact on the environment (GWP =3, ODP =0). Furthermore, no regulations, except for safety, are expected to apply for propane as refrigerant, making it predestined for use in heat pumps. Propane heat pump research and development focuses on developing ***security systems*** [4][5], optimizing ***performance*** [2], reducing ***charge*** [1, 3] and ***comparing*** various ***refrigerants*** i.e. evaluating the different perspectives and making comparisons to other, mainly synthetic, refrigerants [10, 15][12]. This paper will show the first results of a charge-reduced brine-to-water propane heat pump.

2. Baseline for low charge residential heat pump systems

In 2001 and later in 2007, Fernando et al. [7] presented first experimental results of a low-charge propane heat pump. The comprehensive results and findings are part of his PhD thesis [14] on a brine-to-water heat pump with ca. 5 kW heating capacity at -3°C/35°C and a charge of 230g. [6] In 2018, Andersson [1] presented a study on a heat pump capable of 10 kW heating capacity using a refrigerant charge of less than 150g propane (B7/W40) with a non-hermetic compressor. Both studies investigated heat pump concepts, in which unique prototype components as well as an automotive scroll compressor were installed. The employed automotive compressor, however, was neither rated for the use with propane nor was it designed as a hermetic compressor. Another shortcoming was that the source temperature fluctuated strongly because the test environment was too small. The work presented by Andersson provided a baseline for the reduction of charge as well as an identification of the preliminary areas of attention for future research.

There are a few propane-charged systems commercially available, most of which are air-to-water systems for outdoor locations. Outdoor systems are more common due to less security restrictions and concerns. Due to leaking, indoor propane systems could create a hazardous environment. Outdoors any leaked propane would quickly dissipate, thus creating no hazard. Most manufacturers do not employ propane heat pumps for indoor applications due to the high security requirements and the accompanying financial costs. A brief market analysis of available brine-to-water heat pumps from the beginning of 2019 is shown in Figure 1. The black lines show the lines with same charge. The red line marks Fraunhofer ISE's target of a heating capacity between 5 and 10 kW with 150g propane. As seen in the graph, this target results in a specific charge of 15 to 30g/kW, a reduction by a factor of four in comparison to market available heat pumps.

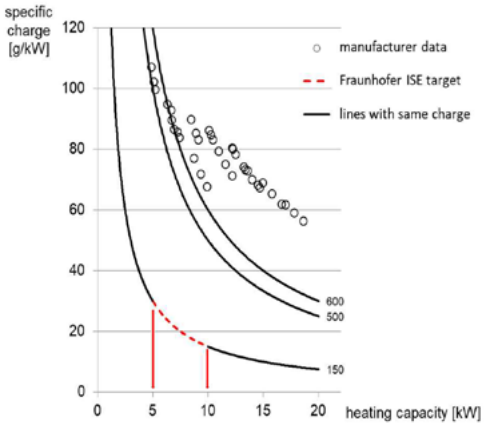

Figure 1: Specific charge over heating capacity of available brine-to-water heat pumps

A more elaborate market study with a wider range of application of air-to-water and brine-to-water heat pumps was done by Palm [11] as part of the LifeFront report [8]. These reports are comparable to the market research done preliminary to this low-charge heat pump development project.

3. Goals and ambitions

The project goal is to create a heat pump using only commercially available components and to achieve 5-10 kW heating capacity with a maximum charge of 150g propane. At the same time, the efficiency of the unit must be maximized for these given boundary conditions. The parameters are marked in red in Figure 1 and give a perspective on the significance of this goal. Additionally the charge-reduced compression cycle shall be analyzed in detail. Specific evaluation criteria for comparison purposes will be defined. The knowledge gained shall be transferred to enable the design of an air-to-water heat pump with similar boundary conditions.

4. Test rig

Main refrigerant circuit

The refrigerant circuit was designed and built as shown in Figure 2. As a side effect of minimizing the pipe length and diameters, the overall dimensions were reduced. With dimensions of 700x500x200mm, the refrigeration circuit is small in comparison to other units with the same capacity. The main components used for the heat pump are shown in

Table 1.

No.	Component
1	Compressor
2	Evaporator: Alfa Laval ACH72- 16AH- F
3	Condenser: Alfa Laval CB65- 16AH- F
4	Filter dryer: ALCO PCN 008925
5	Expansion device: Parker SDR2

Table 1: Main components in the refrigeration circuit.

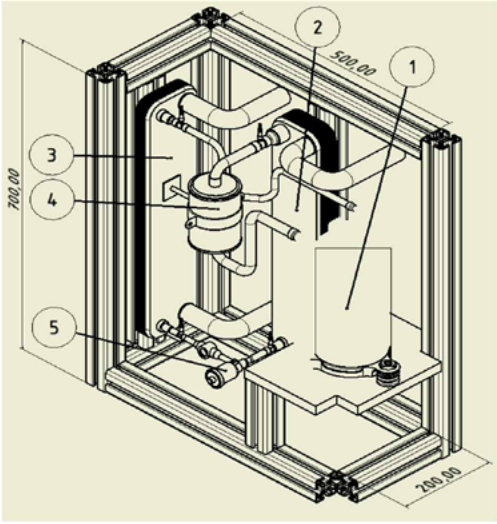

Figure 2: Drawing of the compression cycle

No.	Component
1	Compressor
2	Evaporator: Alfa Laval ACH72- 16AH- F
3	Condenser: Alfa Laval CB65- 16AH- F
4	Filter dryer: ALCO PCN 008925
5	Expansion device: Parker SDR2

During the measurements all changes to the refrigerant circuit have been documented with version numbers. The compressor has been changed during the project duration and from now on will be referred to as system 1 and system 2 respectively. Minor changes result in numbering such as 2.1 ➔ 2.2. This will be clarified if necessary in relevant places.

Measurement procedure

Most measurements were taken in a setup which allowed for variations in charge. First, the initial charge was filled into the heat pump. Operating points were recorded by running the circuit until steady state conditions were reached. Then the measured operation point of the heat pump was run for another 30 minutes in steady state conditions and the mean values during the last few minutes were calculated. The transition to the next operational point was initiated by adding additional 10g of R290 to the system. Once again the system ran until steady state was reached and the described loop was repeated to complete the series of measurements. The temperatures for the secondary circuits were chosen based on typical test parameters in the heat pump sector. For the source temperature -10°C, -7°C, 0°C, 12°C were chosen. These values refer to the inlet temperature. For the sink 35°C, 45°C, 55°C and 65°C were chosen as outlet temperatures of the heat exchanger. For both of the secondary hydraulic circuits, a constant delta T between inlet and outlet of 5K and 3K respectively was maintained as specified in EN14511. Measured data points are designated as "BX/WY" which derives from "brine with temperature X" and "water with temperature Y." The brine always characterizes the source temperature and water the sink temperature.

Test environment

To ensure standardized testing, the conditioning modules, providing the secondary fluids, were used to simulate source and sink and are referred to as secondary modules. These conditioning modules are standardized equipment in the laboratory and have the following adjustable parameters: flow temperature, pressure difference and mass flow. The conditioning module for the sink side is filled with water and the module on the source side with a mixture of ethylene/glycol and water with a freezing temperature of -30°C. Both modules are connected to the building cooling system to ensure operation at all times. All testing was done in a monitored environment with gas detection system and forced ventilation. In case of a propane leakage,

the power supply is switched off and the ventilation enhanced.

5. Results

Simulations

The complete refrigerant circuit was simulated before the physical set up was installed. The simulation software IMST ART was used. Heating capacity simulations are shown in Figure 3. The simulation was done for the operation point B0/W35 with a frequency of 60Hz and 10K superheat. The simulations were based on the available geometric data from the datasheets provided by the manufacturers, excluding compressor volume and oil volume due to stability issues and insufficient available oil data to calculate accurate absorption of the refrigerant in the oil. The simulation predicted the demonstrator would be able to fulfill the goal of a heating capacity of 5-10kW. The output graph of the heating capacity can be seperated in three sections of different operational modes: underfill operation, saturated/flooded operation, overfill operation. Saturated/flooded operation is comonly the operation point for heat pumps and cooling devices. During underfill operation mode, the condenser outflow does not reach a fully liquid state. With increasing charge less vapor is present at the output and a fluid level is established inside the condenser. Therefore, the width of the saturated/flooded area can be extended by the use of a collector or by increasing the inner volume of the condenser. Figure 4 shows the percentage increase in charge for the simulated components, when comparing underfill operation with saturated/flooded operation. The simulations support the assumption of liquid build up inside the condenser.

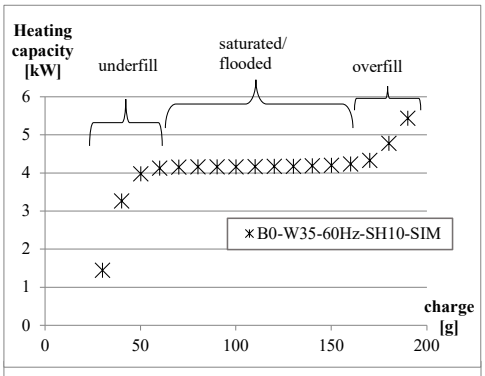

Figure 3: IMST Art results, B0/W35 60Hz SH 10K, system 1

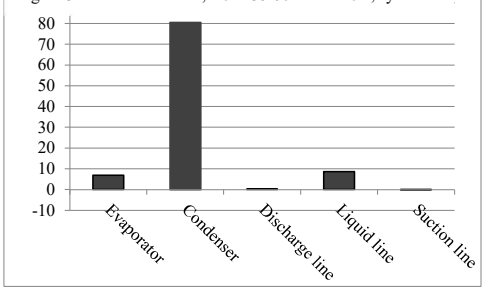

Figure 4: relative percentage charge change for simulated components, comparing underfill operation with saturated/ flooded operation, system 2

Simulation vs. measured values

The results of the simulations and the measurements for the same operation points are compared in Figure 5 and Figure 6. Important to note is the included static 150g charge offset, which was added as a static value to the simulation. Figure 3 and Figure 6 show the same simulation results where the latter includes the static offset, which has a limited number of possible explanations. The following possibilities are considered: inaccurate representation of unused volumes, oil absorption and unknown factors. Nevertheless the liquid accumulation in the condenser mentioned earlier seems to be represented accurately based on the width of saturated/flooded operation. The measurements could not be continued in the over flooded operation state, the refrigerant circuit started to show unstable behavior. The unstable conditions triggered the security shut off of the system. The COP differs significantly as shown in the comparison in Figure 5, however the shape of the curve seems to match roughly. Inefficient behavior, especially of the evaporator, is being considered as the cause for the difference in COP. The prototype is expected to reach the simulated COP values after addressing the known issues like insulation, maldistribution and insufficient EEV. Some of the known issues will be discussed further in the following sections.

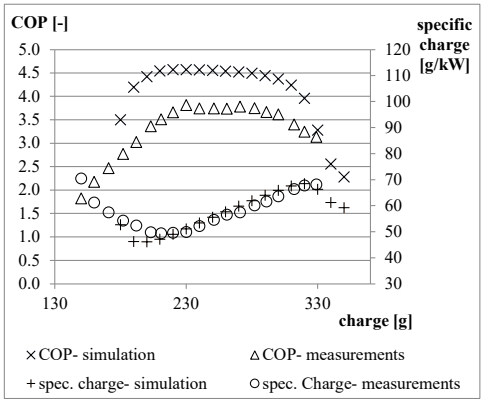

Figure 5: COP and spec. charge, measurement vs. simulation, 150g static offset, in operational point B0/W35 60Hz SH10, system 2

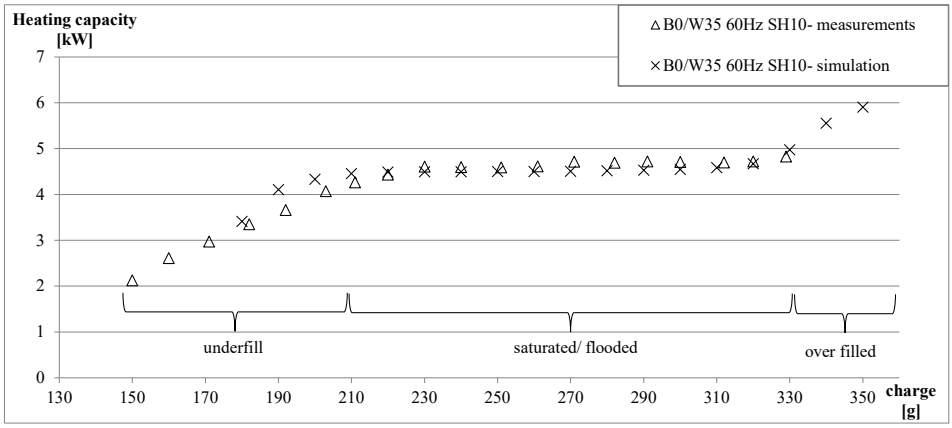

Figure 6: Heating capacity over charge, measurement vs. simulation including a 150g static charge offset, system 2

Measurement results

The simulation showed the three distinct modes of operation. Two of the three distinct modes of operation are also present in the visualization for compressor comparison in Figure 7. The graph also displays the differences between the two systems. For both systems to reach saturated/flooded operation, more charge is needed at operation with lower frequencies. This effect was also present in all measurements. The total range tested was from 30Hz to 120Hz in 10Hz increments. The mass variation measurements shown were not continued with more charge after saturated operation was reached. All measured data points followed the procedure detailed in section Measurement procedure. All measurements shown are done for the temperature pairing of B0/W35. The suction superheat (SSH) has been set to 10K, nevertheless it was not reached for all operation points due to the limited operational window of the EEV. The SSH varied between 5 and 22K. The deviation from 10K is only significant for operation points with the lowest and highest charge. Figure 8 shows the COP values corresponding to the heating capacities of Figure 7. In Figure 7 it can be seen that system 2 reaches a higher heating capacity than system 1 at high frequencies. For lower frequencies the behavior of the two systems is diverse. Until 200g of charge system 1 has a higher heating capacity. Beyond 200g, system 2 has a higher heating capacity. Both systems reach a higher heating capacity with higher charge.

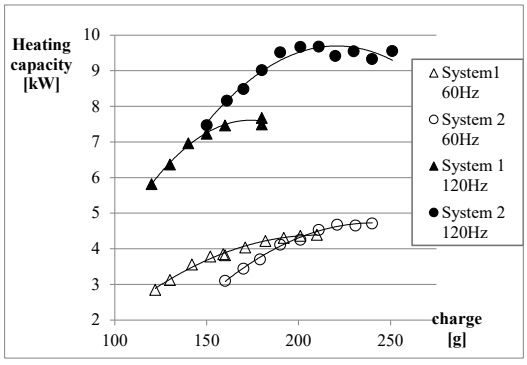

Figure 7: Heating capacity over charge comparing both compressors, all operation points are B0/W35

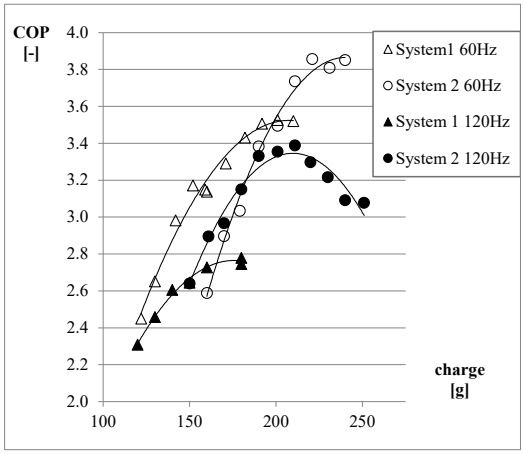

Figure 8: COP over charge graph, comparing both compressors, all operation points are B0/W35

In Figure 8, it can be seen that both systems achieve a higher COP for lower frequencies and both systems achieve their optimal COP in the saturated/flooded operation mode. For lower frequencies, system 1 achieves higher COPs. For higher frequencies it is the other way round.

In order to design an entire heat pump system, stable operation must occur at all possible operating points. Moreover the behavior at all operation points must be well understood in order to give accurate information about performance. For this purpose different parameter variations were measured. In this paper a variation of source temperature and suction superheat will be mentioned.

A reduction of source temperature leads to lower amount of charge necessary to reach saturation/ flooded operation mode. Figure 9 shows the measurement results and the mentioned effect. Possible explanations are different oil absorption and changes in the refrigerant density. The figure also shows the significant impact the source temperature has on the provided heating capacity. Comparing 10°C and -7°C the heating capacity at saturated/flooded operation point drops from 5.9kW to 3.9kW, which corresponds to a difference of 34%. The operation modes underfill and saturated/flooded are once again present in the current visualization.

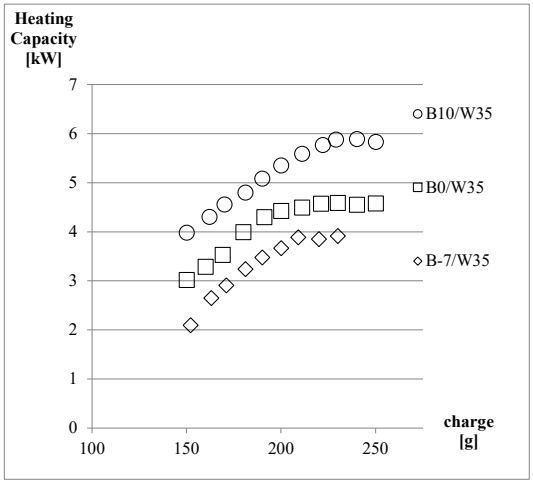

Figure 9: Heating capacity over charge, source temperature variation, system 2, SSH 10K

The second parameter varied is the suction super heat (SSH). Due to the wide range of tested charge, the EEV is not sufficiently sized in either direction to cover all points of operation. Figure 10 shows the operation points in which the EEV was able to perform to the set super heat. Missing points of operation between 140g and 250g did not stick to the set super heat. Figure 10 also illustrates the need for a different means of measuring or indication of performance for EEV's. The superheat does have a significant impact on efficiency. Figure 10 shows the efficiency evolution for the different attempted SSHs. The highest efficiencies around 3.6 were achieved during measurements with an SSH of 10K. Important to note is the different behavior of the COPs during underfill operation. The points for 20K superheat are flat; the points for 10K superheat are steep. Figure 10 illustrates the different operation modes depending on the charge of the system. A possible explanation might be the significantly altered oil sump conditions and therefore different absorption factors. Considering the constant source input temperature and therefore a correlating evaporation temperature, varying superheats have an impact on the suction gas temperature. The varying suction gas temperature has again an impact on the suction gas density and therefore on the mass flow into the compressor. For high superheats the evaporator is used as a gas heater, which lowers the efficiency of the heat exchanger and therefore the entire unit. Any or all of these reasons are possibly part of a high COP optimum at 10K SSH as well as the shifting saturation points. These issues will be addressed in further investigations.

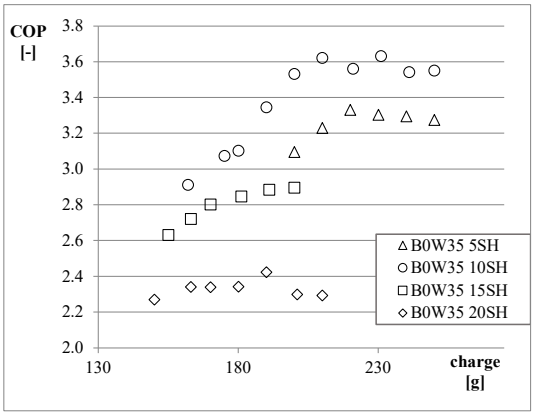

Figure 10: COP over charge, comparing super heat 5K, 10K 15K, 20K, all operation points are B0/W35

Optical analysis

During the measurements, thermography pictures were taken from the condenser as shown in Figure 11 Pictures of the evaporator are shown in
Figure 12. The pictures were taken from a side view onto the heat exchanger plates. Both heat exchangers have 16 plates. The refrigerant flows along the vertical axis of the pictures, running from the inlet to the outlet as marked in Figure 11 and
Figure 12. The thermography pictures were taken with a direct view of the plate heat exchangers with no insulation applied. Therefore the pictures are not taken of a flat surface, thus impairing the resolution and

accuracy of the images. It was attempted to normalize the emissivity, which was set to 1 by applying a thin chalk layer. Based on the relative temperature distribution visible in Figure 11, a maldistribution in the condenser can be assumed. The temperature profile is an u-shaped profile. Perfect distribution would be indicated by a horizontal temperature profile. The evaporator could not be analyzed employing thermography, due to condense water on the surface which washed away the normalizing chalk layer. Due to the low temperatures, ice formed and prevented taking thermography pictures. Therefore, the distribution of the evaporator had to be analyzed by optical information, such as ice formations on its surface. An example of the ice formation is shown in
Figure 12. Only the first few plates show ice formation on the outside of the evaporator. During the testing of the heat pump operation, the last plates seem to be blocked or not charged with any refrigerant which leads to a smaller heat transfer area and a smaller transverse section for the refrigerant to pass through. This results in higher pressure drops and a smaller evaporation temperature to provide the same cooling capacity. Other explanations for the blocked plates could be damaged internal structures. Using water with varying temperatures and surface-mounted temperature sensors, confirmation of no internal damage was obtained.

Due to the maldistribution on both heat exchangers the pressure ratio is higher than necessary. Especially the evaporator showed a very high pressure drop. This results in a higher power consumption of the compressor which again leads to lower COPs of the unit. Both heat exchangers as well as the distribution system of the evaporator will undergo investigation.

Figure 12: Ice formation on evaporator at B0/W35, 60Hz and SH10K, system 1

Discussion

The low charge heat pump has successfully shown the potential of charge reduction and the results provide a solid base to accurately define further research areas. Nevertheless a present tradeoff exists between the optimal COP and the optimal specific charge, as shown in Figure 13. The efficiency maximum is located in the low charge regions of saturated/flooded operation whereas the specific charge minimum is located in the slight underfill operation, which is less absolute charge than the COP optimum needs. The main explanation for this is the strong density drop off in the low quality regions compared to the Δh loss. Figure 14 shows a log p – h diagram for a representative optimal compression cycle. The dashed line with connected arrows indicates the expansion after the EEV during underfill operation. The cycle operates non- subcooled before the EEV, which creates the minimum in specific charge, with a trade off in COP.

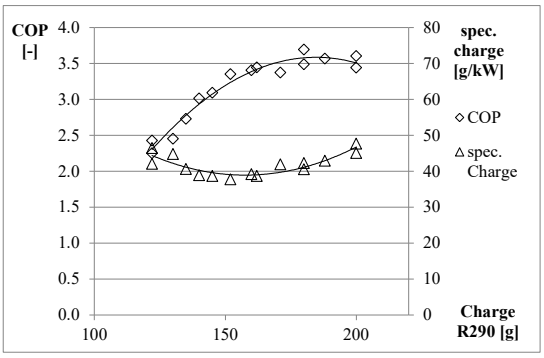

Figure 13: COP and specific charge over total charge, at B0/W35, 60Hz and SSH 10K, system 1

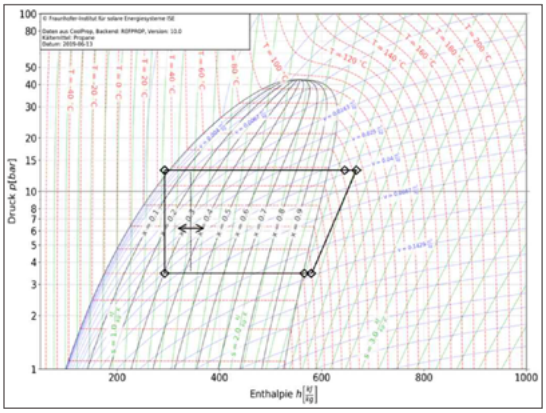

Figure 14 Log p - h diagram, representing the compression cycle

Regarding the charge offset in the simulation results, a few explanations are being considered. The filter dryer material is being tested and evaluated with respect to unknown side effects. Secondly the oil absorption is not yet included in the simulation and this might have a large effect on the offset. Further work will attempt to include the oil absorption in the model to increase the model accuracy.

The work up to this point focused on achieving the targeted heating capacity. The next steps and future focus will be the improvement of COP. The demonstrater is expected to reach competitive COP's within the near future.

Acknowledgment

The authors would like to thank Klas Andersson, Björn Palm and Jose M. Corberan for constructive discussion over the course of the project. Appreciation also belongs to our industry partners for providing the parts for building the demonstrator.

[a]Oak Ridge National Laboratory

Abstract

Growing awareness of the potential environmental impacts of conventional refrigerants (CFCs and HFCs) has led to efforts to identify suitable refrigerants for various heat pump applications with minimum environmental impact. This study is focused on the performance evaluation of various hydrocarbon (HC) and hydroflouroolefins (HFO) as drop-in-replacement for R134a for heat pump water heating (HPWH). A component-based model is used to predict the performance. Key performance parameters such as unified energy factor, first hour rating and thermal stratification in the water tank are investigated. Appropriate experiments are conducted to validate the finding from model. Simulation and experimental findings suggest that both alternative refrigerants could provide comparable system performance to that of the baseline system containing R134a. System refrigerant charge and the condenser discharge temperature are established to investigate the potential of hydrocarbon refrigerants to substitute R134a without significant system modifications

Keywords: HFOs, Hydrocarbons, Propane, Hot Water

1. Introduction

Residential and commercial water heating accounts for approximately 10% of all residential and commercial site energy usage in the United States, making it the fourth largest energy end use in homes [1]. On a global scale, in 2015 water heating consumed about 15–20% of residential energy for OEDC and non-OEDC countries as shown in Fig. 1.

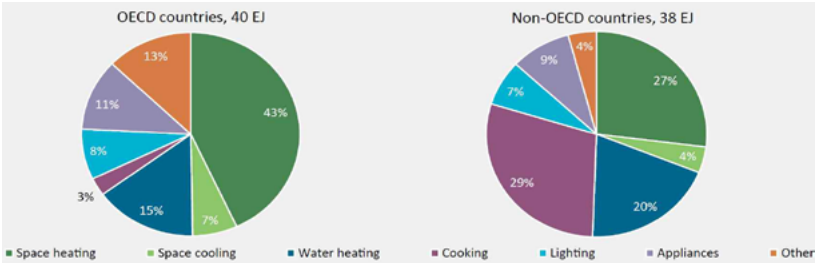

Fig. 1: End uses of residential energy consumed in OECD and non-OECD countries [2]

Despite recent advancements in energy efficiency, most residential water heaters are either conventional natural-gas-fired or electric storage heaters. While such systems are quite simple, they have very low system efficiency. Conversely, under appropriate conditions, electrically driven, vapor compression heat pumps, or

E-mail address: nawazk@ornl.gov

heat pump water heaters (HPWHs), represent a system opportunity with much higher thermal efficiency than conventional electric water heaters, resulting in significant energy savings.

Similar to conventional refrigeration or air-conditioning cycles, HPWHs use a vapor compression refrigeration cycle to transfer heat from a low temperature ambient to a high temperature reservoir, a hot water tank. A key parameter of interest is the working fluid used in the vapor compression cycle. Conventional HPWH systems deployed R-22, which is being phased down due to the high ozone depletion potential (ODP) associated with this fluid. R-134a emerged several years ago as the potential replacement, and most manufacturers have introduced systems with a reasonably higher unified energy factor (UEF) based on this refrigerant. However, concerns about possible global climate change have led to legislative action all around the world to phase down the use of hydrofluorocarbons (HFCs), including R-134a, in a range of heating, ventilation, air conditioning, and refrigeration (HVAC&R) applications, due to their relatively high global warming potential (GWP). Since HPWH systems are essentially heat pumps relying on the vapor compression refrigeration cycle, the technology has been equally affected [3]. Table 1 summarizes some familiar refrigerants with potential impact on the environment.

Table 1: Characteristics and environmental impact of different refrigerants [4]

Refrigerant group	**Refrigerant example**	**ODP**	**GWP_{100}**	**Atmospheric lifetime (years)**	**Flammability**
CFCs	R11, R12, R115	0.6–1	4750–14400	45–1700	Nonflammable
HCFCs	R22, R141b, R124	0.02–0.11	400–1800	1–20	Nonflammable
HFCs	R407C, R32, R134a	0	140–11700	1–300	Nonflammable or mildly flammable
HFOs	R1234yf, R1234ze, R1234yz	0	0–12	-	Mildly flammable
Natural refrigerants	R744, R717, HC (R290, R600, R600a)	< 20	0	Few days	HCs: Highly flammable R717: Flammable R744:Nonflammable

A range of experimental, analytical, and numerical studies have evaluated the performance of HCs for various HVAC&R applications. Broadly, these refrigerant studies used either pure HCs, HC blends, or HC blends mixed with HFCs and hydrofluoroolefins (HFOs). Urchueguia et al. [5] conducted an experimental study of a commercial refrigeration unit using R290 instead of R22. They concluded that the COP increased by 1–3% and the capacity decreased by 13–20% when R290 was used to replace R22. In another similar study. Lee and Su [6] compared the performance of a domestic refrigeration system with R600a to replace R12 and R22. Khalid and Qusay [7] investigated the performance of a residential air-conditioning system under high condensing temperatures using R22, R290, R407C, and R410A. They found that the cooling capacity and the power consumption for R410A were the highest among the four refrigerants and that R290 required less power and refrigerant charge for comparable performance to R22. Song et al. [8] evaluated the performance of an air-conditioning system using R32 and R290 as substitute fluids for R22 and R410A. They found that at the rated conditions, the COP of R32 and R290 was significantly higher than that of R410A and R22. In another similar study, Zhou et al. [9] considered R290 as a potential replacement for R22 in a split air-conditioning unit with different diameters of coiled capillary tubes and various operating conditions. They found that the cooling capacity of the system with R290 was lower than that with R22; however, the energy efficiency ratio was higher.

Multiple studies have focused on using HC mixtures as substitutes for conventional refrigerants. Chao and Teng [10] studied the feasibility of using HC mixtures of R290 and R600a as alternative refrigerants in a small-sized refrigerator originally using R134a. They concluded from a no-load pull-down test that the optimal refrigerant charge for HCs was significantly lower than that for R134a. Rasti et al. [11] used R436A (56% R290 and 44% 600a) as an alternative to R134a in a domestic refrigerator and concluded that the system's on-time ratio was reduced by 13% and that power consumption was reduced by 5.3% as compared to the original system with R134a. Mani and Selladurai [12] conducted an experimental study using R290 and R600a (68% and 32% by mass, respectively) as a drop-in replacement for R12 and R134a and found that the HC mixture had a higher cooling capacity. It is important to note that trans-critical CO_2 HPWH technology also relies on

an environmentally friendly refrigerant, however, issues related to high pressure and variable flow rate pump system along with intermediate heat exchanger makes the technology less feasible compared to HC based HPWH system [13].

2. Analysis strategy

Modelling a HPWH system has been a challenge due to the varying complexities of the subsystems and the integration of the heat pump and water tank. The DOE/ORNL Heat Pump Design Model (HPDM) has been a reliable, public-domain platform for designing, optimizing, and analysing heat pumps of varying complexity for both residential and commercial applications. The platform was used to develop a HPWH system model that included a wrapped tank condenser and accounted for features such as thermal stratification, piston effect, and mixing. The model was calibrated against measured test data and was used to evaluate HPWH performance.

The current study draws upon some component modelling aspects of a previous ORNL HPWH analysis for forced-flow designs [14]. Some of the key HPDM features important to the current study are described here. AHRI 10-coefficient compressor maps have been used to calculate mass flow rate and power consumption as shown by Eqs. (1) and (2), respectively, as functions of evaporation and condensation temperatures [15].

$$\dot{m} = \alpha_1 + \alpha_2 T_{evap} + \alpha_3 T_{cond} + \alpha_4 T_{evap}^2 + \alpha_5 T_{evap} T_{cond} + \alpha_6 T_{cond}^2 + \alpha_7 T_{evap}^3 + \alpha_8 T_{evap}^2 T_{cond} + \alpha_9 T_{cond}^2 T_{evap} + \alpha_{10} T_{cond}^3 \quad (1)$$

$$\dot{W} = \beta_1 + \beta_2 T_{evap} + \beta_3 T_{cond} + \beta_4 T_{evap}^2 + \beta_5 T_{evap} T_{cond} + \beta_6 T_{cond}^2 + \beta_7 T_{evap}^3 + \beta_8 T_{evap}^2 T_{cond} + \beta_9 T_{cond}^2 T_{evap} + \beta_{10} T_{cond}^3 \quad (2)$$

where T_{evap} and T_{cond} are the compressor suction and discharge saturation temperatures, and α and β are the compressor map coefficients for mass flow rate and power respectively. $\alpha_{1,2,...,10}$ and $\beta_{1,2,...,10}$ are the mass flow rate and power coefficients respectively for compressor.

The HPDM uses a segment-to-segment modelling approach, which divides a single tube into numerous mini segments. Each tube segment has individual air-side and refrigerant-side entering states and considers possible phase transition; the ε-NTU approach has been used for heat transfer calculations within each segment. In addition to the functionalities of the segment-to-segment fin-tube condenser model, the evaporator model can simulate the dehumidification process. A wrapped tank condenser model was developed specifically for this investigation, using a segment-to-segment modelling approach. The flow-pattern-dependent heat transfer correlation published by Thome et al. [16] was used to calculate the condenser's two-phase heat transfer coefficient. The tank model includes the thermal conductivity of the thermal paste (used to ensure good contact between the wrapped tank condenser tubes and the tank wall) and the insulation covering the tank. Thus, heat loss from the tank was captured for the full time of the operation. The transient tank model accounts for one-dimensional water temperature stratification due to natural convention. Fig. 2 shows an example case (i.e., mixing caused by advection during water draw) for the CFD model used for the analysis. A residential HPWH was considered as the baseline water-heating unit for performance evaluation and model calibration as shown in Fig 3. The performance of this unit has been evaluated previously at ORNL [17].

3. Results and discussion

The US Department of Energy (DOE) initiated a rulemaking to consider amendments to its old test procedures for covered residential and commercial water heaters, as recommended in the American Energy Manufacturing and Technical Corrections Act. Based on the extensive testing, a new performance evaluation procedure was defined. In the new procedure, the tank water temperature set point is 125°F, and the test conditions for inlet water and ambient air temperature are prescribed as 58°F and 67.5°F (35–45% relative humidity), respectively. Key performance metrics used to evaluate and compare the performance of water heaters (WHs), including HPWHs, are listed below.

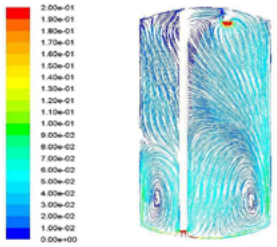

Fig. 2. Streamline for water flow in the tank during draw (m/s).

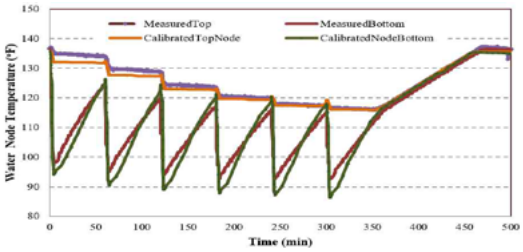

Fig. 3. Temperature stratification variation (measured vs. predicted).

First Hour Rating. FHR is a measure of the available hot water capacity of the WH (in gallons). Per the new DOE test method, hot water (125±15°F) is drawn from the tank as long as the temperature is more than 67±2°F higher than the entering water temperature. Once the temperature drops below the prescribed limit, the supply is stopped until the set point of 125±1.5°F is met again. Following the procedure, the total water drawn from the tank during 1 hour indicates the total capacity of the heat pump and electric resistance heaters.

Unified Energy Factor. UEF is a measure of system efficiency. It is defined as the ratio of the total heat delivered from the system (by heating the water) to the total power required to operate the system. Equation (3) describes the UEF.

$$UEF = \sum_{k=1}^{n} \frac{M_k c_p (T_s - T_i)}{W_i} \quad (3)$$

In Eq. (3) k represents the individual hot water draw, considering that multiple draws are required by the test procedure and that n (total number of draws) can vary according to the method proposed by DOE (small, medium, and large usage pattern), and M is the total mass drawn for each respective draw. T_s, T_i, and W_i represent the supply water temperature, inlet water temperature, and total energy consumed by the unit (power times unit run time), respectively. The previous EF test procedure used a single water draw pattern—six equal water draws of ~10.7 gallons each spaced equally during the first 5 hours of the EF test—and applied it to all WHs (including HPWHs) with a storage tank. In contrast, the new method uses the measured FHR value to define the hot water draw pattern. The FHR analysis concluded that under all parametric conditions, the appropriate draw pattern for the HPWH unit being analysed was for medium usage (FHR varied between 57 and 64 gallons).

4. Parameters for performance evaluation

To optimize system performance, a parametric study was conducted to investigate the impacts of the condenser wrap pattern and the heat loss from the water storage tank. Two representative insulation effectiveness values were considered for the heat loss from the tank, 90% and 95%. The effectiveness is 90% when the tank loses 10% of the energy input to the water. The effectiveness is 95% when half that amount of energy is lost through the tank wall and insulation material to the environment. This essentially accounts for two values for the resistance to heat loss. Similarly, to explore the impact of condenser configuration, two different wrap patterns were considered for analysis as shown in Fig. 4. The counterflow pattern represents the flow of the refrigerant entering from the top section of the tank and moving downwards. In the parallel-counterflow configuration, the refrigerant enters close to the middle of the tank, moves upwards, and then comes back to the middle section to continue downwards (identical to the pattern used by the prototype systems evaluated in the prior experimental study). In both cases, the refrigerant enters the system as superheated vapor, goes through a phase-change process, and exits as a subcooled liquid. Table 2 summarizes the cases considered in current study.

5. Results and discussion

FHR is a direct indication of system capacity. A larger FHR indicates a superior system capacity. It can be observed from Fig. 5 that R290 consistently shows a comparable FHR when compared with baseline R134a values, whereas R600a has an average FHR, close to 57 gallons (lower than R134a). Although the system's design parameters can have some secondary impact, the FHR is a direct indication of the volumetric capacity of the refrigerant. The low value for volumetric capacity for R600a can explain a relatively lower FHR.

Table 2. Simulation cases for parametric analysis

Case number	Wrap pattern	Effectiveness (%)
1	Parallel-counterflow	90
2	Parallel-counterflow	95
3	Counterflow	90
4	Counterflow	95

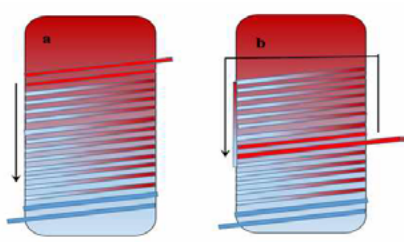

Fig. 4. Condenser wrap configurations: (a) counterflow, (b) parallel-counterflow.

Unified energy factor (UEF) is a direct measure of system efficiency. A larger UEF denotes a better performance. Fig. 6 presents the 24-hour UEF for different refrigerants as the design parameters vary. Heat loss from the tank is seen as a dominant factor, and UEF is higher for the cases with 95% tank insulation effectiveness. On the other hand, the condenser wrap pattern does not have any significant impact, as observed from the values presented in Fig. 6. Among the three refrigerants, R600a has the lowest UEF while for R134a and R290, the values are comparable.

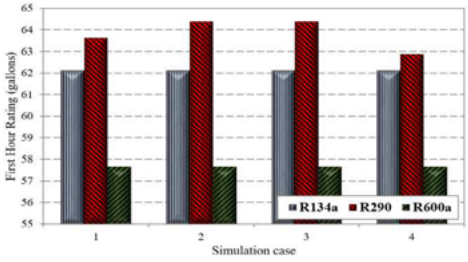

Fig. 5. First hour rating for different refrigerants

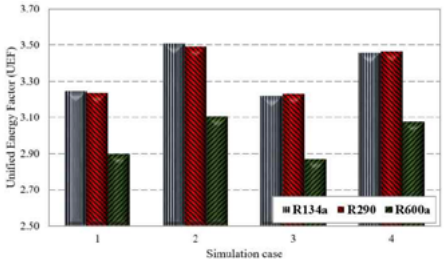

Fig. 6. Unified energy factor for different refrigerants

COP is the typical parameter used to describe the efficiency of a heat pump. It is important to recognize that COP, unlike UEF, represents the efficiency of the heat pump only and cannot be used to indicate the performance of the whole system. However, this is still an important parameter to consider as it shows the stand-alone performance of the heat pump. Fig. 7 presents COP for the different design options. Overall, COP is comparable for all design options, with slightly better performance for parallel-counterflow configuration and 95% tank insulation effectiveness. When the individual performance of different refrigerants is compared for a specific design option, COP is clearly lowest for R600a, as was the case for UEF.

An interesting relationship between insulation effectiveness and supply water temperature is presented in Fig. 8. A higher supply water temperature results in 90% thermal insulation (cases 1 and 3) because of the control mechanism to turn the heat pump on (T = 120°F) and off (T = 125°F), which ultimately lowers the system's UEF. The heat lost with the poorer thermal insulation causes the heat pump's run time to increase, leading to a higher average supply temperature.

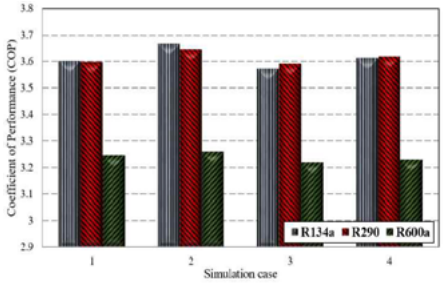

Fig. 7. Coefficient of performance

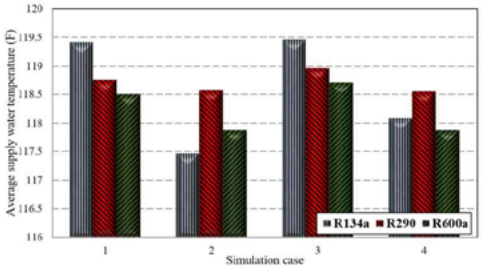

Fig. 8. Average supply water temperature

Total system charge is a critical parameter that has been the focus of continuous effort toward minimization, not only because refrigerants are expensive but also because class A3 refrigerants present serious safety concerns for any HVAC&R application. Fig. 9 compares total system charge in the evaporator and the condenser. Even though there is no significant difference in charge for various design options, it is interesting and encouraging that the charge required for both R290 and R600a is less than half that of the baseline R134a. This can be explained in terms of the lower molecular weights for the R290 and R600a refrigerants which are almost half that for R134a. This shows the potential of HC refrigerants to substitute for R134a and indicates that further development may allow an even smaller charge of flammable refrigerant to be successfully substituted to provide similar performance, thereby reducing safety concerns.

Fig. 10 presents the maximum condenser saturation temperature drop. For better heat transfer performance, a smaller temperature drop, which is directly related to the pressure drop through the condenser, is desired. As shown in Fig. 10, both design options with the parallel-counterflow wrap pattern result in a lower condenser saturation temperature drop, while for the counterflow arrangement, it is higher. The higher condenser temperature drop can be related to the relative amount of condenser containing refrigerant vapor. Since for the counterflow arrangement there is a slower transfer of heat in the top part of the water tank, which contains relatively hot water (due to stratification), a longer heat exchanger length fraction in the vapor (higher pressure drop) region is required. In contrast, for a parallel-counterflow arrangement, vapor refrigerant entering close to the middle of the tank interacts with relatively cold water, ensuring a higher heat transfer rate and shorter vapor region. Analysis of the individual performance of the refrigerants shows that R290 has the lowest values. For counterflow arrangement, both R-134a and R600a show comparable performance; however, for parallel-counterflow configuration, R600a has a higher temperature drop. Since the saturation temperature drop directly depends on the saturation pressure drop, a condenser tube with relatively larger diameter can be helpful; however, this leads to a higher refrigerant charge, which is undesirable for the current application. For a drop-in-replacement study, it is desirable to have a comparable and preferably lower compressor discharge temperature for alternative refrigerants, as this ensures that a similar compressor with existing lubrication can be safely used. The issue is critical due to the flammable nature of refrigerants as well. Fig. 11 compares the compressor discharge temperature for various design options and indicates that maximum compressor discharge temperature is about 10°F lower for R600a and 1–2°F lower for R290 compared to the baseline refrigerant (R134a). This suggests that with respect to oil temperatures for both refrigerants, a safe substitution is possible without significant modification. However, since the volumetric capacity of R600a is lower, a relatively larger compressor is required for comparable performance (i.e., COP and UEF).

Thermal stratification in the storage tank has been studied extensively, and recent findings have shown that higher stratification can lead to improved UEF, a classical feature of CO_2-based HPWHs (Nawaz et al., 2017), since this can provide better heat transfer from the condenser tube to the water. Fig. 12 shows the relative water stratification for different refrigerants and design selections where the difference between the supply water temperature (exiting the water tank) and average tank water temperature is presented. There is no consistent trend when different design selections are compared, though cases 1 and 3 with 90% insulation effectiveness show slightly lower temperature differences. However, the relative water temperature difference is lowest for R600a on average, which is consistent with previous discussion regarding lower UEF and higher heat pump run time for this refrigerant.

6. Conclusions

A simulation study of a wrapped-tank heat pump water heater has evaluated the feasibility of using R290 (propane) and R600a (isobutane) as natural refrigerants to substitute for R-134a. A model based on the DOE/ORNL Heat Pump Design Model was developed to account for both the heat pump and water tank designs, and it was used to study the impact of various design parameters. It has been found that both R134a and R290 showed comparable FHR and UEF. A relatively lower performance for R600a can be attributed to its relatively lower volumetric capacity, which can be resolved by increasing compressor size. The compressor discharge temperature was lower for R290 and R600a than it was for R134a. This suggests that compressors of similar design can be used with these refrigerants and that existing compressor lubricants are feasible. Total system charge for R290 and R600a was much smaller compared to the baseline system (at least 50% reduction). Considering the potential flammability of replacement refrigerants, which are safety class A3, the substitution of R290 or R600a would reduce safety concerns because a relatively smaller amount would be needed to operate the system. Considering the various performance parameters, R290 showed better prospects as a drop-in replacement for R134a, while R600a required a relatively larger compressor size to meet the baseline performance.

Abstract

Absorption heat pumps are traditionally closed systems, while adsorption dehumidifiers are traditionally open systems. Recently a semi-open heat pump and dehumidifier has been proposed, in which ambient atmospheric humidity is absorbed into a solution, desorbed back to vapor in a desorber, condensed to liquid in a condenser, and released back to the ambient as a liquid. In this work, a semi-open sorption heat pump water heater was evaluated under the standard 24-hour duration test procedure used to evaluate water heaters in the US, the uniform energy factor (UEF) test. The results demonstrated that a cycle COP of 1.22 was achieved at air conditions of 19.7°C (67.5°F) and 50% relative humidity. Over the 24-hour period, the heat pump ran twice, with an average heating capacity of 0.825 kW, and an average cycle heating COP of 1.22. The standard load profile withdrew 209.6 L (55.4 gallons) from a 173.8 L (45.9 gallons) storage tank. The water supplied to the tank was 14.4°C (58°F) and the water withdrawn from the tank was always hotter than 45.3°C (113.5°F).

Keywords: semi-open; absorption; ionic liquid; heat pump water heater

1. Introduction

Traditionally, sorption heat pump systems are either: closed (for chilling and heat pumping) or open (for dehumidification). Recent work [1, 2] has explored the possibility of semi-open systems, which utilize ambient humidity as a working fluid of the cycle. This paper presents the performance evaluation of a third generation of semi-open membrane-based sorption heat pump water heater and dehumidifier.

2. Experimental system

2.1. Process and instrumentation diagram

Figure 1 **오류! 참조 원본을 찾을 수 없습니다.** shows a schematic of the experimental heat pump and its coupling to a 46-gallon storage water tank through the water-water heat exchanger. The heat pump has four flow loops: heating oil (state points T1 through T3), solution (state points T5 through T9), process water (state points T10 through T15), and moist air (state points 21 and 22). An additional water loop (state points T16 and T17) exists to isolate the low hydrostatic pressure of the process water loop from the high tap pressure of the

* Corresponding author. Tel.: +1-865-241-2952.
E-mail address: gluesenkampk@ornl.gov

tank. A final water flow path (state points T19 and T20) is the cold tap water source (T19) and hot domestic water supply (T20).

Three fluid loops are present in the absorber: air, process water, and solution. In the absorber, ambient air interfaces with the solution through a membrane that is permeable to water vapor: the solution absorbs water vapor from the air, the temperature of the solution rises, and the solution water content increases. The process water stream flows in the absorber in a counterflow arrangement to the solution, removing heat from the solution. The flow rate of the process water is controlled by adjusting a needle valve downstream of the process water circulation pump. The weak solution leaves the absorber (T7) and is preheated in the SOHX (T8 to T9) before it enters the desorber at T9.

Three fluid loops are present in the desorber-condenser: oil, process water, and solution (condensate may be considered a fourth fluid). In the desorber, the weak solution is heated to desorb some of its water content and increase its concentration. The temperature in the desorber is controlled via the inlet oil temperature (T1) provided by a circulator-heater. Water vapor leaves the solution at high temperature and enters the condenser. The strong solution leaves the desorber at high temperature (T4) and enters the SWHX where it transfers heat to the process water leaving the absorber. The flow rate of the solution is controlled through adjusting the speed of the solution pump. The process water leaves the SWHX (T12) and enters the condenser where it gains heat from the water vapor and condenses it. The process water then leaves the condenser (T13) and enters the water-water heat exchanger (T14) where it heats water that is recirculated from the bottom to the top of the storage tank (T17 to T16). Recirculating from the bottom to the top maintains stratification in the tank to maintain the lowest possible inlet water temperature to the absorber.

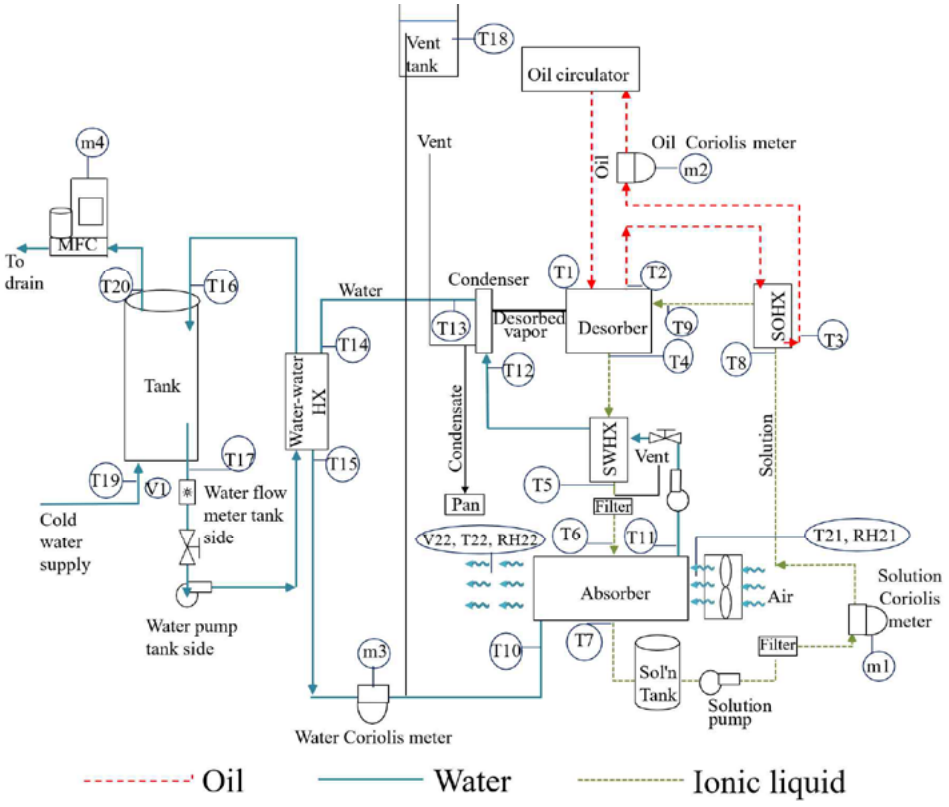

Figure 1: Process and instrumentation diagram of the instrumented experimental test setup.

Cold domestic water flowed to the bottom of the storage tank and hot water was drawn from the top, in a stratified configuration. The inlet temperature of the domestic water was controlled by a water temperature

conditioning unit to within ±0.5°C of the setpoint. The flow rate of the domestic water was controlled through a flow controller with a remotely adjustable setpoint. The water storage tank was outfitted with 16 thermocouples distributed along with the height of the tank. Measurement instruments and sensors and their uncertainties are summarized in Table 1 **오류! 참조 원본을 찾을 수 없습니다.**.

Table 1: Measurements and their systematic uncertainties.

Measured parameter	Instrument/Sensor	Systematic uncertainty
Temperature	T-Type Thermocouple	0.5°C
Relative humidity	Capacitive humidity sensor	1.5%
Airflow rate	Differential pressure	2%
Domestic water flow rate	Mass flow controller	0.224 lpm
Oil flow rate	Coriolis flowmeter	0.5%
Solution flow rate	Coriolis flow meter	0.5%
Process water flow rate	Coriolis flowmeter	0.5%

2.2. Absorber

A schematic and photograph of the absorber are shown in Figure 2. The absorber is of special importance in this system due to its unique design requirements and novel design. The absorber was fabricated with polycarbonate and hydrophobic porous polymeric membranes sheets. Two sheets of polycarbonate with machined channels for water flow were thermally-bonded and chemically treated to make the surface hydrophilic. Following the thermal bonding of internal water channels, the polymeric membrane sheets were thermally-bonded to the fins machined on the reverse side of the polycarbonate sheets. The fins provided structural support to the membranes and assisted in ionic solution flow distribution. The solution and water manifolds were attached to the absorber with adhesive. The air flows across the membranes through a 12mm gap between the membrane panels.

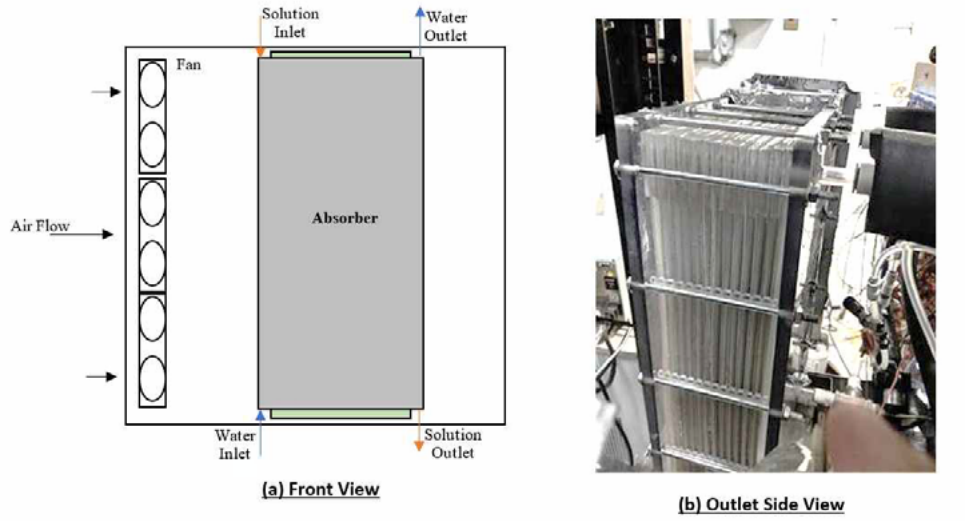

Figure 2: (a) Front view schematic of the absorber. (b) Outlet side view photograph of the absorber.

Table 2 summarizes the difference between the absorbers used in previous experimental studies by Chugh et al. [1], [2]. The table shows that the absorber in this work has approximately double the active absorber mass transfer area, with comparatively less increase in component volume.

Table 2: Comparison of the absorber used in the previous generation and this study.

Absorber	Generation 1 [1]	Generation 2 [2]	This study
Number of panels	4	7	13
Active air surface area [m^2]	0.42	0.92	1.89
Active plate volume [m^3]	0.0084	0.0080	0.0119
Active surface area/volume ratio [m^{-1}]	50	115	159
Material used	Waterside: Metal (Cu/SS frame)	All polymer (polycarbonate)	All polymer (polycarbonate)
	Solution-water interface: stainless steel sheet	Thermal and adhesive bonding, CNC machining	Thermal and adhesive bonding, CNC machining
	Solution-side fins: 1.5 mm tall (additively manufactured polymer)	Solution-side fins: 1 mm tall	Solution-side fins: 0.6 mm
Membrane pore size	1 µm	1 µm	1 µm
	Not bonded on the fins	Thermally bonded on fins	Thermally bonded on fins

2.3. Desorber-Condenser Module

The integrated desorber-condenser module, as shown in Figure 3, used a superhydrophobic membrane to separate the desorber and condenser within one housing. A structure of surface features, similar to what was used in the the absorber, was used to enhance the desorption rate, as reported in previous studies [2], [3]. The desorbing and condensing sides were bolted together with gasket material. The desorber was leak tested with Nitrogen gas up to 5 PSI.

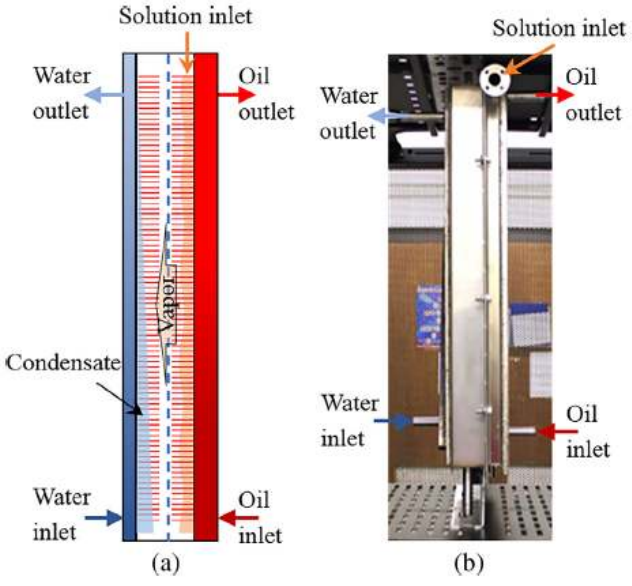

Figure 3: (a) Cross sectional schematic of the desorber-condenser component, with membrane shown as a dotted blue line. (b) Outlet side view photograph of the desorber-condenser. Reprinted with permission from "Experimental evaluation of a semi-open membrane-based absorption heat pump system utilizing ionic liquids," by D.Chugh et al., 2019, Appl. Energy, 239, p.921. *[2].*

2.4. Heat Exchangers

Two counter flow heat exchangers were used in the heat pump section for heating of water and solution. One heat exchanger transfers heat from the solution to water after desorption, and the second one transfers heat from the oil to the solution before desorption. Hot silicone oil was used as the source of energy input. The temperature of the oil was controlled using a temperature-controlled circulating bath.

The heat pump was integrated with a nominal 50-gallon water heater storage tank. The domestic water into the water heater storage tank was conditioned with a laboratory water supply system to deliver water at 58°F ± 2°F (14.4°C ± 1.1°C).

2.5. Data reduction

The COP of the system was calculated using equation (1). The Cp_{oil} was measured using a differential scanning calorimeter (DSC) as 1.8 $kJ^{1}kg^{-1}K^{-1}$ in the relevant temperature range.

$$COP = \frac{Q_{water}}{Q_{oil}} = \frac{\dot{m}_{water} * Cp_{water} * \left(T_{water,cond\ out} - T_{water,abs\ in}\right)}{\dot{m}_{oil} * Cp_{oil} * \left(T_{oil,desorber\ in} - T_{oil,SHX\ out}\right)} \quad (1)$$

3. Test operation

The test procedure for the 24-hour uniform energy factor test is outlined in the Electronic Code of Federal Regulations (e-CFR, [4]). The test procedure outlines all test conditions, sensor requirements and supply/outlet water temperature requirements. When all installation requirements have been met, the first-hour rating test is performed. This was done for the water heater used in the current work and the results showed that a medium usage draw pattern was required. The details of the medium usage draw pattern are given in Table 3.

Table 3: Medium usage draw pattern [4].

Draw No.	Time during test [hh:mm]	Volume [gallons (liters)]	Flow rate [GPM (L/min)]
1	0:00	15.0 (56.8)	1.7 (6.4)
2	0:30	2.0 (7.6)	1 (3.8)
3	1:40	9.0 (34.1)	1.7 (6.4)
4	10:30	9.0 (34.1)	1.7 (6.4)
5	11:30	5.0 (18.9)	1.7 (6.4)
6	12:00	1.0 (3.8)	1 (3.8)
7	12:45	1.0 (3.8)	1 (3.8)
8	12:50	1.0 (3.8)	1 (3.8)
9	16:00	1.0 (3.8)	1 (3.8)
10	16:15	2.0 (7.6)	1 (3.8)
11	16:45	2.0 (7.6)	1.7 (6.4)
12	17:00	7.0 (26.5)	1.7 (6.4)

To initiate the 24-hour simulated-use test, the water in the water heater tank was first conditioned as outlined in the test procedure. The test was initiated by withdrawing the volume of water specified in Table 3 for the first draw. Among other measurements, the average storage tank temperature and ambient temperature were recorded for the entirety of the test. Additional draws were initiated at the required elapsed times as given in Table 3 **오류! 참조 원본을 찾을 수 없습니다.**. The maximum allowable deviation from the specified volume of water removed for any single draw taken at a nominal flow rate of 1 GPM or 1.7 GPM was ±0.1 gallons (±0.4 liters). The mean of the hot water discharge temperature and the cold-water inlet temperature for each draw were recorded, along with the net volume of water removed. The tank, inlet/outlet, and ambient temperatures, water volume withdrawn, and total energy consumption of the heat pump were all used to determine the UEF.

4. Results

4.1. COP and Capacity

The COP of the system during heat pump operation is shown in Figure 4. The heat pump involves coupled heat and mass transfer phenomena in the absorber with three different fluids (air, ionic solution, and water), where the heat pump recovers the latent heat from the humid ambient environment. In this study, the ambient air was conditioned at the UEF test condition requirement of 19.7°C/ 50%RH. The heat pump was operated for a total of 6 hours and 18 minutes during 24 hours of UEF testing. The runtime of the heat pump was divided into two segments with a 6 hour non-operational period between them. The average heating and dehumidification COP during the first four-hour segment of heat pump operation were 1.18 ± 0.04 and 0.36 ± 0.03, respectively. The average and standard deviation in heating COP and dehumidification COP during the second (2 hours and 18 minutes) segment were 1.34 ± 0.14 and 0.45 ± 0.09. These standard deviations represent fluctuations in the value, and is not an instrumentation uncertainty. During the operation of the heat pump, the average water heating thermal power was 853 ± 92 W for the first operation segment and 1002 ± 270 W for the seccond. The increase in COP during the second segment could be attributed to higher solution and water flowrate into the absorber, as summarized in Table 4.

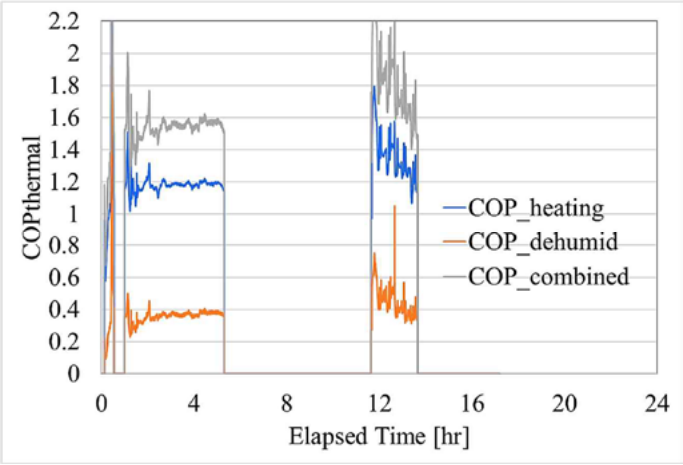

Figure 4: The thermal COP of the system during the operation of the heat-pump.

4.2. Absorber

Table 4 summarizes the absorber performance and its inlet solution and water conditions. The average concentration of the solution at the inlet and outlet of the absorber was around 88% and 84%, respectively. The concentration of the solution was measured with a Milton Roy Benchtop Refractometer at half-hour intervals. During this period, the average condensate rate was 5.66 to 5.76 mL/min. The condition of ambient air during the 24-hour UEF testing is shown in Figure 5. On average, the air absolute humidity dropped through the absorber by 1.36 ± 0.06 to 1.49 ± 0.1 g water vapor per kg dry air, and rose in dry bulb temperature by 2 to 3°C.

Table 4: Average and standard deviation of absorber parameters during operation.

Heat pump on/off	Weak solution concentration [%]	Strong solution concentration [%]	Delta solution concentration [%]	Condensate rate [mL/min]	Solution inlet temperature [°C]	Water inlet temperature [°C]	Solution mass flow rate [g/s]	Water mass flow rate [g/s]
First heat pump segment	83.72 ± 0.4	88.21 ±0.5	4.43	5.66	23.91 ±0.3	17.64 ±0.8	2.32 ± 0.1	5.79 ± 0.3
Second heat pump segment	84.10 ±0.6	88.05 ±0.5	3.95	5.76	24.8 ±0.9	19.69 ±0.9	3.09 ± 0.2	6.79 ± 0.5

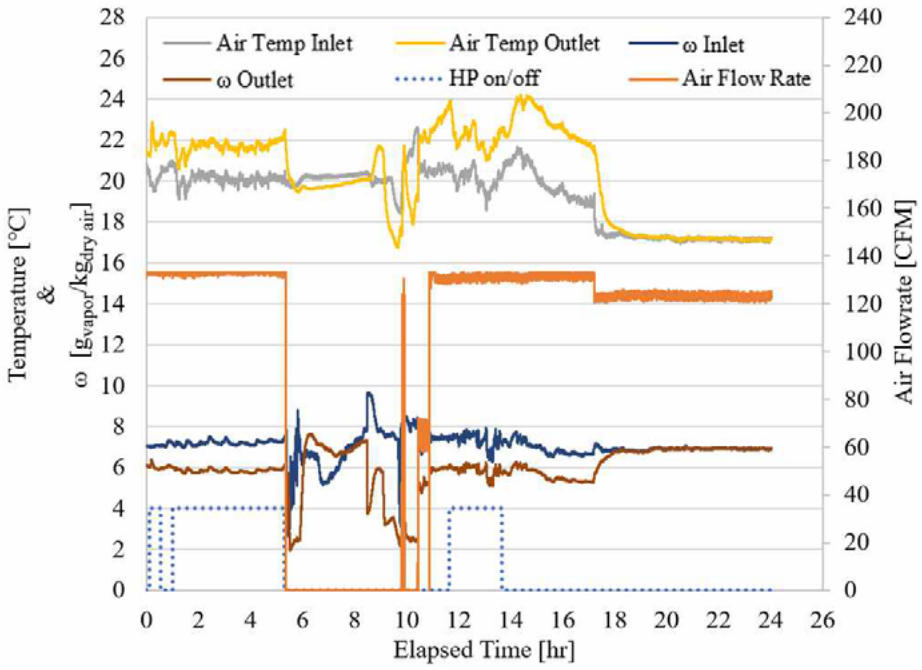

Figure 5: Air conditions during the 24-hour UEF testing. ω is the humidity ratio of the air.

Figure 6 compares the performance of the system evaluated by Chugh et al. [1], [2] and this study. The primary difference between this study and the previous studies by Chugh et al. is the absorber. The difference between the absorbers used in previous studies and this study was previously summarized in Table 2 **오류! 참조 원본을 찾을 수 없습니다.**. Chugh et al. [2] achieved a COP of 1.24 with an inlet water temperature of 18°C and ambient conditions of 21.3°C/60%RH; and a COP of 1.22 with inlet water temperature of 16°C and air conditions of 19.9°C/49%RH. In this study with an improved absorber, we achieved a COP of 1.26 at less favorable airside conditions (19.9°C /49%RH) and less favorable water inlet temperature conditions (18.4°C), and with similar water and solution flowrate. The improvement in the performance of the new absorber is attributed primarily to the increase in the active absorber surface area.

Another point of comparison is that Chugh et al. [2] achieved a COP of 1.22 with inlet water temperature of 16°C and air conditions of 19.9°C/49%RH. The present study achieved a higher COP with much less favorable water inlet conditions (18.4°C).

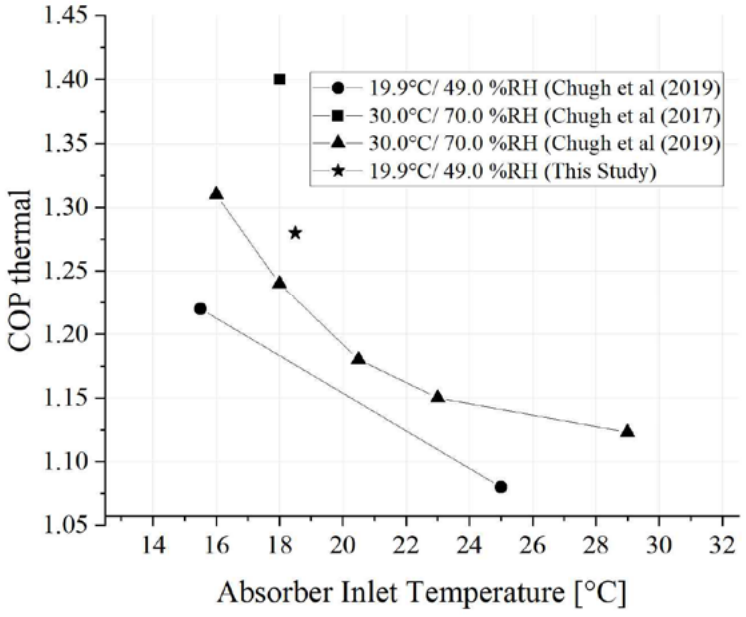

Figure 6: Comparison of the current absorber performance with previous absorber in a similar test set-up. The previous results were from Chugh et al. (2017 [1], Chugh et al. (2019)[2].

4.3. Water Storage Tank

A residential water heater has supply water at 51.7 ± 2.8°C (e-CFR, [4]). Therefore it desirable that the heat pump delivers the requirement temperature lift to the water in the water storage tank during charging and draw. If the heat pump delivers water at any condition below 49°C, the UEF test would be invalidated. The temporal and spatial water temperature distribution is shown in Figure 7. During the UEF test, the tank hot water outlet temperature and top tank temperature was maintained above 48.9°C during draws and charging. This UEF test demonstrates that the heat pump evaluated in this study can deliver water above the current testing standards requirement of 48.9°C at an ambient condition of 19.7 ± 0.6°C and 50 ± 2 %RH.

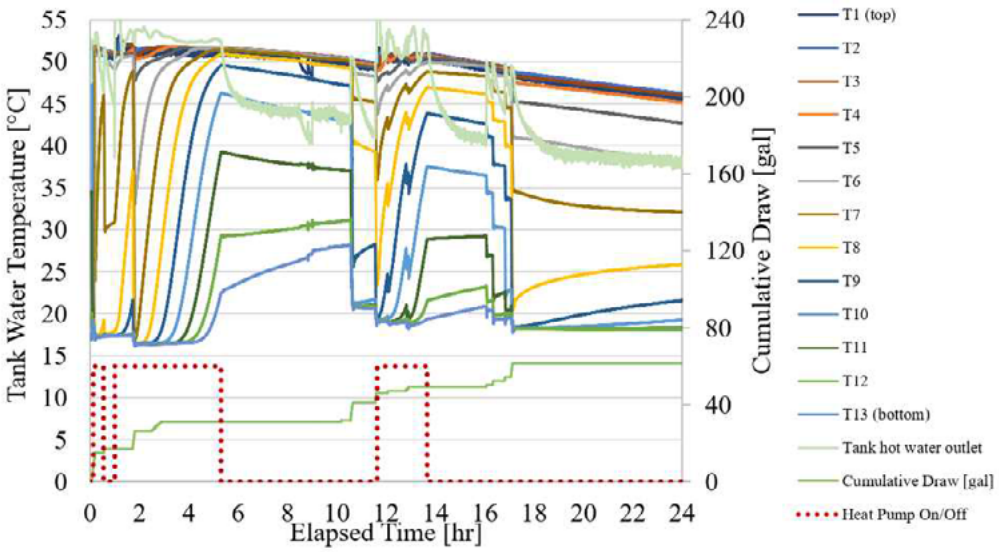

Figure 7: The water temperatures in the 50-gallon water storage tank throughout the 24-hour test.

5. Conclusions

A semi-open, membrane-based heat pump water heater experimentally followed the US standard water heater test method. While directly utilizing water vapor from the surrounding air as a working fluid, the cycle demonstrated an average cycle COP of 1.22 and 825 W water heating capacity, in surroundings of 19.7°C (67.5°F) and 50% relative humidity. The medium use load profile from the US DOE UEF test procedure was met without relying on any other heat source.

NOMENCLATURE

CFM	cubic feet per minute
COP or $COP_{thermal}$	coefficient of performance (useful heat / thermal energy consumed)

Abstract

This paper describes the results of an experimental study on the heat transfer characteristics of a commercially available solid-state thermoelectric heat pump device, when applied in an application heating water in minichannels. Each TE device was sandwiched in between two aluminum minichannel heat exchangers, with water flowing through the minichannels in opposite directions. Measurements of the TE substrate temperatures, water temperatures, water flow rates, input voltage and current to the TE were used to determine the heating and cooling capacity and coefficient of performance. The parameters that were varied during the study included the water flow rate, incoming water temperature and current supplied to the TE. These results were compared to manufacturer specifications and theoretical prediction using classical TE equations (based on available TE property data) and showed significant differences. The results are part of a larger study on thermoelectric clothes drying for residential applications.

Keywords: Thermoelectric; heat pump

Nomenclature

$\dot{m}_{hw}$	Mass flow rate for hot water, kg/s
$\dot{m}_{cw}$	Mass flow rate for cold water, kg/s
$c_{p,hw}$	Specific heat capacity for hot water, kJ/kg·K
$c_{p,cw}$	Specific heat capacity for cold water, kJ/kg·K
COP_{heat}	Heating coefficient of performance
COP_{cool}	Cooling coefficient of performance
$T_{hs,avg}$	Average hot-side substrate temperature, °C
$T_{cs,avg}$	Average cold-side substrate temperature, °C
$T_{hw,avg}$	Average hot water temperature, °C
$T_{cw,avg}$	Average cold water temperature, °C
ΔT	Temperature difference between average hot- and cold-side substrate temperatures (also DT), K
q_{hw}	Heating capacity, W
q_{cw}	Cooling capacity, W
UA_{hot}	Overall heat transfer coefficient on hot-side, W/K
UA_{cold}	Overall heat transfer coefficient on cold-side, W/K
W_{elec}	Electrical power input to TE, W

1. Introduction

Thermoelectric (TE) modules are ubiquitous devices that rely on the Peltier effect for heat pumping [1]. Although typically less efficient than traditional vapor-compression based heat pumps [2], it is possible to use TE heat pumps for certain applications which take advantage of their modularity and simple design. For example, TEs have been studied in recent years for improving or augmenting existing types of building heating and cooling systems [3-6]. Most recently, Zhao et al studied radiative sky cooling-assisted thermoelectric cooling for building applications [6]. They showed that by integrating TEs with other technologies, the COP could be improved significantly, demonstrating potential large-scale adoption of TE cooling. The use of the integrated TE cooling allowed for better control of the heat transfer fluid temperature (in addition to providing supplemental cooling) and made the performance of radiative sky cooling subsystem less susceptible to changes in ambient conditions. A case study involving a two-story residential building with thermal storage tank, radiative cooling surface and 101 TE modules was able to achieve an annual cooling COP of 1.87. Both daytime and nighttime cooling of the radiative sky cooling subsystem were analyzed.

In addition to building heating and cooling applications, TEs have also been considered for many other types of equipment, including refrigeration [7], personal thermal comfort [8], electronics cooling [9] and appliances such as clothes dryers [10, 11]. For example, Liu et al have conducted a thermodynamic analysis of a transcritical CO_2 refrigeration cycle integrated with thermoelectric subcooler and ejector [7]. They found that a 39% increase in maximum cooling coefficient of performance (COP) was possible by using the thermoelectric subcooler + ejector compared to the baseline cycle. Simultaneously, a lower discharge pressure was achieved. The authors have also conducted past studies on a clothes drying application which utilize TE heat pumps [10, 11]. These studies showed that the energy efficiency of traditional electric clothes dryers (which using heating elements) could be improved by as much as 40% by using a TE heat pump designed in such a way to control temperature lift and achieve optimum TE performance.

Based on current research, it has become increasingly important to properly characterize the performance of TE modules, as this information is valuable to update TE models and predict the overall system performance whenever TEs are used in different applications. Along those lines, the current work describes an experimental effort to measure the heating and cooling performance of a TE module as a function of applied voltage, current and other parameters. The experimental measurements are used to determine heating and cooling COP and overall heat transfer coefficient for a TE module installed in between two minichannels heat exchangers through which water flows. The experimentally measured results are also compared to manufacturer-provided specifications on TE performance.

2. Experimental setup

The experimental setup consisted of a single 40 × 40 mm TE module installed between two flat aluminum minichannel heat exchangers through which water flowed in opposite directions. An aluminum spacer block was used to maintain a small gap in between the hot and cold minichannel heat exchangers, as illustrated in Fig. 1.

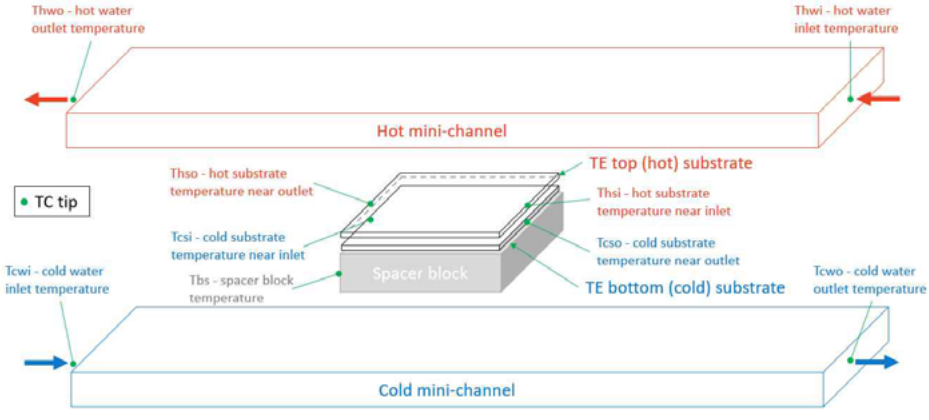

Fig. 1. Schematic showing installation of TE module and thermocouple (TC) locations

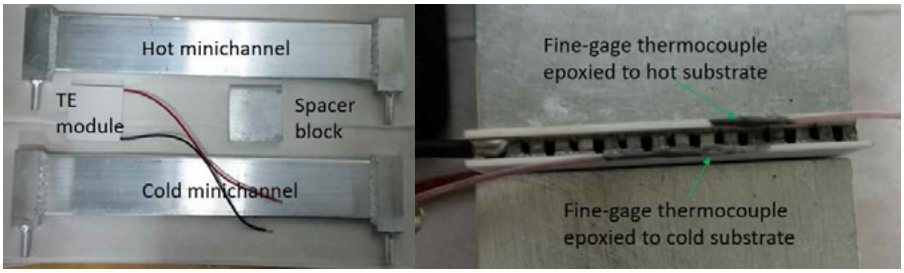

As shown in Fig. 1, various temperature sensors were used in the experimental setup to measure substrate and water temperature. Thermocouple probes were used to measure the water temperatures, while fine-gage thermocouple wires were used to measure surface temperature of the TE substrate and spacer block. Water mass flow rates were measured by using a precision weighing scale and high-accuracy timer to determine that rate at which an empty container was filled. The water temperatures were used with the water mass flow rates to determine the heating and cooling capacity of the TE module. The voltage applied to the TE and current flowing through the TE were used to determine the electrical power consumed. The substrate temperatures were used along with electrical power to determine the overall heat transfer coefficient between the TE and water.

The specifications of the commercially available TE [12] are given below in Table 1. The TE was chosen based on the nominal temperature difference between hot and cold sides, average heating and cooling capacity, operating voltage and current.

Table 1. TE specifications from manufacturer datasheet [12]

Hot substrate temperature, T_h [°C]	27	50
Temperature difference between hot and cold side of the module when cooling capacity is zero at cold side, ΔT_{max} [°C]	74	83
Voltage applied to the module at ΔT_{max}, V_{max} [V]	16.8	18.08
DC current through the modules at ΔT_{max}, I_{max} [A]	8.4	8.4
Cooling capacity at cold side of the module under ΔT = 0 °C, Q_{Cmax} [W]	90.0	98.0
AC resistance [Ω]	1.50	1.66

A photo of the various components in the experimental setup before assembly is shown in Fig. 2a. Figure 2b shows a close-up image of the TE hot and cold substrates and placement of the fine-gage thermocouples.

(a.) (b.)

Fig. 2. (a.) components used in experimental setup before assembly and (b.) close-up photo of thermocouple placement on TE substrate

A single mechanical clamp was used to hold the assembly together, as shown in a photo of the completed experimental setup with insulation (Fig. 3). All mating surfaces were coated with a thermal compound [13] to reduce interfacial thermal resistance.

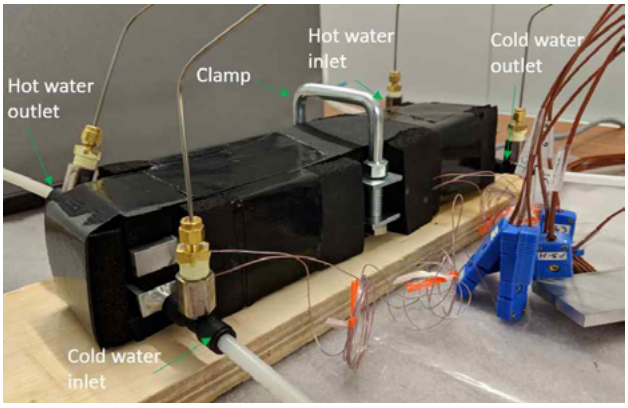

Fig. 3. Completed experimental setup with insulation

A heated recirculating bath was used to maintain a constant inlet temperature on the hot side and tap water was used on the cold side. Needle valves were used on both sides to adjust the water flow rates as needed. An Extech Switching Mode adjustable DC power supply was used to apply a voltage to the TE module. Voltage and current were recorded from the front panel display of the power supply.

3. Experimental method and data reduction

The TE module performance was characterized as a function of the hot-side inlet water temperature and current. The experiment matrix is shown below in Table 2. The quantities for water flow rates and inlet temperatures were based on previous work on thermoelectric clothes drying [11].

Table 2. Experiment matrix for TE module performance characterization

Hot side water mass flow rate [g/s]	Cold-side water mass flow rate [g/s]	Hot-side inlet water temp. [°C]	Cold-side inlet water temp. [°C]	Current [A]
9.66	19.24	40	Tap, ~20	5.00
9.66	19.24	40	Tap, ~20	7.00
9.66	19.24	40	Tap, ~20	8.30
9.66	19.24	55	Tap, ~20	7.00
9.66	19.24	55	Tap, ~20	7.90
9.66	19.20	75	Tap, ~20	7.00
9.66	19.20	75	Tap, ~20	8.30

The experiment was initiated by first measuring the water flow rates on the hot and cold sides and adjusting them to the desired values in Table 2. Next, the setpoint on the heated recirculating bath was adjusted to the desired hot-side inlet water temperature in Table 2. When conditions were steady, the power supply for the TE module was turned on. The power supply functioned in “constant current” mode and current was adjusted to the desired value in Table 2. The steady state voltage and current readings on the power supply front panel were recorded. The changes in substrate and water temperature were recorded continuously at 1 sample/s for a total of 300 s, after which the power supply was turned off for 60 s. This process was repeated three times for each experiment, to ensure that the results were reliable and repeatable.

The overall heat transfer coefficient, UA, between the TE substrates and the water was calculated using Eqs. (1) and (2) for the hot- and cold-sides, respectively (nomenclature for temperatures as defined in Fig. 1):

$$UA_{hot} = \frac{\dot{m}_{hw} c_{p,hw} (T_{hw\,o} - T_{hw\,i})}{(T_{hs,avg} - T_{hw,avg})} = \frac{q_{hw}}{(T_{hs,avg} - T_{hw,avg})} \quad (1)$$

$$UA_{cold} = \frac{\dot{m}_{cw}\, c_{p,cw}\, (T_{cw\,i} - T_{cw\,o})}{(T_{cw,avg} - T_{cs,avg})} = \frac{q_{cw}}{(T_{cw,avg} - T_{cs,avg})} \quad (2)$$

The heating and cooling COPs were calculated using Eqs. (3) and (4), respectively:

$$COP_{heat} = \frac{q_{hw}}{W_{elec}} \quad (3)$$

$$COP_{cool} = \frac{q_{cw}}{W_{elec}} \quad (4)$$

4. Results and discussion

All experiments in Table 2 were completed. Example results of temperatures measured during the first two experiments are shown in Fig. 4 (nomenclature as defined in Fig. 1).

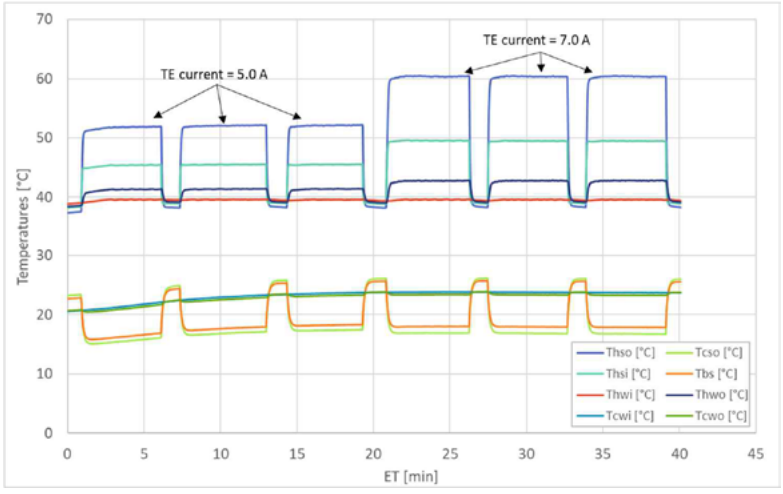

Fig. 4. Results of temperature measurement for experiments for V = 11.2 V, I = 5.0 A and V = 16.1 V, I = 7.0 A (Note: T_{csi} not shown due to erroneous measurements)

As illustrated above, all experiments were performed three times with the exact same conditions to ensure repeatability and reliability of the data. From the measurements in Fig. 4, the highest temperatures occurred on the TE hot substrate; the substrate temperature increased in the direction of the water flow by as much as 11°C (T_{hsi} vs. T_{hso} in Fig. 4). The results also showed that the average temperature of aluminum spacer block was similar to that of the cold side TE substrate. Detailed results of the above experiments are given in Table 3.

Table 3. Detailed results for experimental data shown in Fig. 4

Current [A]	Voltage [V]	Average hot-side substrate temperature [°C]	ΔT [K]	Heating capacity [W]	Cooling capacity [W]	UA_{hot} [W/K]	UA_{cold} [W/K]	Heating COP	Cooling COP
5.0	11.2	48.54	33.00	69.13	31.40	8.48	5.54	1.23	0.56
5.0	11.2	48.78	31.93	71.40	32.38	8.61	5.49	1.28	0.58
5.0	11.2	48.80	31.41	72.30	32.08	8.68	5.33	1.29	0.57
7.0	16.1	54.97	38.08	127.36	34.69	9.23	5.16	1.13	0.31
7.0	16.1	54.93	38.07	128.19	34.33	9.31	5.12	1.14	0.30
7.0	16.1	54.92	38.13	128.82	34.09	9.37	5.09	1.14	0.30

As shown above, the overall heat transfer coefficient on the hot side was greater than on the cold side. The experimental results were found to be consistent from test to test when all conditions were kept the same. To illustrate the comparison between experimentally measured values and manufacturer provided data, an overlay graph was created. Figure 5 shows such an overlay; the manufacturer data [12] shows the cooling capacity of the TE module at a hot-side substrate temperature of T_{hs} = 50°C, as a function of applied voltage, for various temperature differences between the hot and cold TE substrates (DT or ΔT). It is important to note that the manufacturer data are not derived from experimental measurements, but rather from solutions of the classical thermoelectric equations [1] which characterize TE performance as a function of substrate temperatures, TE properties and applied current. The closest experimental results from Table 3 which could be compared to the manufacturer data were for the TE current of 5.0 A (the average hot-side substrate temperature and DT from the three experiments were 48.7°C and 32.1 °C, respectively).

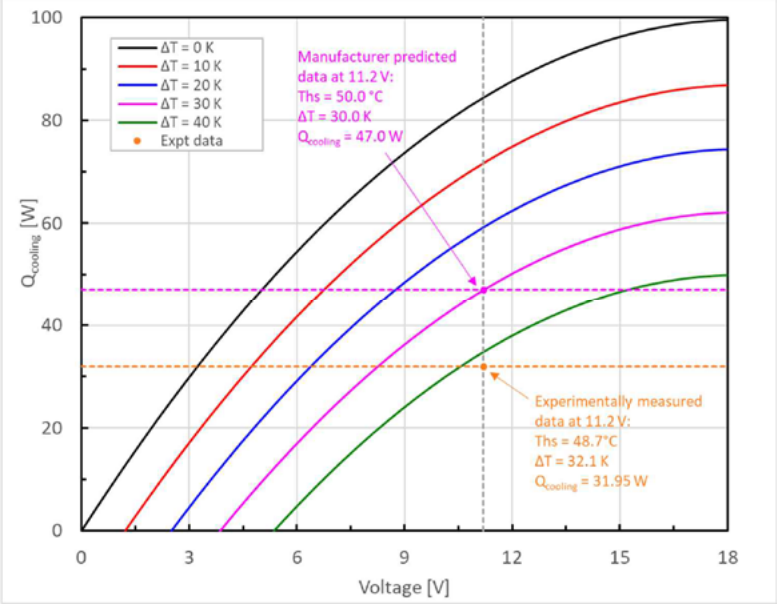

Fig. 5. Experimental data points overlaid on manufacturer data [12] for TE cooling capacity at a hot-side substrate temperature of 50°C as a function of voltage for various DT values (i.e. temperature difference between TE hot and cold substrate)

As shown above, there was a significant difference in the average measured cooling capacity (31.95 W, at a voltage of 11.2 V and DT = 32.1 K) and the cooling capacity expected from manufacturer data (~47.0 W) at the same voltage and DT (magenta line). Furthermore, the average measured cooling COP for this case was 0.57, whereas the manufacturer provided data indicated a cooling COP of 0.86 (51% higher). The results

showed that there was a discrepancy between the experimentally measured values and manufacturer provided data, possibly due to differences in material property values used in the calculations. For the experimental data, heat losses and measurement sensor uncertainty contributed to the overall uncertainty. It should be noted, however, that the above results were for a single operating point averaged over three identical experiments. More experiments will need to be performed with various water flow rates, temperature differences, voltages/currents to obtain an overall performance map. In addition, compensation for any heat losses should be applied in future work to improve the experimental accuracy.

5. Conclusions

The performance characteristics of a single TE module were measured in an experimental setup with water as the heat transfer fluid. The results show that the measured data are consistent and show significant differences compared to manufacturer-provided values for heating capacity, cooling capacity, and COP as a function of input voltage and current. For example, the manufacturer-specified cooling capacity was 51% higher than measured for one operating point. As such, if TE modules are to be used in system models for different applications, care must be taken to accurately characterize their performance for the particular application.

Impact of Variable Speed Components on the Seasonal Performance of a Residential Air-Source Heat Pump

Fatih Meral[*,a], Oliver Obst[a], Nicholas P. Salts[a], Eckhard A. Groll[a]

[a]Purdue University, School of Mechanical Engineering, Ray W. Herrick Laboratories,
177 S Russell St, West Lafayette, IN 47907, United States

Abstract

Heat pumps utilizing variable-speed compressors and other capacity control techniques offer significant seasonal efficiency improvements over traditional single-speed systems by reducing system cycling losses and corresponding system inefficiencies. However, the majority of residential heat pumps operated in the United States (US) utilize single-speed Permanent Split Capacitor (PSC) compressors and offer few capacity control options. This paper presents testing results of a novel electronic drive that enables the variable-speed control of conventionally single-speed PSC motors in compressors and fans using a low power inverter. The focus of this research is to improve the cooling seasonal performance of a 2-ton (6.7 kW) off-the-shelf residential air-source heat pump by replacing its PSC scroll compressor with a PSC rotary compressor and applying the low power inverter to enable variable speed control of the PSC motors. This paper also presents the impact of a variable speed indoor blower with an electronically commutated motor (ECM) and two variable speed outdoor fans: the first with a variable speed PSC motor enabled by the electronic drive and the second with a conventional variable speed ECM motor. The modified heat pump has been tested in psychrometric chambers for Seasonal Coefficient of Performance (SCOP) / Seasonal Energy Efficiency Rating (SEER). The results show that a SCOP/SEER improvement of nearly 33% is possible using a low power inverter for the PSC compressor combined with variable speed ECM indoor and PSC and ECM outdoor fans. Results also indicate a total SCOP/SEER improvement of 40% is possible by changing from a PSC scroll compressor to a PSC rotary compressor while also utilizing variable speed fans.

Keywords: air-source heat pump, inverter, SEER, Variable Speed Control, PSC

1. Introduction

The increasing demand for energy, which has so far primarily been produced from fossil fuels, represents an enormous burden on the environment and the climate. Fossil fuel power plants generated 82% of the energy worldwide needed in 2018 [1]. CO_2 emissions, amounting to approximately 36 billion metric tons in 2018, must be reduced to a large extent in order to curb global warming [2]. Therefore, the use of fossil fuels must be greatly reduced, but energy costs should not rise to the same extent. This raises the question of ways to save resources. One possibility is to increase the efficiency of existing Heating, Ventilation and Air Conditioning (HVAC) heat pump cycles in order to save energy especially due to the fact that 40% of the total energy consumption in the US is being due to buildings mainly for cooling and heating [2]. The US market for these systems is primarily dominated by fixed-speed single-stage systems with low seasonal energy efficiency ratios (SEER).

* Corresponding author.
E-mail address: fmeral@purdue.edu .

This could be explained in part by the expected useful lifespan of heat pumps, which is estimated between 9 and 15 years, which contributes to the number of single-speed systems due to the fact that systems with variable speed operations have only gained popularity in the last few years. In addition, the SEER requirement for split-system central air conditioners was increased by the department of energy (DOE) to at least 13 for all units which were manufactured after January 1st, 2015 [3]. The SEER requirement is higher in certain areas of the US. Split-system HVAC units typically deliver from 2 tons (6.7 kW) to 5 tons (17 kW) of cooling capacity for US residential installations. A typical residential vapor compression air conditioning and heat pump system contains four primary components. These components are a condenser, evaporator, expansion device, and a compressor and dedicated fans for the heat exchangers both of which are fixed-speed components.

These fixed-speed components have a significant impact on the efficiency which can be achieved by HVAC units. Fixed speed Permanent Split Capacitor (PSC) motors for compressors, outdoor fans and indoor blowers are traditionally used for low SEER systems, whereas high SEER HVAC units have variable speed control of these elements, which is connected to higher manufacturing costs. These high efficiency systems are providing the ability to modulate the system capacity to match the cooling or the heating load depending on the required cooling capacity which avoids cycling losses inherent to fixed-speed systems at part load. The market share of the high efficiency systems is lower than single-stage systems due to the ability of manufacturers to meet the required efficiency regulations through lower cost approaches, such as increasing the heat exchanger surface area [4]. These approaches are limited considering the restricted space of an HVAC system and will become less cost effective for manufacturers due to the increasingly restrictive efficiency regulations instated by the DOE. An alternative method to increase the efficiency of systems, which use fixed-speed PSC components is to use a low power electronic drive that has been designed to enable variable speed operation of conventionally fixed-speed components. The design and operation of such an electronic drive is described in detail by Chretien et al. [5, 6].

This paper focuses on the performance impact of variable speed components by applying the low power electronic inverter drive that is specifically designed to be used as a modification to an existing single-stage heat pump (SSHP). This drive has been connected to a residential off-the-shelf split-system SSHP with a SEER rating of 13. The modified SSHP allows for the control of system capacity via compressor speed, indoor fan speed and outdoor fan speed. The modified system will be referred to as a variable speed heat pump (VSHP) due to the control it provides over component speeds. The SEER has been calculated for the baseline SSHP with a PSC scroll compressor, the baseline SSHP with a PSC rotary compressor and the inverter modified VSHP in order to compare the systems. This comparison is presented, and future work is discussed.

2. Methods

In this work we selected an off-the-shelf SSHP with a PSC scroll compressor and experimentally determined the baseline SEER for evaluating the inverter and its impact on a residential split-system SSHP. Previous research on the topic of the low power inverter have shown that HVAC systems using PSC rotary compressors have a higher SEER than similar systems with PSC scroll compressors when modified with the inverter [7]. Therefore, the PSC scroll compressor has been removed and a PSC rotary compressor was installed. After the baseline SEER for the new compressor is determined, the inverter is installed to enable the variable speed operation for the compressor, indoor fan and outdoor fan. The variable speed SEER was experimentally determined and compared to the fixed-speed SEER of the off-the-shelf system.

2.1 Baseline Heat Pump and Psychrometric Rooms

The air-source heat pump was installed and instrumented in a pair of temperature and humidity-controlled psychrometric chambers for testing both the scroll and rotary compressor. One room of the psychrometric rooms is for simulating indoor conditions and the other for simulating the outdoor conditions. The heat pump was installed and tested according to the AHRI 210/240-2019 [8] standard for the rating of unitary air source heat pump equipment. The SSHP consists of an outdoor and an indoor unit. The outdoor unit contains the compressor, condenser, outdoor fan, and a four-way valve. The indoor unit includes the evaporator, thermostatic expansion valve (TXV), and indoor fan. The baseline system is a 2-ton (6.7 kW) heat pump with a PSC scroll compressor and a SEER rating of 12. The nominal indoor airflow rate is 1360 m^3/h, the nominal compressor speed is 3600 rotations per minute (RPM) and the system is charged with 2.7 kg of R410A to ensure consistent subcooling in the liquid line and therefore an accurate mass flow reading. The compressor is

a fixed speed PSC scroll compressor, the indoor fan is a constant volume flow rate fan using an electronically commutated motor (ECM), and the outdoor fan uses a PSC fixed speed motor, whose speed is 1075 RPM.

2.2 Inverter Mechanism

The inverter allows for variable speed operation of a traditional heat pump, which has fixed-speeds for compressor as well as indoor and outdoor fan. Figure 1 shows the schematic drawing of the inverter and heat pump connection inside the psychrometric chambers. The inverter is installed in series between the power grid and the indoor as well as outdoor unit. The inverter converts the AC voltage from the 230V power supply and a 60 Hz frequency into a DC voltage and allows the voltage and frequency to be changed and therefore allows to change the speed of the individual components. This system allows the independent control of the speeds of the compressor and fans.

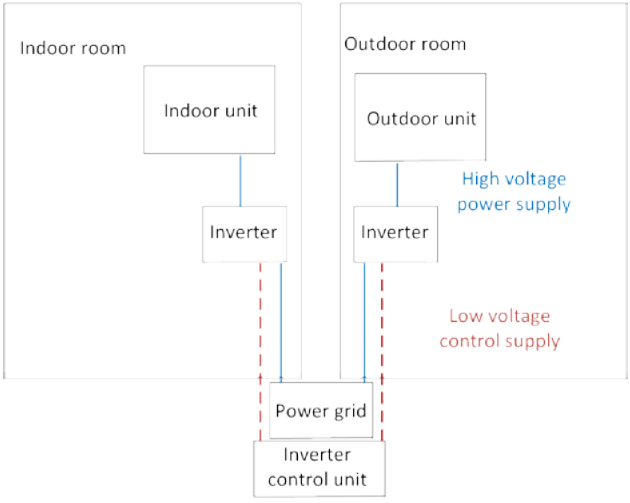

Figure 1. Inverter connection

2.3 Heat Pump modified with an Inverter

The purpose of the modified heat pump with the inverter is to allow the control of the variable speed operation for the compressor, indoor fan, and outdoor fan on existing SSHPs. The main application for such a device is for existing single-speed HVAC systems that are in service, so this experimental characterization captures the actual implementation of this inverter system effectively. The inverter is installed by connecting it in-line between the power source and the components to be controlled, allowing the motor speeds of each component to be adjusted manually and independently of one another during the laboratory experiments. The first modification made to the baseline heat pump was the exchange of the PSC scroll compressor to a PSC rotary compressor, followed by the connection of the inverter to the PSC rotary compressor. The third modification consisted of the connection of the inverter to the PSC outdoor fan, and in the final modification step the PSC outdoor fan was replaced by an ECM outdoor fan. An ECM indoor fan was used during the duration of the laboratory testing. Variable speed operation is inherent to ECM technology and therefore, while the electronic drive was used to control ECM fan speeds, the inverter component, which enables control of PSC motor frequency, was not used in line with the ECM fans.

2.4 Data Collection and Analysis

The data is collected through a National Instruments cRIO-2091 using a visual interface (VI) written in LabVIEW. The power consumption of the indoor fan, the outdoor fan, and the compressor are measured separately with watt transducers. The cooling capacity of the heat pump is determined using the refrigerant and air enthalpy method. A schematic of the refrigerant loop of the heat pump in cooling mode is shown in Figure 2.

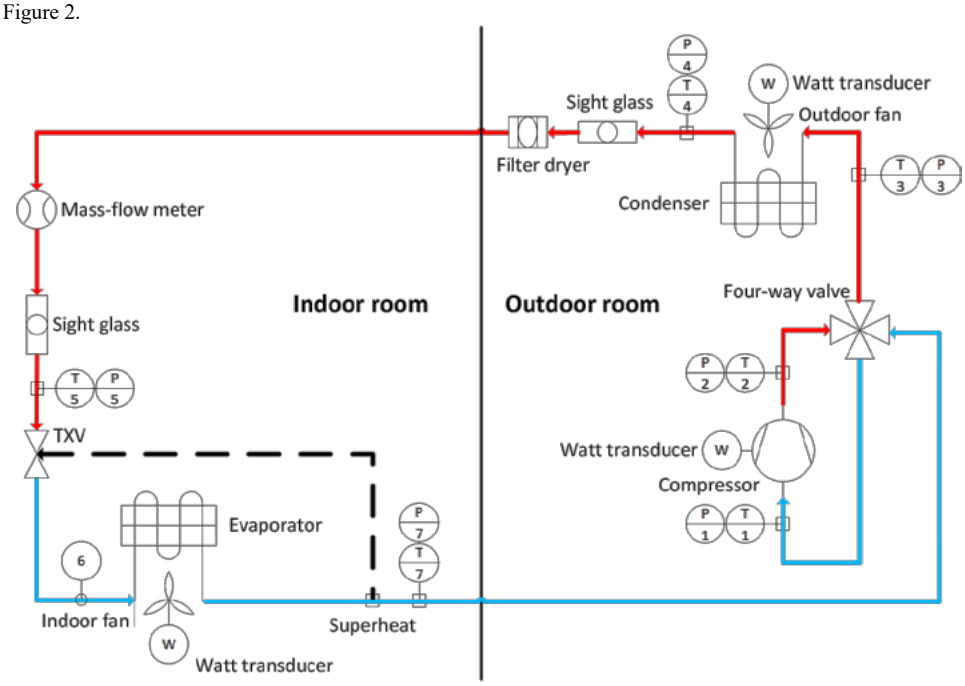

Figure 2. Heat pump schematic

The state points 1 through 5 and 7 in Figure 2 are determined by measuring the pressure and the temperature of the refrigerant. In order to determine the state point 6 between the TXV and the evaporator assumptions of an isenthalpic expansion across the TXV and no pressure drop for the section between the outlet of the TXV and the outlet of the evaporator are made. The mass flow rate of the refrigerant is measured by using a Coriolis-effect mass flow meter oriented for liquid measurement at the outlet of the condenser. All refrigerant and air properties have been determined using the software Engineering Equation Solver (EES) [9].

The cooling capacity of the refrigerant-side of the evaporator can be calculated from an energy balance derived from the first law of thermodynamics and the measured state points along with the listed assumptions resulting in equation 1.

$$\dot{Q}_{\text{evap}} = \dot{m} \cdot \Delta h_{evap} = \dot{m} \cdot (h_7 - h_6) \quad (1)$$

The net capacity is calculated by subtracting the heat added to the air by the indoor fan, which can be assumed to be equal to the power consumption of the indoor unit, from the evaporator capacity shown in equation 2.

$$\dot{Q}_{\text{net}} = \dot{Q}_{evap} - \dot{W}_{indoor} \quad (2)$$

The air-side capacity of the system is calculated from the first-law energy balance across the indoor unit as shown in equation 3. This equation accounts for the change in enthalpy of the air stream and also accounts also for the small amount of water that is condensed out of the air stream.

$$\dot{Q}_{\text{net}} = \dot{m}_{air} \cdot \Delta h_{evap} - \dot{m}_{water} \cdot h_{water} \quad (3)$$

The air volume flow rate is determined using a nozzle box connected to the duct work of the indoor unit and is designed as outlined in ASHRAE Standard 37-2009 [10]. The air volume flow rate is calculated iteratively according to equation 4 using the area of the duct work (A_i). The expansion factor (Y) and the coefficient of discharge (C_i) are also established in ASHRAE Standard 37-2009.

$$\dot{V}_{air} = Y \cdot \sqrt{\frac{2 \cdot \Delta p_{nozzle}}{\rho_{air}}} \sum_{0}^{k} C_i \cdot A_i \quad (4)$$

The mass flow rate of the air is determined by equation 5.

$$\dot{m}_{air} = \dot{V}_{air} \cdot \rho_{air} \quad (5)$$

The dry-bulb temperature of the air is measured with a 3x3 thermocouple grid at the inlet and outlet of the indoor unit. The relative humidity of the inlet air is determined by using a relative humidity sensor. The dew point of the outlet air is determined by sampling the outlet air at a rate of 1 liter/min and passing it through a chilled mirror dew point sensor. The inlet air enthalpy, outlet air enthalpy and outlet water enthalpy are calculated using EES using these measured values. The condensed water mass flow rate is determined as shown in equation 6.

$$\dot{m}_{water} = \dot{m}_{air} \cdot (\omega_2 - \omega_1) \quad (6)$$

The coefficient of performance (COP) is unitless and defined as the ratio of the cooling capacity divided by the total power consumed by the heat pump.

$$\text{COP} = \frac{\dot{Q}_{net}}{\dot{W}_{total}} \quad (7)$$

2.5 Test Matrix

The baseline heat pumps with fixed-speed components as well as the inverter modified heat pumps with variable speed components have been tested according to the guidelines set by AHRI Standard 210/240-2019 [8]. The test matrix shown in Table 1 contains the ratings tests for a SSHP, while Table *2* shows the ratings tests for a VSHP. Temperature values have been co-listed in both English and SI Units because the SEER calculation requires the input of temperatures in °F.

Table 1. ANSI/AHRI test matrix for a heat pump with a single speed compressor and constant volume indoor fan.

Test description	Air entering outdoor unit °F/°C		Air entering outdoor unit °F/°C		Air volume rate
	Dry–bulb	Wet–bulb	Dry–bulb	Wet–bulb	
A (required)	95.0 / 35.0	75.0 / 23.9	80.0 / 26.7	67.0 / 19.4	Full–load
B (required)	82.0 / 27.8	65.0 / 18.3	80.0 / 26.7	67.0 / 19.4	Full–load

Table 2. ANSI/AHRI test matrix for a heat pump with a variable speed compressor and indoor fan.

Test description	Air entering outdoor unit °F/°C		Air entering indoor unit °F/°C		Compressor speed	Air volume rate
	Dry–bulb	Wet–bulb	Dry–bulb	Wet–bulb		
A_2 (required)	95.0 / 35.0	75.0 / 23.9	80.0 / 26.7	67.0 / 19.4	Maximum	Full–load
B_2 (required)	82.0 / 27.8	65.0 / 18.3	80.0 / 26.7	67.0 / 19.4	Maximum	Full–load
E_V (required)	87.0 / 30.6	69.0 / 20.6	80.0 / 26.7	67.0 / 19.4	Intermediate	Intermediate
B_1 (required)	82.0 / 27.8	65.0 / 18.3	80.0 / 26.7	67.0 / 19.4	Minimum	Minimum
F_1 (required)	67.0 / 19.4	53.5 / 11.9	80.0 / 26.7	67.0 / 19.4	Minimum	Minimum

2.6 SEER Analysis

These test matrices are used to determine the SEER for the system. This rating is a standard method used to rate the cooling performance of heat pumps in the US. A seasonal analysis is necessary to characterize the actual benefits of the VSHP, which come in form of the ability to match part load conditions, relative to a SSHP. This research will use the SEER rating to quantify the improvement in performance of the baseline SSHP compared to the inverter modified VSHP.

Each test matrix contains optional tests to determine the coefficient of cyclic degradation (C_D). This factor is used to account for the loss in efficiency of the heat pump during periods of cycling on and off. The standard calls for an assumed value of 0.25 for the coefficient of cyclic degradation if all optional tests are not performed. Due to significant time requirement to carry out the optional tests, a value of 0.25 is assumed in this analysis. This value resulted in the calculated SEER of the baseline SSHP to be equal to the SEER declared by the manufacturer. The same coefficient of cyclic degradation was assumed for the VSHP. The official online calculation tool provided by AHRI was then used to calculate the SEER for the SSHPs and VSHPs. A full description of the SEER calculation can be found in the AHRI Standard 210/240.

3. Results

All heat pumps tests are shown in Table 3. The first test was baseline testing of the off-the-shelf single stage heat pump with the PSC scroll compressor (SSHP1). Next, the PSC scroll compressor was exchanged for a PSC rotary compressor for the second baseline test (SSHP2). Both SSHP1 and SSHP2 tests used a constant volume flow rate setting for the ECM indoor fan. The inverter was then connected to the PSC rotary compressor and the heat pump was tested as a VSHP (VSHP1). After this test, the PSC outdoor fan was connected to the inverter, which enabled the variable speed control for the fan (VSHP2). Finally, the PSC outdoor fan motor was replaced by an ECM motor in order to compare an inverter driven PSC outdoor fan, which is usually installed in SSHPs and a more expensive ECM-powered outdoor fan that enabled the variable speed option without an inverter and is typically installed in VSHPs with a higher SEER rating (VSHP3). All VHSP tests were performed using the ECM indoor fan in variable speed mode. The baseline test results for the SSHP1 are shown in Table 4.

Table 3. Phases of testing the heat pump.

Test	Compressor Type	Outdoor Fan Motor	Variable Speed Components	Fixed Speed Components
SSHP1	Scroll	PSC	None	Compressor Indoor Fan Outdoor Fan 1
SSHP2	Rotary	PSC	None	Compressor Indoor Fan Outdoor Fan 1
VSHP1	Rotary	PSC	Compressor Indoor Fan	Outdoor Fan 1
VSHP2	Rotary	PSC	Compressor Indoor Fan Outdoor Fan 1	None
VSHP3	Rotary	ECM	Compressor Indoor Fan Outdoor Fan 2	None

Table 4. SSHP1 test results.

Test	Indoor Air Flowrate	Static Head	Cooling Capacity	Compressor Speed	Outdoor Fan Speed	Indoor Power	Outdoor Power	Total Power	COP	SCOP
[-]	[m^3/hr]	[Pa]	[kW]	[%]	[%]	[W]	[W]	[W]	[-]	[-]
A	1338.84	142.4	6.7	100	100	206	1755.4	1961.4	3.49	3.88
B	1341.72	143.2	7.3	100	100	213	1509.9	1722.9	4.31	

For the baseline test, the cooling capacity matched the manufacturer value of 2 tons (6.7 kW) with a SCOP rating of 3.88. Overall excellent agreement with rated performance is achieved. The cooling capacity is validated by comparing the refrigerant and air side calculation method. For all tests both calculation methods matched within 7% which indicates accurate cooling capacity readings. Table 5 contains the baseline test results for the SSHP2.

Table 5. SSHP2 test results.

Test	Indoor Air Flowrate	Static Head	Cooling Capacity	Compressor Speed	Outdoor Fan Speed	Indoor Power	Outdoor Power	Total Power	COP	SCOP
[-]	[m^3/hr]	[Pa]	[kW]	[%]	[%]	[W]	[W]	[W]	[-]	[-]
A	1291.68	142.9	7.2	100	100	206.4	1786.4	1992.8	3.6	4.08
B	1323	143.7	7.8	100	100	213.5	1512.3	1725.8	4.54	

By changing the PSC scroll compressor to a PSC rotary compressor the SCOP rating increased by 4.98% to 4.08. The COP for the A-test increased by 3.24% to 3.6 and for the B-Test by 5.34% to 4.54, which indicates a higher cooling capacity for both tests. Table 4 and Table 5 show that the overall SCOP rating of the heat pump with the rotary compressor is higher than the heat pump using the scroll compressor. Typically, a single stage scroll compressor is more efficient than a similarly sized system with a rotary compressor, which is not the case for the tested units. The reason for this is delivered by Figure 3, which indicates that the isentropic efficiency of the rotary compressor is significantly higher than the scroll compressor.

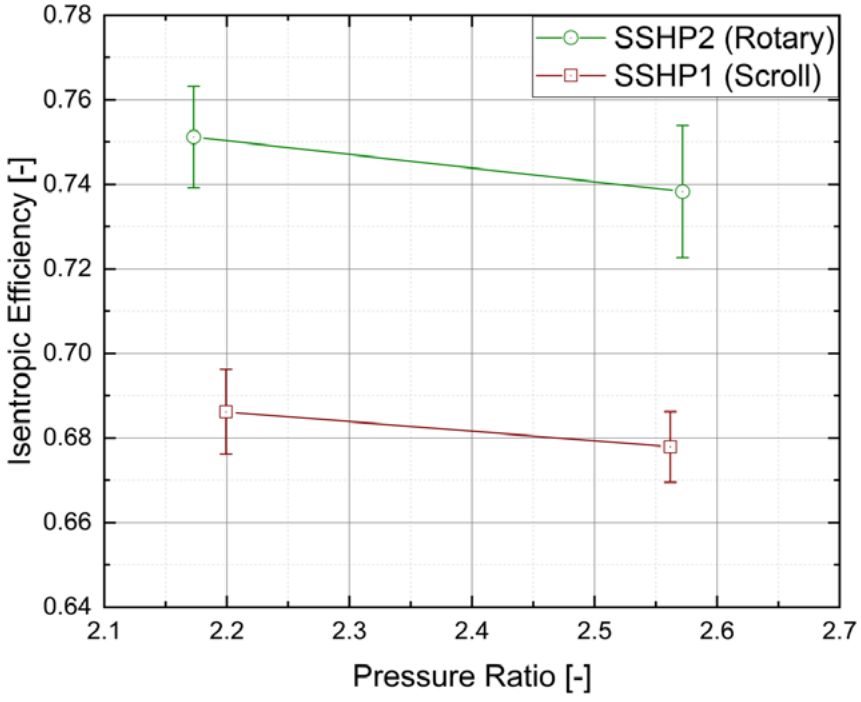

Figure 3. Isentropic Efficiency vs. Pressure Ratio for the A and B test of the AHRI Standard 210/240-2019.

Table 6 shows the results of testing the inverter modified VHSP with only the compressor connected to the inverter, operating in variable speed mode.

Table 6. VSHP1 test results.

Test	Indoor Air Flowrate	Static Head	Cooling Capacity	Compressor Speed	Outdoor Fan Speed	Indoor Power	Outdoor Power	Total Power	COP	SCOP
[-]	[m^3/h]	[Pa]	[kW]	[%]	[%]	[W]	[W]	[W]	[-]	[-]
A_2	1291.68	142.9	7.2	100	100	206.4	1786.4	1992.8	3.6	
B_2	1323	143.7	7.8	100	100	213.5	1512.3	1725.8	4.54	
E_v	1006.92	80.4	4.8	57	100	107.1	921	1028	4.66	4.88

F_1	828.72	58.4	3.7	35	100	74.98	440.1	515.1	7.12	

The inverter modified heat pump enabled variable speed control over the compressor and the ability to match part load conditions. The SCOP rating of the heat pump was improved by 19.63% to 4.88 by just connecting the compressor to the inverter. An overall SEER improvement of 25.59% was achieved, compared to the SSHP1. Table 7 shows the results of testing the inverter modified VSHP with the compressor and the outdoor fan connected to the inverter and operating in variable speed mode.

Table 7. VSHP2 test results.

Test	Indoor Air Flowrate	Static Head	Cooling Capacity	Compressor Speed	Outdoor Fan Speed	Indoor Power	Outdoor Power	Total Power	COP	SCOP
[-]	[m^3/h]	[Pa]	[kW]	[%]	[%]	[W]	[W]	[W]	[-]	[-]
A_2	1291.68	142.9	7.2	100	100	206.4	1786.4	1992.8	3.61	
B_2	1350	143.7	7.8	100	100	213.5	1512.3	1725.8	4.54	
E_v	1005.84	78.53	4.7	57	79	103.5	892	995.5	4.75	5.18

F_1	855.36	58.03	3.7	35	66	74.78	372.7	447.51	8.24	

The SCOP rating of the heat pump was improved to 5.18 by adding the variable speed option to the PSC outdoor fan and still providing the same cooling capacity. This SEER improvement is an increase of 27.1% compared to the SSHP2 and 33.43% compared to the SSHP1. The testing results for the inverter modified heat pump with an ECM for the outdoor fan are shown in Table 8.

Table 8. VSHP3 test results.

Test	Indoor Air Flowrate	Static Head	Cooling Capacity	Compressor Speed	Outdoor Fan Speed	Indoor Power	Outdoor Power	Total Power	COP	SCOP
[-]	[m^3/h]	[Pa]	[kW]	[%]	[%]	[W]	[W]	[W]	[-]	[-]
A_2	1324.08	143.1	7.2	100	89	206.4	1786.4	1992.8	3.61	
B_2	1324.44	143.8	7.7	100	89	213.5	1512.3	1725.8	4.54	
E_v	1007.64	79.81	4.8	57	67	103.5	892	995.5	4.75	5.42
B_1	857.88	58.46	3.4	35	53	75.09	515.3	590.4	5.83	
F_1	859.32	60.63	3.4	35	53	74.78	372.7	447.51	8.24	

By using an ECM outdoor fan instead of an inverter modified PSC outdoor fan the SCOP could be improved additionally by 4.52% to 18.48. The seasonal COP (SCOP) and SEER of the different heat pump test cases are shown in Figure 4.

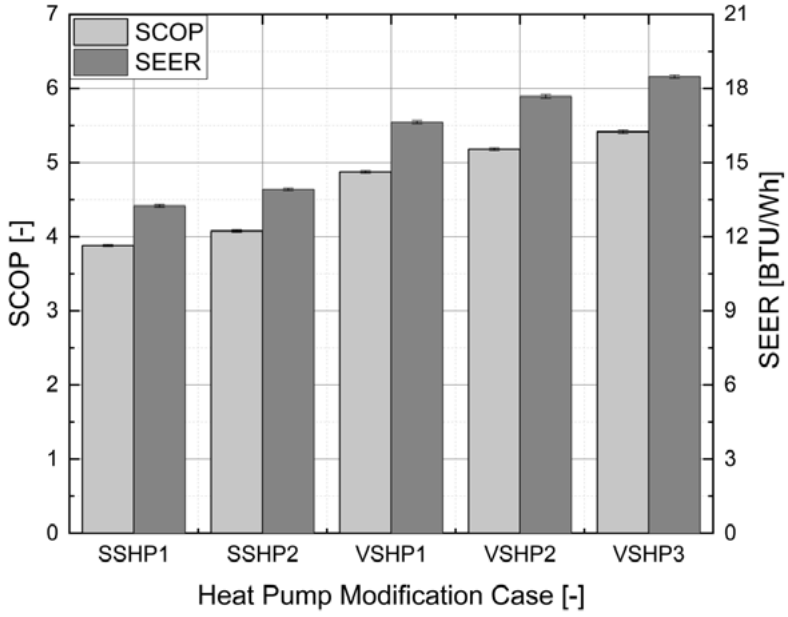

Figure 4. SCOP and SEER of the different heat pump test cases.

Table 9 shows the different heat pump modification cases with the SCOP, the SEER and the improvement in percentage. Table 9 and Figure 4 are indicating that the largest single improvement occurred from SSHP2 to VSHP1 by operating the PSC rotary compressor in variable speed mode along with a variable speed indoor ECM fan. The SEER could be improved by over 19% compared to the same heat pump setup without the electronic drive. Table 9 and Figure 4 also show that operating the PSC outdoor fan in variable speed mode has a significant impact. Operating the PSC outdoor fan in variable speed mode (VSHP2) shows an increase of more than 27.1% compared to SSHP2.

Table 9. Seasonal COP and SEER comparison for all test cases.

Test Case	SCOP	SEER	Improvement compared to SSHP1	Improvement compared to SSHP2
[-]	[-]	[BTU/Wh]	[%]	[%]
SSHP1	3.88 +/- 0.0149	13.25 +/- 0.0508	-	-
SSHP2	4.08 +/- 0.0156	13.91 +/- 0.0533	4.98 +/- 0.96	-
VSHP1	4.88 +/- 0.0187	16.64 +/- 0.0638	25.59 +/- 1.05	19.63 +/- 0.82
VSHP2	5.18 +/- 0.0199	17.68 +/- 0.0678	33.43 +/- 0.97	27.10 +/- 0.73
VSHP3	5.42 +/- 0.0208	18.48 +/- 0.0707	39.47 +/- 1.14	32.85 +/- 0.89

4. Conclusions

The results of this paper indicate that the use of an electronic drive to control the motor speeds of both PSC and ECM components improves the seasonal performance of an existing single-speed heat pump significantly. The highest SEER improvement was achieved by operating the PSC compressor and ECM indoor fan in variable speed mode with the help of the electronic drive. This shows that performance improvements can be made to an HVAC system that uses fixed-speed components by only modifying the power delivery system. In addition, the results clearly show that operating the outdoor fan in variable speed mode has a significant impact

on the SEER rating. Furthermore, operating the PSC outdoor fan using the inverter can be nearly as efficient as a conventional ECM outdoor fan.

Future work on this project is to connect the inverter control unit to the thermostat of a modified variable-speed unit. We would like to provide an automatic control of the inverter by changing the speed of the components depending on the ambient condition without input from the end user. This would be automatically determined by the ambient and user set point temperature with an optimization algorithm. Additional studies should be conducted to investigate the impact of the inverter drive for the heating mode of the heat pump and further the reliability of fixed-speed compressors and outdoor fans being operated in variable speed mode. One way to do this could be done by performing life cycle testing on an inverter modified heat pump with a fixed-speed compressor and outdoor fan paired to an inverter.

Disproportionation risk study for HFO-1123 compositions as Low-GWP refrigerants

Hidekazu Okamoto*, Tetsuo Otsuka, Hiroki Hayamizu, Tatsuya Ueno

AGC Inc., Marunouchi 1-5-1, Tokyo, 100-8405, Japan

Abstract

In this study, we reported the risk assessment evaluation of the HFO-1123 containing refrigerant mixture that was previously developed as an alternative to HFC-32 and R410A refrigerants. Based on conventional knowledge, the refrigerants containing HFO-1123 might inherent safety risk of an autocatalytic disproportionation reaction. In order to address this issue, we evaluated the probability of air conditioner unit failure by this reaction process using the the risk assessment technique that was previously use for HFC-32. Disproportionation reaction occurs when the refrigerant is exposed to an ignition source under high-temperature and high-pressure conditions similar to the conditions inside the compressor unit. We performed a risk assessment of disproportionation of a HFO-1123/HFC-32 refrigerant mixture (40% /60% by weight). Our study concluded that by adding additional safety measures such as manual recovery unit, the safety risk of HFO-1123/HFC-32 refrigerant mixture at the same level of HFC-32 refrigerant.

Keywords: Refrigerant ; Low-GWP; HFO-1123; Disproportionation; RAC; Risk assessment

1. Introduction

In recent years, HFC-32 has become a popular alternative refrigerant to R410A for residential air conditioners (RACs). According to the ASHRAE classification, R410A is classified as A1 non-flammable substances. HFC-32, however, is classified as A2L mildly flammable substance and therefore must be subjected to flammability risk assessment [1-2]. More recently, hydrofluoro-olefins (HFOs) have accepted as next generation refrigerants with lower global warming potential (GWP) property. And previously we have proposed a refrigerant containing trifluoroethylene (HFO-1123) for residential air conditioning applications. The typical physical properties of HFO-1123 and other refrigerants are shown in Table 1 [3]. HFO-1123 has a boiling point close to that of HFC-32 compared to other HFO refrigerants that have been proposed as an alternative for R410A. It is possible to provide a mixed refrigerant with small temperature glide in a variety of composition range [3]. Figure 1 shows that HFO-1123 can form a mixed refrigerant that has small temperature glide over a wider range than HFO-1234yf and HFO-1234ze(E). Although this excellent property, fluorinated ethylene compounds, such as tetrafluoroethylene (HFO-1114), is known to cause an autolytic disproportionation reaction generating significant heat. There are, in fact, reports on previous explosion accidents at chemical plants [4]. HFO-1123 is also known to und[1]ergo disproportionation in the presence of an ignition source (equation 1) [5]. Therefore the safety issue of HFO-1123 needs to be addressed before introducing them into practical use as adequate refrigerants. To clarify this risk, we evaluated the probability of unit failure by the disproportionation reactions for mixed refrigerants containing HFO-1123, using fault-tree analysis (FTA), a technique used previously in assessing the flammability risk of HFC-32 [2].

2. Scope of Risk assessment

2.1. Incident probability allowance

Referning to ISO/IEC Guide 51 of the probability of an incident that is allowed in a risk assessment (“allowance” below), we performed a study using the R-Map methodology proposed by National Institute of Technology and Evaluation (NITE) to estimating incident frequency and to quantifying the frequency of an occurrence. In the case of chemical plants and other large-scale facilities, which are under a variety of regulations, the allowance is set below 10^{-5} events/year. And for household appliances that typically require mimimum maintenance, the allowance is set below 10^{-8} units/year (on a 1-million unit basis) based on the probability of a major incident occurance. In other words, for a product that has 1 million units being distributed per year, there needs to be less than one fatal injury every hundred years. In this study, refering to our previous work on allowances for air conditioners [1-2], we specified a target probability of incidents in use of 10^{-10} units/year or less, because the extent of damage from disproportionation is unclear and we assume the maximum damage under R-Map.

2.2. Possible ignition sources

Disproportionation is known to happen when an ignition source is present under both high temperature and high pressure conditions [6]. Therefore, there is minimum risk of disproportionation when the refrigerant leaks at atmospheric pressure. However the risk is significantly high inside the compressor of air conditioning unit where elevated pressures and temperatures exist. Thus we hypothesized that the ignition sources could be caused by (a) static electricity caused by a refrigerant flow, (b) spark of layer short circuit or lead wire short circuit resulting from melted insulation coating due to either faulty manufacture of the insulation member or abnormally high temperature, and (c) frictional heat by contacting between compressor rotor and casing. The estimated amount of energy of the three respective ignition sources are as follows. In the case of ignition source (a), the possible charge of static electricity in everyday space is up to about 12 kV when the relative humidity is low. When the capacitance is 100 pF, the discharge energy is 7.2 mJ [7]. In safety assessments for flammable gas facilities, the standard for spark energy is that a maximum of 20 mJ (or 40 mJ) is considered good, so we took 40 mJ as the static spark energy. As for (b), we assessed ignition sources comprehensively for this paper using fault-tree analysis (FTA). And lastly, as for (c), since the compressor rotor is metallic and has high thermal conductivity, therefore under normal operations, it has no risk of becoming an ignition source.

3. Results and Discussion

3.1. Risk assessment of disproportionation in constant-speed air conditioners

A mixture of HFO-1123/HFC-32 refrigerants (40% /60% by weight: GWP: 405) was used in our study as the model case of HFO-1123 containing refrigerant system in our risk assessment. For conditions under which an ignition source might appear leading to disproportionation under operating conditions for RACs, we performed a comprehensive analysis by using the FTA methodology [8]. To investigate the cases of abnormal operation, we carried out simulation tests of abnormal operation using actual equipment [8]. As the result, the greatest temperature and pressure rise was observed in the heating operation with either a three-way valve closed or a forgotten opening valve after installation or subsequent regular services (A). Other abnormal operations being considered in our study were the condenser side fan stoppage during operation (B) and contact fusion of compressor relay (C). Figure 2 shows the FTA of possible failure modes that could lead to ignition sources. The failure mode I and the failure mode II show the events that may create ignition sources due to the above abnormal operations, while the failure mode III shows the events that can create ignition sources due to either mechanical failures or the like during normal operation.

In the failure mode I and II, the safety device and controller mounted on the compressor will stop functioning with continuous live current due to intermittent repetition of operation. These will cause the compressor to stall, the motor essentially becoming a low-resistance heater and rapidly heating up with increasing pressure. The compressor's interior would exceed the temperature at which the windings melt, leading to break down of the insulation and current sparking lead to disproportionation.

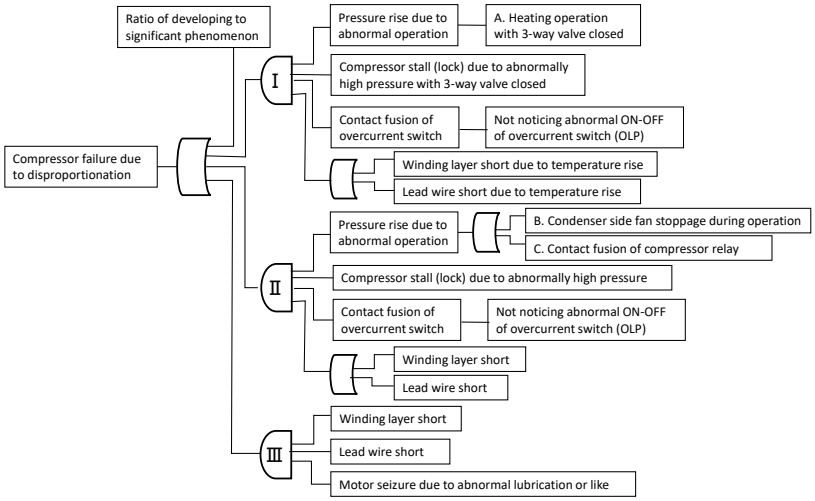

Fig. 2. FTA leading to disproportionation inside residential air conditioners

3.1.1. Risk assessment of disproportionation due to abnormal operation

For values and safety equipment used for our risk assessment, we took the probabilities of functional failure to be at the line between safety-integrity level (SIL) 3 and 4 at safety device that operate high-frequency in Table 2 (10^{-8} times/h). Based on JIS room air conditioner standard (JIS C 9612: 2013), the assessment was held for total yearly running time of a residential air conditioner, we used the 2500 h/year, and based on that get a failure rate for ordinary electrical components of 2.5×10^{-5} ($= 10^{-8} \times 2500$), and we used a human error of 3×10^{-3} [9].

Table 2. Functional safety of electric, electronic, and programmable electronic safety systems under IEC61508 (JIS C0508)

	Safety level	Average probability of functional failure in design per work request
Safety device that operate low-frequency	SIL 4	10^{-5} to less than 10^{-4}
	SIL 3	10^{-4} to less than 10^{-3}
	SIL 2	10^{-3} to less than 10^{-2}
	SIL 1	10^{-2} to less than 10^{-1}
	Safety level	Average frequency of dangerous failure of safety function (times/ h)
Safety device that operate high-frequency	SIL 4	10^{-9} to less than 10^{-8}
	SIL 3	10^{-8} to less than 10^{-7}
	SIL 2	10^{-7} to less than 10^{-6}
	SIL 1	10^{-6} to less than 10^{-5}

Figure 3 shows the flowchart of disproportionation which result from heating operation with the three-way valve closed (abnormal operation mode I). We assessed the probability of an incident resulting from abnormal operations going unnoticed as shown in the Table.3. In this scenario, which assumes the compressor reaching an internal temperature above 250°C, the winding and lead wire have a probability of dielectric breakdown of 1. When using our model refrigerant (HFO-1123/HFC-32:40 wt%/60 wt%), we calculated that disproportionation resulting from a spark ignition source caused by this dielectric breakdown would have a probability of 1 as well. Disproportionation resulting from heating operation with a three-way valve closed has a probability of 9×10^{-9} instances/year.

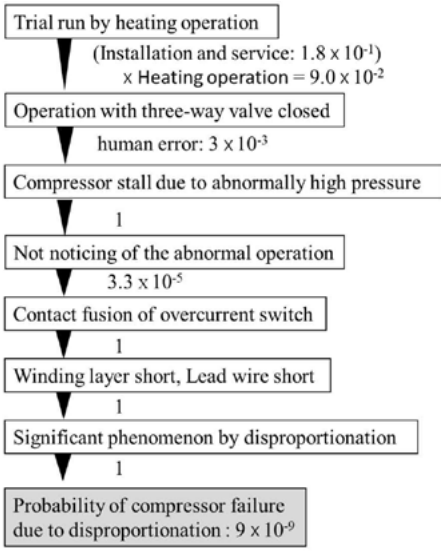

Fig. 3. Flowchart of heating operation with three-way valve closed

Table 3. Probability of anomalous operation going unnoticed

By installers and service personnel			By user		Incidence by mode
Test run	Test run contents	Miss rate	Setting conditions	Miss rate	
done 0.997	Perform until normal operation confirmation (10 min): 0.997	3×10^{-3}	One unit per room 0.9	3×10^{-3}	8.1×10^{-6}
			Several unit per room 0.1	1×10^{-2}	3.0×10^{-6}
	Startup confirmation only (10 sec): 3×10^{-3}	1	One unit per room 0.9	3×10^{-3}	8.1×10^{-6}
			Several unit per room 0.1	1×10^{-2}	8.1×10^{-6}
No test drive was performed 3×10^{-3}		1	One unit per room 0.9	3×10^{-3}	3.0×10^{-6}
			Several unit per room 0.1	1×10^{-2}	3.0×10^{-6}
Total					**3.3×10^{-5}**

Figure 4 shows the flowchart of the probability of disproportionation which result from the fan being stopped on the condenser side during operation (abnormal operation mode II-B). We calculated the probability that abnormal operation would go unnoticed as shown in Table 4.

In this case, in a simulation using only the compressor, the temperature and pressure of refrigerant at the compressor's outlet port would not climb as in the case where the three-way valve is closed; even if there were a short circuit of the winding and lead wire causing a spark ignition source that would not result in disproportionation, and the probability of that happening is calculated as low as 10^{-6} [8]. In addition, the probability of disproportionation resulting from the condenser-side fan being stopped during operations, according to the flowchart, is estimated in the range of 9.3×10^{-14} instances/year.

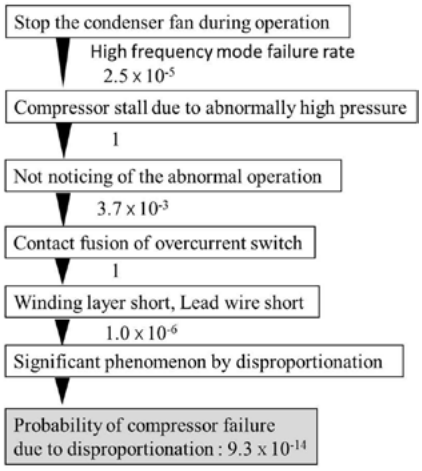

Fig. 4. Flowchart of condenser-side fan stopping during operation

Table 4. Probability of anomalous operation going unnoticed

By user		Incidence by mode
Setting conditions	Miss rate	
One unit per room 0.9	3×10^{-3}	2.7×10^{-3}
Several unit per room 0.1	1×10^{-2}	1×10^{-3}
Total		**3.7×10^{-3}**

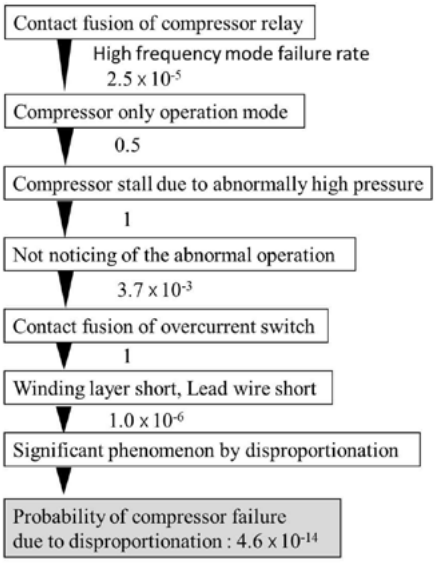

Fig. 5. Flowchart of runaway mode caused by compressor relay spot-welding itself

Figure 5 shows the flowchart of the probability of disproportionation which result from the compressor being in runaway mode due to the compressor relay (an electromagnetic contact device) spot-welding itself (abnormal operation mode II-C). We calculated the probability that abnormal operation would go unnoticed as shown in Table 4. In this case as well, even if there were a dielectric breakdown on the winding and lead wire causing a spark ignition source, the accourance would not result in disproportionation since probability of that happening is as low as 10^{-6}. Following the flowchart, the probability of disproportionation occurring due to its relay spot-welding itself as a result of the compressor being in runaway mode is estimated to be 4.6×10^{-14} instances/year. Combining together the results the above flowcharts, the total probability of an incident during one year that as the probability of a single unit have a disproportionation incident resulting from anomalous operations modes in the classes I, II-B, and II-C is 9×10^{-9} (as shown in Table 5).

Table 5. Probability of disproportionation per unit (total of three anomalous operations modes)

Mode	Probability (instances/year)
I. Cooling operation with three-way valve closed	9×10^{-9}
II-B. Condenser-side fan stopped	9.3×10^{-14}
II-C. Compressor relay spot-fusing	4.6×10^{-14}
Total	9×10^{-9}

3.1.2 Risk assessment of disproportionation due to normal operation

The flowchart in Figure 6 shows mode described in section III of Figure 2, for disproportionation resulting from normal operations. The probability of a lead wire short circuit or a layer short circuit in the windings during operation can be assumed to be 10^{-6}. Conversely, when a short circuit occurs in the temperature and pressure ranges prevailing under normal operations, the likelihood that this would lead to disproportionation is dramatically different due to the ignition energy that would cause spark ignition. We concluded an experiment in order to simulate spark ignition similar to a winding layer short circuit or lead wire short circuit inside a pressure vessel charged with refrigerant, and evaluated for disproportionation in a variety of temperature and pressure ranges [10-11].

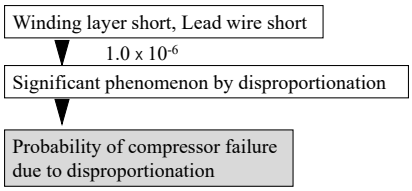

Fig. 6. Flowchart of the disproportionation mode during Nomal operation

Using equipment with ignition electrodes inside a pressure resistant reaction chamber (Figure 7), we confirmed the presence or absence of disproportionation phenomenon by observing temperature and pressure rises after ignition in a chamber with a fixed gap type ignition electrode. With this type of ignition electrodes, the breakdown potential gradient is extremely large in the system where a high-density fluorine-containing refrigerant with large breakdown voltage for use in RACs is present. Thus, it is necessary to apply an extremely high voltage or use a very small inter-electrode distance for generation of sparks. For the purpose of this study, the risk assessment needs to simulate the conditions of home power supply. And it was difficult to employ spark generation by the ignition method specified in the ASTM standard (ASTM E681-94, 1994) [12] because of the problem of easy short-circuiting of electrodes by the soot resulting from the disproportionation reaction (equation 1). Hence, we devised a movable gap type spark ignition system (see an enlarged view in Figure 7) and conducted the evaluation by an ignition method simulating spark phenomena that would occur in the compressor of air conditioners [10]. The spark generation mechanism is described in detail below. When a voltage is applied to one of the copper plates of ignition device, current begins to flow (the insert in Figure 7). A magnetic field is generated in accordance with Ampere's circuital law, and the current flowing due to the generated magnetic field is subjected to outward force of the circuit. By this force, the tungsten screws set on the cupper plate repel each other and separate (the insert in Figure 7). An electrical spark occurs at the moment when they separate. The power source used was an AC power source that is generally used for room air conditioners. In determining the ignition energy, the time change of current and voltage was monitored using an oscilloscope (Tektronix, TDS5054B), and the energy value was calculated using equation (2) by the time integration of current I(t) and voltage V(t) between the point (t_1) where the resistance value rises steeply and the point (t_2) where the resistance value returns back to the original value.

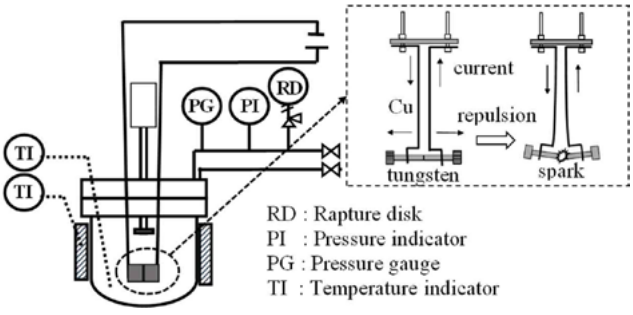

Fig. 7. Explosion apparatus with spark ignition electrode

$$E = \int_{t_1}^{t_2} I(t) \cdot V(t) dt \quad (2)$$

In normal operations, the operating conditions for the mixture refrigerant containing HFO-1123 have a maximum temperature of 130°C and a maximum attainable pressure of 4 MPa, referring to HFC-32's envelope diagram near its boiling point [13]. Based on the calculation using REFPROP [14], temperature of 86°C and pressure of 3.5 MPa, and taking into account a safety margin, we considered that these figures are reasonable.

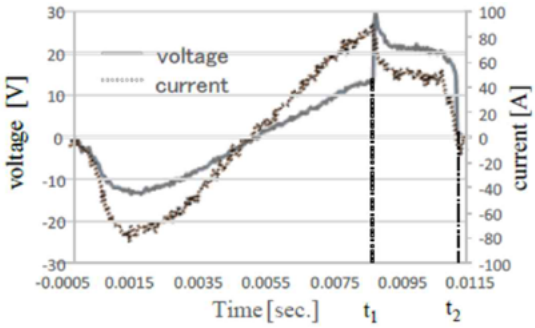

Fig. 8. Voltage and current intensity vs time

Then, we evaluated whether disproportionation occurs in the presence of various kinds of ignition energy at 130°C and 4 MPa. Figure 9 shows the results of 108 spark ignition tests at 130 °C, 4 MPa plotted versus the spark energy of the refrigerant mix with 60% by weight HFO-1123 and 40% by weight HFC-32. Our test was conducted with a composition having a higher amount of HFO- 1123 than the composition that was the subject of this risk assessment (HFO-1123 / HFC-32: 40 wt% / 60 wt%). This is because a very large amount of ignition energy is required to generate disproportionation for that composition. We regard disproportionation as being a phenomenon with the same probability as explosive combustion [4], and calculated a minimum ignition energy (MIE) using statistical analysis. It was difficult to generate consistent spark energy with the spark ignition device used in our experiment, making it difficult to perform the regression analysis used in ordinary statistical analysis. The logistic regresion method has been the major procedure to calculate the ignition probability distribution. But Rudz et al. [15] compared three methods, which are cumulative logistic distribution, cumulative normal distribution, and cumulative lognormal distribution. They concluded that a cumulative lognomal distribution was the most suitable for their experimental results. They reported the ignition probability by a cumulative logistic distribution and a cumulative normal distribution, was not zero when the ignition energy is zero. It was not appropriate to discuss low probability around 10^{-8} for the safety evaluation of this risk assesment. Therefore in our study the lognomal model was used to caluculate the minimum ignition energy distribution of disproportionation. By using the 108 measured values shown in Figure 9, as in the previous report [10], the parameters of equation (3) were determined as follows, and the ignition probability for each energy was calculated. Table 6 shows some ignition probabilities calculated from equation (3) with given ignition energies.

$\mu = 3.863$, $\sigma = 0.233$.

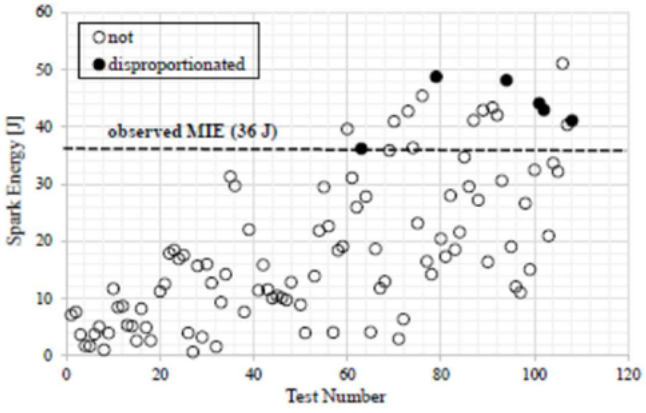

Fig. 9. Plot of 108 tests vs spark energy (HFO-1123/HFC-32:60wt%/40wt%, 130°C, 4MPa)

$$P(x) = \frac{1}{2}\left(1 + erf\left(\frac{ln(x) - \mu}{\sigma\sqrt{2}}\right)\right) \quad (3)$$

Based on these results, we assessed the probability of disproportionation occurring using the flowchart in Figure 6, and determined that the probability of this phenomenon changes depending on the spark ignition energy inside the compressor. Our result suggests that the probability will be even lower than that shown in Table 7 when using the model refrigerant (HFO-1123/HFC-32: 40 wt%/60 wt%) of this risk assessment.

Table 6. Calculated ignition probabilities and given ignition energies at 130°C, 4Mpa (HFO-1123/HFC-32 : 60wt%/40wt%)

130℃, 4Mpa		Spark energy
Observed	Exp.	36 J
Calculated	DEP* 50%	48 J
	DEP* 1%	28 J
	DEP* 0.001%	20 J

* Disproportionation event probability

Table 7. Probability of disproportionation per unit (under normal operations)

Expected spark ignition energy	Probability of winding layer short or lead wire short	Probability of disproportionation from ignition	Probability of disproportionation per unit
48 J	1.0×10^{-6}	0.5	0.5×10^{-6}
28 J		1.0×10^{-2}	1.0×10^{-8}
20 J		1.0×10^{-5}	1.0×10^{-11}

3.2. Summary of risk assessment & safety measures

For residential air conditioner unit, with a mixture refrigerant of HFO-1132/HFC-32, the risk of disproportionation is mainly determined by the spark energy from a winding layer short circuit or lead wire short circuit that might occur in the equipment. There is almost no statistical research into the spark energy from winding layer short circuits in air conditioning equipment, and it can be assumed that this will vary considerably depending on the equipment's design, the usage environment, and etc. For our model case, we assumed a typical compressor used in RACs (constant-speed, 3.48 kW cooling and heating type, single-phase power supply at 50 Hz, using R410A refrigerant) connected to ordinary household lines, in which the compressor rotor is locked and current is flowing causing the windings to heat up, leading in turn to a dielectric breakdown, we measured the spark energy from this. We assessed two kinds of motors, with distributed windings or concentrated windings. Results are shown in Table 8.

Table 8. Evaluation of spark ignition energy occurring within the compressor

	Test conditions		Spark phenomenon result		Conditions on sparking	
	Winding type	Grounded	Spark energy [J]	Number of sparks	Temp. [°C]	Pressure [MPa]
1	Concentrated	Yes	0.01–0.02	Several	233	8.9
2	Concentrated	Yes→No	0.01–0.1	Several	243	9
3	Concentrated	No	0.01	Several	338	9.4
4	Distributed	Yes	0.1–40	7	236	8.7
5	Distributed	No	0.01–20	85	238	9.5
6	Distributed	No	0.01–23	92	245	8.7

Table 8 shows that a concentrated-winding motor produces a maximum spark energy of 100 mJ, while a distributed winding motor can produce up to 40 J. This result shows that the spark energy that can be generated inside the compressor differs greatly depending on the winding system and the compressor design.

To prevent disproportionation in this kind of air conditioner with the refrigerant being studied, it would be necessary for allowance to be quantitively on the order of 10^{-3}, and qualitatively, there would need to be independent protection measures that would allow for one to fail.

Following are possible independent protection measures that would allow for one to fail.

A) A refrigerant mixture that would not disproportionate in the presence of spark energy that would result from normal operations or the worst-case scenario envisioned for abnormal operations (Figure 2, mode I). Specifically, a refrigerant with less HFO-1123 in the refrigerant composition would be one solution, but increasing the ratio of HFC-32 in the refrigerant composition has the disadvantage of increasing the GWP. Instead, another HFO refrigerant (such as HFO-1234yf), which would not increase GWP, should be considered for addition to the refrigerant composition.

B) Refrigerant with restrictions for use

B-1) Require two or more manual-recovery protection devices (detection by pressure, temperature, current, etc.) for at least one instance.

B-2) In addition to an overcurrent switch, require an additional manual-recovery protection device that can directly disconnect the compressor circuit.

Table 9 shows probability of disproportionation when the above measures in place.

Table 9. Revised disproportionation probabilities

Type of problem		Base spec	Remedy		
			1. Auto-recovery safety device	2. Manual-recovery safety device	3. Non-Disproportionating composition
Equipment in cooling operation		9×10^{-2}	9×10-2	9×10^{-2}	9×10^{-2}
Operating with 3-way valve closed		3×10^{-3}	3×10^{-3}	3×10^{-3}	3×10^{-3}
OLP inoperative (short)	trial-run action overlooked	9×10^{-3}	9×10^{-3}	9×10^{-3}	9×10^{-3}
	On/off during operation overlooked (≒ 1 month)	3.7×10^{-3}	3.7×10^{-3}	3.7×10^{-3}	3.7×10^{-3}
2nd protective device inoperative	On/off overlooked (next month)		7×10^{-1}		
	Manual recovery protective device inoperative			3×10^{-4}	
Disproportionation		1	1	1	0.2
Disproportionation leading to serious outcome		1	1	1	1.0×10^{-3}
Probability of disproportionation (incidents per year per unit)		9×10^{-9}	6.3×10^{-9}	2.7×10^{-12}	1.8×10^{-12}

4. Conclusion

This study investigated a risk assessment of a refrigerant consisting of 40 wt% HFO-1123 and 60 wt% HFC-32, which could be adopted as an alternative to R410A with a much lower GWP, as used in RACs. The study calculated the probability of significant incidents resulting from disproportionation while operating the air conditioners. The results show that the probability of a significant incident from foreseeable abnormal operations of the equipment, which have the highest risk mode could not cross the threshold of 10^{-10} units/year. This threshhold is the target of probability for serious incidents being allowed for residential products. In addition, we recommed some kind of additional safety measures, such as the addition of protection measures with manual recovery, which would allow for one to fail, would be necessary to bring the risk below the target threshold.

We conducted a risk assessment of the refrigerant in equipment under normal operations, assessing the energy for a layer short circuit in the windings or a lead wire short circuit, that might occur inside a compressor under normal operations, and the probability of these events. Although the result clearly highlights these important factors and conclusive, because of limited literature on the subject, further assessment of the risk would be necessary.

Improving Risk Assessment Of Refrigerant Leakage Hazards: Going Beyond Physical Testing

Sangamesh Hosur[a*], Mahmood Tabaddor[b]

Abstract

Simulation based risk assessment of refrigerant leakage hazards calls for accurate prediction of concentrations of the leaked refrigerant gas into an indoor environment. Although computational fluid dynamics (CFD) is seen as a promising tool to model complex dispersion scenarios, it is necessary that it be properly validated against reliable experimental data before the predictions can be used with confidence. In this paper, validation of the model is carried out for some scenarios involving a propane gas leak in to a confined space with various leak flow rate and locations. More importantly, we introduce a new risk metric to measure the probability of fire when there is leakage of a combustible propane gas into a confined space. This risk metric can only be obtained from the rich data generated by CFD modeling. This risk metric tracks the volume of combustible propane gas that lies between the upper and lower flammability limits. The results demonstrate how the risk metric provides a simple of fire risk ranking for different leakage scenarios.

1. Introduction

A global effort to reduce the greenhouse warming potential of refrigerants for refrigeration systems has reduced the overall candidate list to refrigerants that exhibit higher flammability than their predecessors. This has required additional investigations to ensure that the potential fire/explosion hazards associated with leakage of a flammable refrigerant are properly addressed and mitigated. The main means to gaining data to support risk assessments has been through physical testing [1].

However, there is a challenge and a limit to using physical testing to methodically understand the potential risks associated with leakage of a combustible refrigerant in confined spaces. One obvious challenge is that physical testing, especially if it could involve fire and explosion, is expensive and time consuming. Yet more importantly, each physical test is only a single data point and so, many tests must be run to cover scenarios of interest, which requires significant funding. Another limitation of physical testing is that it is only possible to capture data at discreet points during the physical test. These discrete points are usually selected to address the specific question the test was designed to answer and so the data collected may not provide sufficient insight into the testing conditions or allow for generalization.

An alternative to physical testing, or rather a complement, is the use of computational modeling tools. These tools have been used sporadically to help understand the risks associated with leakage of combustible refrigerants [2,3]. For modeling, the key challenge is to validate the simulation, that is to demonstrate via experimental evidence that the model predictions are accurate [4,5,6]. In one research report [1], the results of testing and simulation were compared, yet the validation of the simulation was not properly conducted. In other similar research conducted on refrigerant leakage hazard, the published reports [2,3] demonstrated good

E-mail address: sangamesh.hosur@ul.com

agreement between the model predictions and those from the test, and yet only a single point was selected for this conclusion. This is not enough to establish high confidence validation and could potentially hide flaws in the model that become more prevalent when used for other leakage scenarios.

Also, there is a challenge of using a few discrete points to assess the fire/explosion risk of a combustible refrigerant leakage scenario. When the intent is to determine if ignition of the leaked refrigerant is possible, the exact location of the ignition sources are critical and ignition outcomes could change drastically depending on the location of the ignition source(s) and local gas concentration levels. Also, the risk scenario of an active combustible gas leak is time dependent and therefore, a single fire or no fire outcome from an ignition source activated at an instant of time is not sufficiently informative of the full transient state.

The intent of our research is to demonstrate two things: (1) rigorous validation evidence for a simulation of refrigerant leakage in gaseous form in a confined space. And, (2) a new, simple risk metric for assessing the potential fire/explosion hazards associated with leakage of refrigerant into a confined space. This metric can only be obtained from the rich data provided by such computer-based engineering tools.

2. Physical Test Set-up

The experimental setup that was simulated was carried out at the fire testing facilities at UL [7]. A 3.6 m by 2.4 m by 2.4 m room was constructed within the facility as shown in Figure 1(b). The room was constructed with dimensions in accordance with ISO 9705 [8]. The room contained an obstruction of 1.83 m by 0.91 m by 0.91 m size at the center of the room. The room was equipped with refrigerant sensors at select locations to measure the leaked propane gas concentrations as shown in Figure 1. The location co-ordinates were measured from the experimental set up and transferred on to the computational domain to maintain corresponding sensor locations. The refrigerant was leaked in a gaseous form with controlled mass flow rate. Two locations were selected for leak introduction, one near the top and one near the bottom of the room (red dots shown in Figure 1b). The leak was introduced at one location at a time. Ignition sources were placed at one location in the room where a spark was generated at a specified point in time. Further details about the experiment can be found in the UL test report [7].

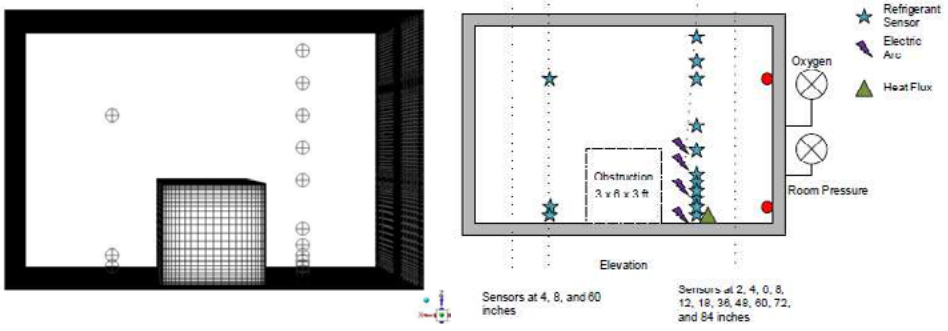

Fig. 1. (a) Sensor locations in computational domain (b) Sensor locations in test ISO room

3. CFD Simulation

The model for refrigerant gas leakage for the physical testing described in previous section was developed using ANSYS Fluent 2019 R2. CFD analysis was carried out to investigate the influence of refrigerant release rate and location on the spatial and temporal refrigerant concentration levels in a test room. The simulation provides predictions of the gas concentrations throughout the room for each scenario. The key challenge is to properly capture the physics of turbulence, diffusion and buoyancy which help determine the concentration gradient within the room. For the purposes of this research, a combustion model was not included as the focus for this simulation is on the gas concentration levels within the room prior to ignition. Though combustion is not modeled, fire risk can be determined by monitoring the gas concentration levels throughout the room over time and by comparing those values to the upper and lower flammability limits for the refrigerant gas.

3.1. CFD Model Description

Refrigerant leakage is modeled in Fluent CFD software which includes the key behaviors such as transient, turbulent species transport, mass diffusion, energy transfer and buoyancy [9]. The concentration of diffused gas is predicted by solving convection-diffusion equation.

$$\frac{\partial(\rho\, Yi)}{\partial t} + \nabla.(\rho\, U\, Yi) = -\nabla.(\boldsymbol{J}) + Ri + Si \quad (1)$$

Where Y_i mass fraction of i^{th} species. R_i is the net rate of production of species by chemical reaction (this is null in this case as no chemical reaction taking place.) and Si is the rate of creation by addition from the dispersed phase plus any user-defined sources. An equation of this form will be solved for $N\text{-}1$ species where N is the total number of fluid phase chemical species present in the system. Since the mass fraction of the species must sum to unity, the N^{th} mass fraction is determined as one minus the sum of the $N\text{-}1$ solved mass fractions.

The mass diffusion due to the mixing action of the chaotic turbulent velocity fluctuations is given as

$$\boldsymbol{J} = -\left(\rho Di,m + \frac{\mu t}{Sct}\right)\nabla.\mathrm{Yi} - Dt,j\frac{\nabla \mathrm{T}}{T} \quad (2)$$

where Sct is the turbulent Schmidt number, μt is the turbulent viscosity and Dt is the turbulent diffusivity. The default Sct 0.7 is used as turbulent diffusion is much higher than the laminar diffusion.

3.2. Geometry and Meshing

The ISO 9705 room was replicated in the computational domain (Figure 2). The room included two inlets which were located at 0.2 m and 1.8 m height from the floor on one wall opposite to a door. Each inlet allowed for controlled leakage of the propane gas. The flow conditions for the experimental project [7] was designed to represent a variable mass release at expected temperature/pressure conditions of a leak point in the subcooled liquid line. The fact that it would release as a gaseous form was confirmed from release temperature and pressure measurements [7]. During each test, only a single inlet was activated. A 3 mm gap between the door and floor was included in the model with the length of the gap being 0.9 m. The obstruction in the middle of the room was also modeled as a no-slip, no-penetration boundary condition of the computational domain.

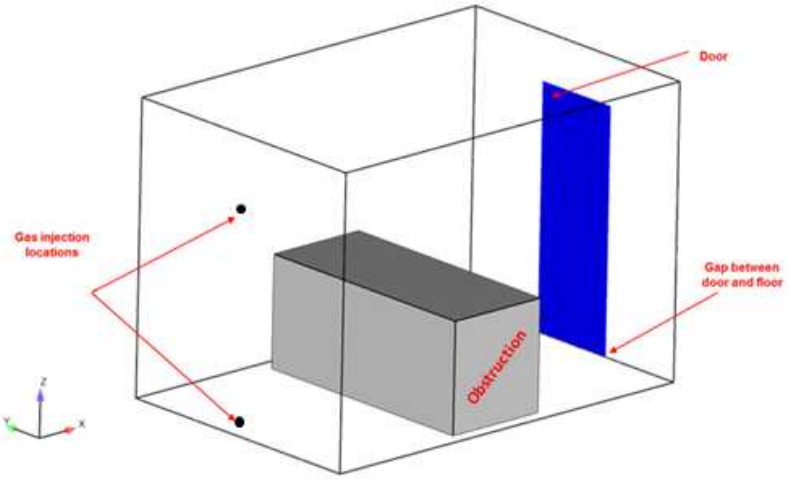

Fig. 2. Geometric model of test room

The entire computational domain was meshed using hex elements employing ANSYS ICEMCFD (Figure 3) [10]. A mesh sensitivity study was carried out with two different mesh sizes. An analysis of the results shows that the difference between the coarser (1.2 million cells) and fine mesh (4.2 million cells) were marginal (Figure 4). The coarser mesh has been applied to all subsequent calculations to reduce computational time.

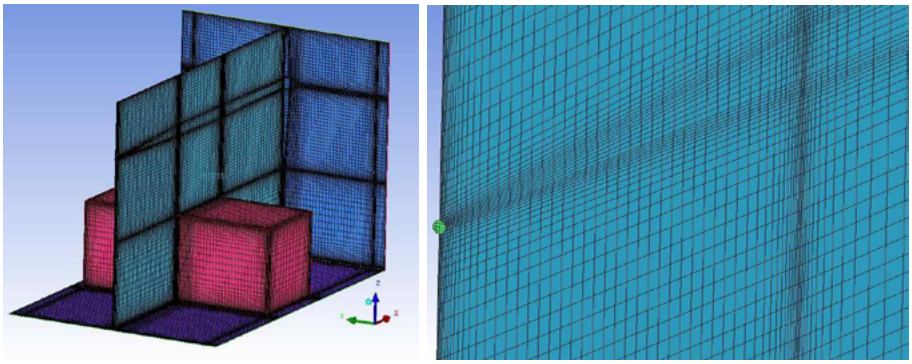

Fig. 3. Mesh of test room with mid plane showing mesh distribution

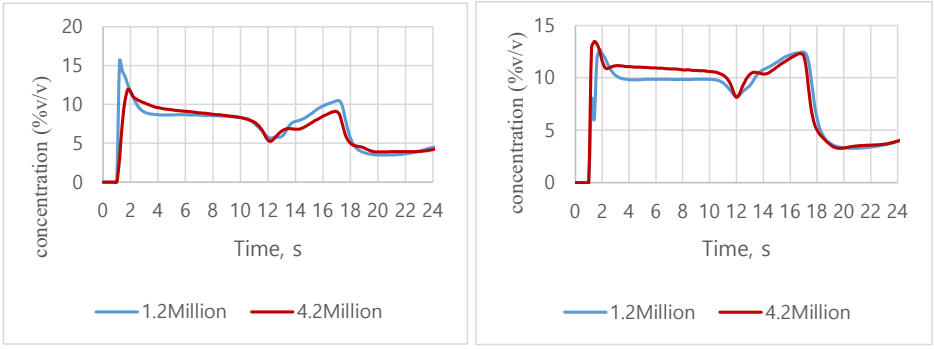

Fig. 4. Mesh sensitivity results for sensor 1 (left) and sensor 2 (right)

3.3. Fluid Properties and Boundary conditions

The fluid properties considered for simulation in accordance with test set up are shown in the Table 1.

Table 1. Thermo-physical Fluid properties

Gas property	Air	Propane
Molecular weight (g/mol)	29	44.1
Density (Kg/m3)	1.225	1.8985
Dynamic Viscosity (N s/m2)	1.789e-05	7.816e-06
Thermal conductivity (W/mK)	0.0242	0.0172
Specific heat Cp (J/K kg)	1006	1646.8
Mass diffusivity (m2/s)	NA	0.1

For this study, four different refrigerant gas leakage scenarios were studied. The factors under consideration were the gas leakage rate, total gas quantity and the location (height) of the leak. The opening size was kept constant at 25 mm diameter. Actual test times varied as the objective of these tests was to introduce varied quantity mass of gas for each scenario (Table 2). As such the test times are variable and were only considered up to the point of ignition in the test in keeping with the physics of the model.

Table 2. Scenarios being modeled

Scenario	Target Mass flow rate (g/s)	Total Mass of gas introduced (g)	Release height (m)	Simulation time (s)	Discharge temperature (°C)
CP06	6.4	97	0.2	15	20.0
CP10	6.7	198	0.2	29	20.5
CP21	6.7	201	1.8	30	18.8
CP26	40	417	1.8	9	15.0

The actual mass flow was obtained from the experimental mass flow meter. A sample variable mass flow plot has been shown in Fig. 5. The variation of mass was observed at fraction of seconds at the beginning and before end of the leaking process. The walls were assigned no slip conditions and adiabatic in nature. The entire room was initialized with air at 1 atm pressure and 25ºC.

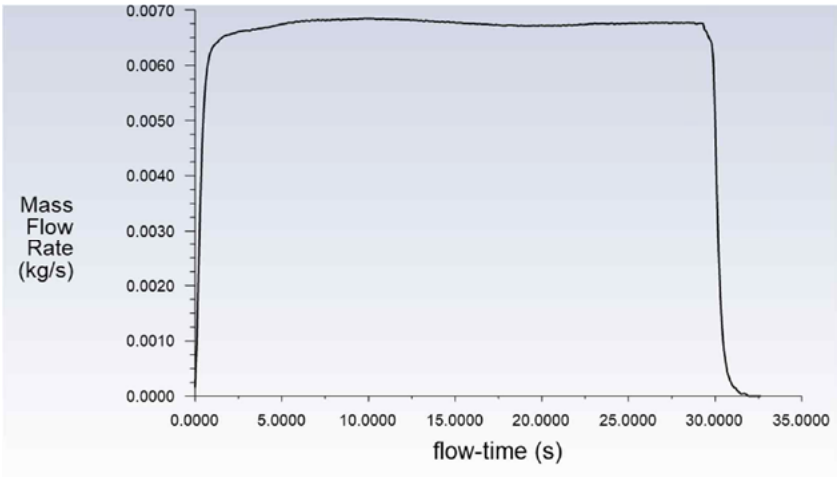

Fig. 5. Variable mass flow for CP21 scenario

4. Model validation

Model validation is essential to check the correctness of solution and its consistent behavior across the different flow conditions [11]. For this project, a rigorous validation was carried out by comparing available experimental concentration values obtained from sensors installed inside the room with simulation concentrations obtained at the same locations over a specified simulation time. Fourteen concentration sensors were located inside the room during physical testing. In this paper, only a single sensor, which was in front of an inlet, will be discussed for each scenario. Yet results hold true for all the other sensors and is not discussed in this report.

The graphs in Figure 6(a, b, c and d) show the variation of propane concentration over time and space. These plots possess a common trend: an initial spike in the concentration values for the simulation as opposed to a gradual increase exhibited by the experimental data. This is due to the fact that when jet of gas hits the sensor points, simulation shows an instantaneous response where as physical test sensors were not local point sensors. Instead, they extracted the gas locally and then transported it to the main sensor that makes the

concentration measurement. To account for this delay, deconvolution of the experimental data was necessary by taking average values of concentrations over certain time period. Nevertheless, some error is expected in the test data, especially when the leak first starts, and unfortunately, test error was not available. Though as time passes, the simulation and experiment values are much closer to each other and follow a similar growth pattern. The important point here is that sometimes modelling is more accurate than the experimental results, or rather, more accurately reflects what is happening within the point of interest.

It is observed in Figure 6(a) that there is an initial rise due to the fact that actual mass flow rate at the inlet was gradually increased to the target value. Whereas, in the other cases, it was almost an impulse input and so the simulation results exhibit a more sudden increase. This is the expected behaviour, though not what is seen in the experimental data. For example, Figure 6(d) shows a very severe and almost impulsive increase in concentration levels in the simulation. This makes sense since it is a very high mass flow rate. The experimental data does not appear to represent what is actually happening inside the room.

5. Risk Matrix

When a combustible gas is released into a confined space where an ignition source could be present, there is a possibility of a fire and/or explosion taking place. Part of the risk is determined by the gas concentration levels. For combustion of gases, the concentration level must reside within an interval defined by the lower and upper flammability limits [12]. The upper and lower flammability limits for the refrigerant in this study, propane, are 2.1% and 9.5% by volume, respectively [13]. Concentration volume within these limits is called as Flammable Volume (FV). The power of computer simulation is that it can measure and track the size and location of FV of the leaked gas. This will not only contribute to the probability of a fire, but also to predict the magnitude of an event. By tracking the size and location of the FV and normalizing it by the volume of the room, a new risk measure called Normalized Flammability Volume (NFV) is defined which represents the probability of a fire/explosion occurring assuming the ignition sources are randomly distributed in the domain of interest. In some case, the domain of interest is simply the entire volume of the room.

Though, it is possible that the ignition sources are not distributed throughout the room but within a smaller fraction of the room. In such case, the Flammability Volume is normalized by a portion of the volume of the entire room, called the volume of interest (VOI), where the ignition sources are most likely to reside. The NFV (unitless) values reside between 0 and 1 with a higher value suggestive of a higher probability and risk of fire/explosion. So more generally,

$$NFV = FV\ (in\ VOI)/\ VOI \tag{3}$$

NFV values are calculated by considering full room and bottom half room volumes which are shown in Figure 7(a,b) for three scenarios. It was observed (Figure 7(a)) that CP-26 possessed higher NFV value (full room as VOI) than the other two cases. which was due to the fact that a higher quantity (400 g) of refrigerant was injected. In CP-06 and CP-21, the quantity of injected refrigerant was almost same, yet CP-06 possessed higher NFV (assuming full room as VOI) due to lower injection point in the room and the resulting accumulation of concentration due to the presence of the obstacle. Risk of fire hazard is high in CP-26 compared to CP-06 and CP-21.

But when the VOI was set to the lower half volume of the room, CP-06 possessed higher risk (higher NFV) with null risk for CP-21 and 26. It was observed that, when the refrigerant gas injected from top inlet then the concentration was not built-up at bottom half due to diffusion and turbulent behavior of refrigerant gas flow. But flammable volume was restricted near the inlet zone only.

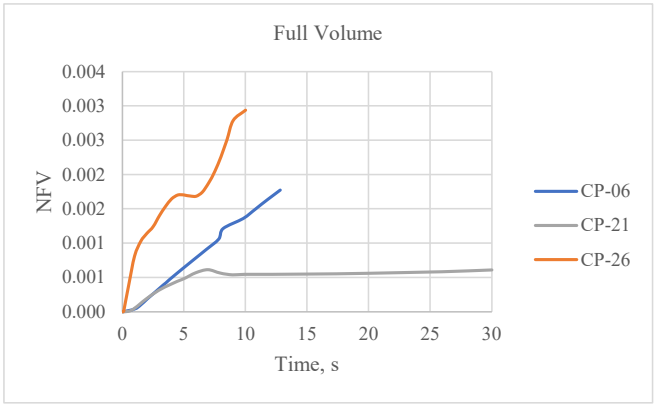

Fig. 7 (a). Comparison of NFV values considering full room between CP-06, 21 and 26 scenarios

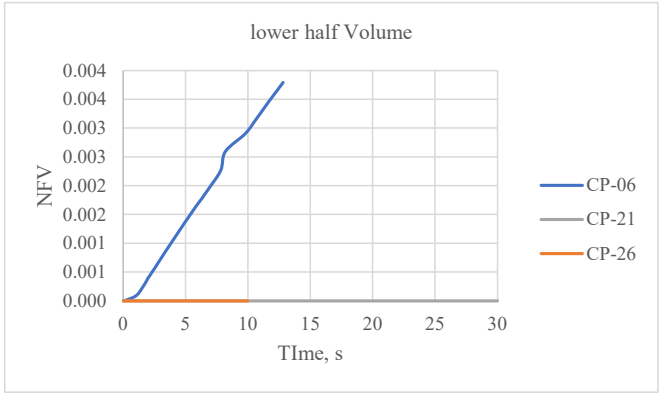

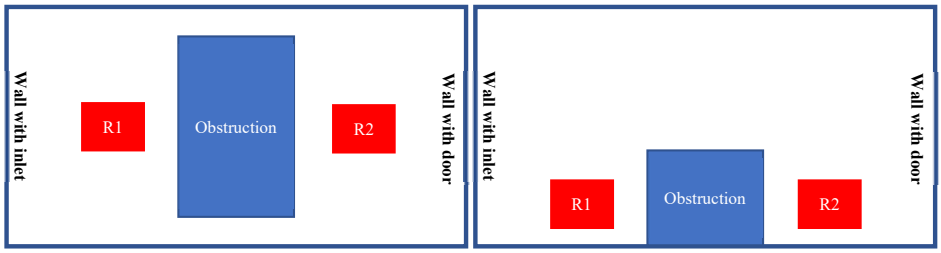

Fig. 7 (b). Comparison of NFV values considering bottom half room between CP-06, 21 and 26 scenarios

To further demonstrate the role of the VOI, two VOIs of dimensions 3 cm by 3 cm by 3 cm were created inside the room. The first region (R1) was placed between wall with inlet and obstruction. The other region (R2) was placed between obstruction and wall with the door as shown in the schematic layout in Figure 8(a and b). These regions are virtual in nature and indicate that the ignition sources exist within them.

(a). Plan view (b). Elevation view

Fig. 8. Schematic layout of room depicting virtual regions

The graphs in Figure 9(a and b) shows some trends for NFV. The scenario, with leakage from the bottom of the room (CP-06), lead to highest values of NFV in R1. In the same scenario, R2 exhibited zero NFV. In other words, R1 has more risk of fire as compared to R2. The scenario with leak from bottom tends to pose high risk of fire in the vicinity of R1 due to the fact the propane gas accumulates around it by obstruction in the form of obstruction. It takes plenty of time for propane gas to recirculate around the obstruction and reach R2. Till then the propane concentration dilutes due to diffusion which results in negligible values of NFV in R2. In other words negligible risk of fire. Among scenarios CP-06 and Cp-26, CP-06 exhibits the highest value of NFV hence high risk of fire, followed by CP-26 with very negligible NFV values. This analysis gives a more refined insight in that if the ignition sources are known to reside in a specific volume then it might be more relevant to reduce the size of the normalization volume as much as possible to get more exact value of NFV.

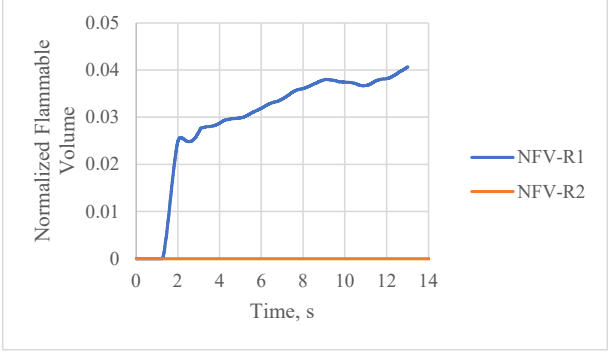

Fig. 9 (a). NFV values over time for CP-06 (Inlet at 0.2m height from floor).

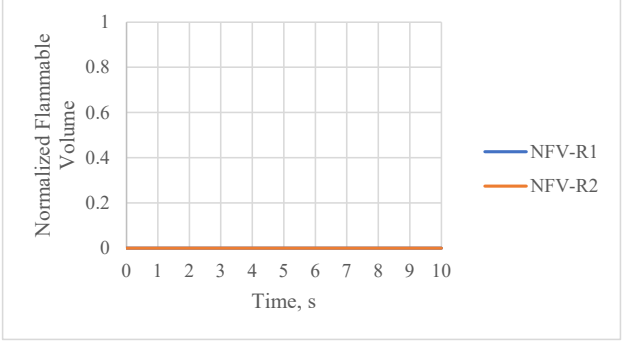

Fig. 9 (b). NFV values over time for CP-26 (Inlet at 1.8m height from floor)

6. Conclusion

In this paper, a new risk metric, normalized flammability volume (NFV), one that represents the probability of fire/explosion during refrigerant gas leakage into a confined space is introduced. The power of this simple, fire risk metric is that it can track the changing nature of the risk (probability of fire) during a leakage event when combustible gas is being introduced into a confined space. The gas concentration levels are determined by the physics of the flow and details of the room. This paper also demonstrated the value in using the risk metric to help rank different scenarios. Of course, if there is knowledge of the locations of potential ignition sources, then the NFV can be finetuned to provide an even more accurate measure. This risk metric is not available from physical testing and can only be obtained from high fidelity and validated CFD models.

Second, though a validation study was carried out to demonstrate the accuracy of the computational model, it turned out that the predictions of the model were more likely to reflect the reality within the leaked compartment versus what was measured in the experimental setup due to challenges of the particular sensor used. So in some cases, computational models can actually be an improvement over data generated by physical tests.

Experimental comparison of R1224yd(Z) and R1233zd(E) in a high temperature heat pump

Cordin Arpagaus* and Stefan Bertsch

NTB University of Applied Sciences of Technology Buchs, Werdenbergstrasse 4, 9471 Buchs, Switzerland

Abstract

High temperature heat pumps (HTHP) with heat supply temperatures of 100 to 160 °C will increasingly become commercialized in the coming years, especially for drying, sterilization and evaporation processes in the food and chemical industries. There is significant research towards testing new environmental-friendly refrigerants with low GWP for use in HTHPs. Besides natural refrigerants, the synthetic hydrochlorofluoroolefins (HCFO) R1224yd(Z) and R1233zd(E) (GWP < 1) are suitable substitutes for the hydrofluorocarbons (HFC) R245fa and R365mfc (GWP > 800). This paper examines the experimental performance of R1224yd(Z) and R1233zd(E) as a drop-in test in a laboratory HTHP with 5 to 10 kW heating capacity. The developed heat pump is single-stage, operates with a variable speed piston compressor, and contains a continuously adjustable internal heat exchanger (IHX) for superheating control. The performance data were measured at 30, 50, and 70 K temperature lift (40 to 80 °C heat source, 80 to 150 °C heat supply). The integration of the IHX in the heat pump cycle significantly increased the efficiency and the heating capacity over the entire operating map. The experimental results with R1224yd(Z) at W60/W110 indicate a COP of 2.8 (basic cycle) and 3.2 with IHX integration (+14%). The drop-in test showed that the heating capacity of R1224yd(Z) was on average 9% higher than that of R1233zd(E). The measured COP data of R1224yd(Z) were comparable to R1233zd(E) in the whole operating map. The deviations were within the measurement uncertainty of ± 0.2 COP. Moreover, an increase in the temperature glide on the heat sink side from 5 to 25 K further increased the COP by +9%, which is promising in processes with low return temperatures. Overall, the experimental results are promising for use in HTHPs and the developed laboratory HTHP system allows testing alternative HCFO and HFO refrigerants in the future.

1. Introduction

The range of electrically driven high-temperature heat pumps (HTHP) for industrial applications has grown steadily in recent years. There are at least 26 industrial HTHP products available on the market that can provide heat at sink temperatures from 90 to 160 °C [1–4]. HTHP technology is expected to play a key role in the decarbonization and electrification of the industrial sector. By switching from fossil fuels to renewable energies and increasing energy and resource efficiency, the CO_2 footprint can be significantly reduced.

The use of industrial HTHP is particularly interesting for heat recovery applications and for various industrial processes such as drying, steam generation, sterilization, paper production or food preparation. From a research perspective, HTHP technology is being further developed and the limits of supply temperatures and performance indicators are being further researched. To further increase system efficiency, multi-temperature heat pump systems are another suitable approach for using several heat sources and heat sinks with different temperature levels [5].

Various experimental R&D projects are currently in progress at international level to push HTHP technology from laboratory scale to industry. The main research objectives are: (1) Extending the limits of heat source and sink temperatures to higher levels, (2) improving heat pump efficiency (COP) through advanced multi-stage cycles and oil-free compressors, (3) developing temperature resistant components such as compressors and valves, and (4) developing and testing new environmentally friendly low global warming potential (GWP) synthetic refrigerants.

The partially fluorinated hydrocarbons (HFC) R134a, R245fa and R365mfc have a GWP of 1'300, 858 and 804 [6], and in most industrialized countries are confronted with a "phase-down", i.e. reduction of production and consumption. In Europe, the F-gas regulation [7] prohibits the use and reduces the market availability of greenhouse gases. The goal is to gradually reduce consumption by 79% by 2030. From 2022 on, only refrigerants with a GWP < 150 may be used in new commercial heat pumps. In Switzerland, the permissible use of refrigerants is regulated in the Chemicals Risk Reduction Ordinance (ChemRRV) and industrial heat pumps with a (cooling) capacity of >600 kW are affected by the HFC ban.

Natural refrigerants such as water (R718) [8–10], CO_2 (R744), ammonia (R717), or hydrocarbons like butane (R600) [11–13], propane (R290) or pentane (R601) [14] are promising environmentally friendly substitutes. However, special heat pump cycle designs with multi-stage compression (e.g. vapour compression) or sophisticated safety measures due to flammability (A3) are required, which can increase system costs.

In recent years, the 4th generation of new synthetic refrigerants has been developed consisting of various hydrofluoroolefins (HFO) and hydrochlorofluoroolefins (HCFO), which have very low GWPs, are non-flammable and have great potential for use as refrigerants in HTHP. The thermodynamic properties of these synthetic refrigerants such as R1336mzz(Z), R1233zd(E) and R1224yd(Z) allow heat pump operation at condensation temperatures from 140 to 160 °C [15,16]. Although HCFO refrigerants like R1233zd(E) and R1224yd(Z) contain a chlorine atom in their structure and do not comply with the legal requirements of the Montreal Protocol (Zero Ozone Depletion Potential, ODP), there are national regulations, such as the Swiss ChemRRV, which allow the use of HCFO refrigerants with an OPD <0.0005 (e.g. refrigerant R1233zd(E) or R1224yd(Z)) since 1 June 2019.

At the NTB Buchs, an HTHP on a laboratory scale was developed as part of the SCCER-EIP project [17]. The HTHP has a single-stage design, works with a reciprocating compressor with variable speed and contains a variable internal heat exchanger (IHX) for superheat control. A viscous POE oil (173 mm²/s at 40 °C) was used to achieve sufficient lubrication with the refrigerants at high temperatures. The basic functionality of the HTHP and first experimental results with R1233zd(E), R1224yd(Z) and R1336mzz(Z) have already been presented at several conferences [18–24].

The aim of this study is to experimentally investigate the efficiency of R1224yd(Z) (AMOLEA®1224yd, AGC Chemicals, 99.9% purity, 99.7/0.3 Z/E isomer ratio) and R1233zd(E) (Solstice®zd from Honeywell) in the same HTHP laboratory plant using a drop-in test. Starting from a reference point at W60/W110 (50 K temperature stroke), a parameter study is performed to measure the operating characteristics (i.e. heating capacity and COP) as a function of the temperature lift of the heat pump in the range from 30 to 80 °C heat source and 70 to 150 °C sink temperature. In addition, an overview of the thermophysical, environmental and safety aspects of the refrigerants is given.

2. Refrigerants

Table 1 shows the essential thermodynamic, environmental and safety properties of the tested HFO / HCFO refrigerants R1336mzz(Z), R1233zd(E), R1224yd(Z) in comparison to HFC R245fa.

R1233zd (E) has a critical temperature of 165.6 °C, a critical pressure of 36.2 bar and is available under the brand name Solstice®zd from Honeywell [25] or as Forane®HTS 1233zd from ARKEMA [26]. Although R1233zd(E) contains a chlorine atom that may participate in the catalytic destruction of the ozone layer, the atmospheric lifetime is sufficiently short, i.e. about 14 days [27] or 40.4 days [28], so that the fluid does not reach the stratosphere after leakage and thus does not participate in ozone depletion. Depending on the study, an ODP of 0.00034 [28]or 0.00030 [29] is estimated.

Today R1233zd(E) is mainly used as a blowing agent for duroplastic foams and aerosols. In air conditioning it is used for large chillers with radial compressors [30]. It is recommended for applications in HTHP and Organic Rankine Cycles (ORC). At high operating temperatures, a small portion of R1233zd(E) can isomerize to R1233zd(Z). Wissam et al. [26] confirm the efficacy of a stabilizer with R1233zd(E) over pure unstabilized R1233zd(E) to significantly reduce Z-isomer formation at high temperatures. The stabilized product showed high stability at 180 °C after 14 days aging with metals and oils. At 220°C and 14 days aging, a very low degree of isomerization (< 0.5%) was observed.

So far there are only limited experimental studies on the use of R1233zd(E) in HTHP applications [31]. First results were presented at the DKV Conference 2018 [18], the ICR 2019 [20] and the 2nd HTHP Conference [24] with the laboratory HTHP developed at NTB Buchs. Compared to a simple cycle, the integration of an IHX led to a 15% increase in COP under W60/W110 conditions [20]. The maximum sink temperature tested was 150 °C, whereby a COP of 2.1 was achieved at the operating point W80/W150 (70 K temperature range).

Another HTHP test facility is being developed at the University of Ulster to test R1233zd(E) within the CHESTER project [31,32]. Simulation results from Shah et al. [31] showed up to 8% higher COP than with R245fa. Further investigations are underway to test R1233zd(E) and oil miscibility.

Table 1. Thermophysical, environmental and safety properties of R1224yd(Z), R1233zd(E), R1336mzz(Z) and R245fa suitable for HTHP applications [6,19,36–42,25–29,33–35]

Refrigerant	R1224yd(Z)	R1233zd(E)	R1336mzz(Z)	R245fa

R1224yd(Z) is another HCFO refrigerant developed for use in centrifugal chillers [19,30,33,35], for power generation in ORC applications [34], and in HTHP for waste heat recovery [33]. AGC Chemicals (Asahi Glass) markets the product as Amolea™1224yd [42], where AMOLEA stands for "AGC Makes Hydrofluoroolefins as Alternatives". R1224yd(Z) differs from R1233zd(E) by a slightly different molecular structure (Table 1). The physical properties are close to R245fa. The equations of state and mass transport data were evaluated by Akasaka et al. [44] and Miyara et al. [45]. The critical temperature is 155.5 °C and the saturation vapour pressure is slightly lower compared to R245fa (about 13% at 120 °C) [46]. With an ODP of almost zero (0.00023 [36]), a GWP of 0.88 and an atmospheric lifetime of 20 days, the environmental impact is estimated to be low [36]. In addition, AMOLEA™1224yd is non-combustible (A1) and toxicity is given with an occupational exposure limit (OEL) of 1'000 ppm [47].

At the ICR 2019 conference Kaida et al. [46] presented first experimental results on R1224yd(Z) in a commercial SGH165 heat pump from KOBELCO (with economiser cycle and internal heat exchanger). "Drop-in" tests at operating point W50/W95 (45 K temperature increase) showed a 3% higher heat capacity and 12 % higher COP compared to R245fa. The performance increase was attributed to a higher refrigerant mass flow, a lower viscosity and a lower required pressure ratio (higher adiabatic compressor efficiency). In addition, R1224yd(Z) is also well compatible with the most common metals, plastics and elastomers [30,34,48] and has good miscibility for various types of oils [46,48,49]. The chemical resistance and compatibility of AMOLEA™1224yd is comparable to that of R245fa. Overall, R1224yd(Z) has been suggested as a suitable R245fa alternative for HTHP.

R1336mmz(Z) has a higher critical temperature of 171.3 °C than R1233zd(E) and R1224yd(Z). This allows condensation at temperatures up to about 160 °C. Chemours has been marketing R1336mzz(Z) since 2018 under the brand Opteon™ MZ for HTHP in process technology and special applications in the high temperature range. The safety class is A1 (non-flammable) and the GWP is 2. The ODP is 0 and the service life in the atmosphere is only 22 days [6]. The refrigerant is thermally stable up to 250 °C and is suitable for ORC and applications for heat recovery and steam generation [50–53]. Laboratory tests have shown that the material compatibility with copper and steel is similar to that of R245fa. Highly viscous polyol ester (POE) is recommended as lubricant as it is completely miscible over wide temperature ranges and compositions [51,53].

Figure 1 shows the vapour pressure curves and the pressure enthalpy and temperature entropy diagrams of the refrigerants. The thermophysical properties were calculated using the Engineering Equation Solver Software (EES) [54] from F-Chart. Figure 1 shows that R1233zd(E) and R1224yd(Z) have a slightly lower vapour pressure than R245fa. Furthermore, the critical pressure of R1224yd(Z) is about 3 bar lower than that of R245fa, while the critical temperatures are almost the same (see also Table 1). In the case of R1233zd(E), the saturated steam pressure is slightly lower than that of R1224yd(Z), while the critical temperature is about 11 K higher. The p-h diagram indicates that R1224yd(Z) has a lower evaporation enthalpy than the other fluids.

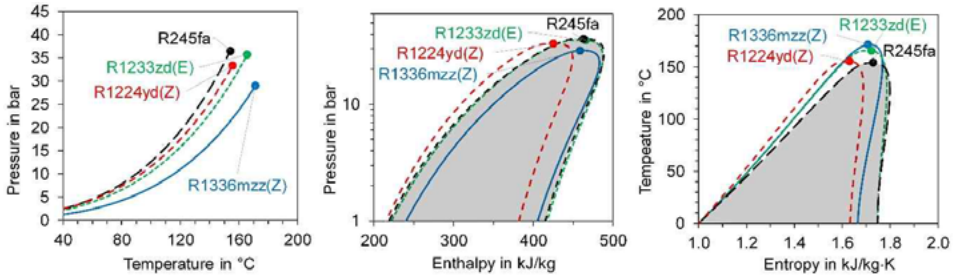

Fig. 1. Vapour pressure curve (p-T diagram), pressure enthalpy (p-h) and temperature entropy (T-s) diagrams of the refrigerants R1336mmz(Z), R1233zd(E) and R1224yd(Z) compared to R245fa (substance data from [54])

Another topic that is repeatedly in the media, apart from GWP and ODP, is the decomposition products of refrigerants in the atmosphere and their effects on human health and the environment [55]. In the EU, this topic has been become public, mainly by the use of HFO R1234yf in car air conditioning systems. The atmospheric degradation of HFC, HCFC and HFO refrigerants is initiated by reaction with OH radicals, resulting in halogenated carbonyl compounds which are further oxidised to hydrofluoric acid (HF), hydrochloric acid (HCl), formic acid (HC(O)OH), or CO_2 and in some cases form trifluoroacetic acid (TFA, $CF_3C(O)OH$) [29,39–41,56].

For comparison, the >C=C< double bond in HFO and HCFO reacts with OH radicals two orders of magnitude faster than HFC R134a [41]. The molar yield of TFA in R134a is about 7 to 21%, while for R245fa it is <10% [39]. Due to the long atmospheric lifetime of 13.4 and 7.7 years [39], the gaseous TFA can spread widely in the atmosphere, descend to earth via rainfall and accumulate in various waters such as rivers, streams, lakes and wetlands, as well as terminal sinks such as salt lakes, playas and oceans [55,56]. HF and HCl neutralize quickly due to the buffer capacity of the surface water [41].

Since HFO and HCFO decompose much faster into their final products, they can occur locally at the point of emission and have direct effects. The molar yields of TFA formation from degradation depends on the refrigerant type [20]. HFO R1234yf leads to a 100% molar yield of TFA. R1233zd(E) decomposes to max. 2% TFA [29], whereas the yield for R1336mzz(Z) (with two CF_3-CH= groups) is likely to be <20% [40]. Since R1224yd (Z) has a similar molecular structure to R1234yf, the molar yield of the degradation to TFA is 97% [43].

The effects of TFA on the environment have been investigated in various studies and found to be negligible, since TFA occurs in large quantities in oceans [41,56]. The oceans already contain more than 200 million tons of TFA from natural sources such as volcanic activity. Henne et al. [40] considered a worst-case scenario for Europe in which all car air-conditioning systems are filled with R1234yf, which has 100% TFA as a decay product, and this is emitted. This would have an impact of 0.04% on the global TFA content in the oceans, which is well below the no-effect level of the most sensitive algae.

Solomon et al. [56] estimated in the worst case of unregulated use of HCFCs, HCFCs and HFOs up to 2050 with an additional amount of maxiaml 15.3 ng TFA per litre of sea water in the oceans compared to the average 200 ng existing at the beginning of the millennium. The risk for aquatic organisms was classified as negligible.

Nevertheless, according to current knowledge, studies on the precise effects of TFA accumulation in freshwater and on land on human health and the environment are still in their early stages.

3. Experimental setup of the HTHP laboratory facility and test procedure

Figure 2 illustrates the setup of the HTHP laboratory plant with the principle diagram. All components used are commercially available without modifications. A semi-hermetic reciprocating compressor (Bitzer, 2DES-3Y New Ecoline) with variable speed drives the HTHP. An external frequency converter (Vacon 100) adjusts the compressor speed within the permissible limits (30 to 60 Hz corresponds to 870 to 1'750 rpm). An integrated temperature sensor prevents the motor windings from overheating. The switch-off temperature is approx. 110 °C. The fan of the compressor was not in operation during the experiments.

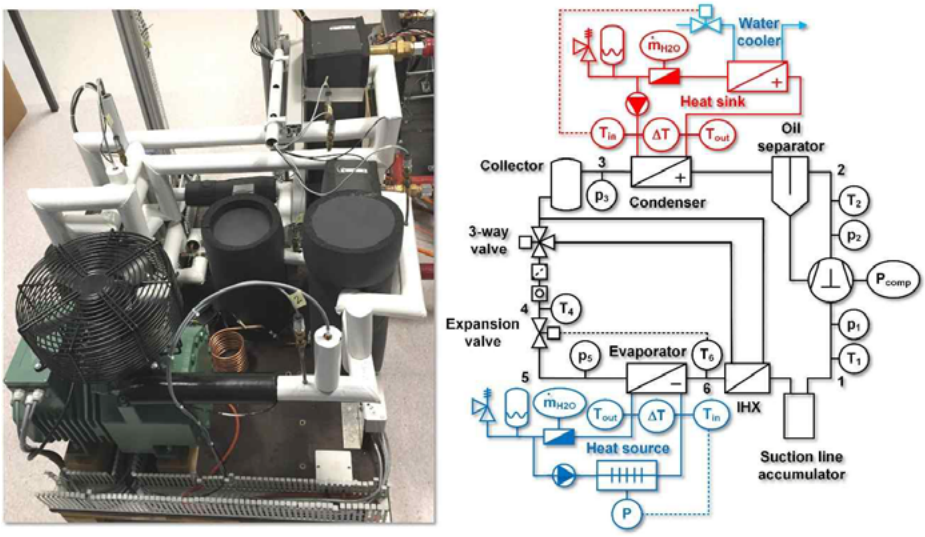

Fig. 2. Experimental setup of the HTHP laboratory facility with principle diagram

The HTHP consists of a simple heat pump cycle with condenser, evaporator and an IHX. The heat exchangers used are compact plate heat exchangers (SWEP) with low pressure drop. The IHX transfers the heat from the hot liquid refrigerant to the suction gas after the condenser outlet, thereby increasing the suction gas temperature (T_1) and ensuring sufficient superheating. The superheat is measured between the evaporator and the IHX (T6) and was set to 5 K for all tests. The superheat was controlled by the expansion valve (Siemens, MVL661.15-0.4) and a PI control in LabVIEW™.

The refrigerant mass flow through the IHX is continuously adjustable from 0 to 100% via a three-way valve (Siemens, M3FK15LX15). A setting of 0% IHX corresponds to the operation of a simple heat pump cycle without IHX, while at 100% the IHX is fully integrated into the cycle. A liquid receiver (Bitzer FS56) serves as a refrigerant collector after condensation and provides liquid refrigerant upstream of the expansion valve. A suction gas accumulator (ESK Schultze, FA-22) prevents the direct penetration of liquid refrigerant into the compressor. The filling quantities of the refrigerants R1233zd(E) and R1224yd(Z) were 4.2 kg and 3.6 kg respectively.

A POE oil (Fuchs, Reniso Triton SE 170) with a viscosity of 173 mm²/s at 40 °C (17.6 mm²/s at 100 °C) was used to achieve sufficient lubrication at the high operating temperatures. An oil separator (Temprite, Coalecent 922M) is installed on the high-pressure side to collect the oil and return it to the compressor via a cooling pipe. As safety measure, a high pressure/low pressure pressostat protects the compressor and all other components. A filter dryer is integrated in the system to absorb residual moisture. The copper pipes and the circuit components are insulated with temperature-resistant Armaflex®HT.

The inlet temperature of the heat source ($T_{source,in}$) can be set between 30 and 80 °C and the outlet temperature of the sink ($T_{sink,out}$) between 70 and 150 °C. The heat source circuit simulates potentially available waste heat from an industrial process and includes a controllable electric heater (Backer ELC, 10 kW), a water pump (Speck Pumpen, HT-AY-2251-PM.0005) with adjustable flow and an expansion vessel with safety valve. The electric heater controls the inlet temperature of the heat source and a control valve (BELIMO, 2-way zone valve with rotary actuator) at the inlet of the water cooler controls the inlet temperature of the heat

sink to the condenser (both by PI controls in LabVIEW™). The heat sink is a potential application (e.g., steam generation or drying process) and includes a water cooler that releases the generated heat to the environment.

The temperatures are measured with thermocouples (type K, class 1) calibrated in a silicone oil bath of 20 to 110 °C with an accuracy of ± 0.1 K. Thermocouples with differential temperature measurement are installed at the inlets and outlets of the heat pump. The water mass flow meter in the heat sink circuit is a calibrated Coriolis sensor (E+H, Promass 300 F) with a measurement error of ± 0.05%. A power sensor (Infratek, ITL101) measures the electrical power consumption of the compressor with an accuracy of ± 3%. A CompactRIO® from National Instruments (cRIO-9022 with 8 card slots) in combination with LabVIEW™2017myRio is used for data acquisition and control of the test setup with a sampling time of one second. Further details on the components and sensors are described in Arpagaus et al. [21,23].

4. Test procedure

After heating up the heat pump system to a desired operating point (heat source and sink temperatures), a temperature spread of 3.0 ± 0.1 K at the heat source and 5.0 ± 0.1 K at the heat sink (based on standard DIN EN 14511 [57]) was manually adjusted by means of the water pumps speed (mass flow) in the two hydraulic circuits. The HTHP was operated for several minutes per operating point in a stationary state and average values of at least five minutes were used for the data analysis.

The COP and the 2nd law efficiency (η_{2nd}) of the HTHP were determined from the measured heating capacity ($\dot{Q}_{sink}$) and the electrical power consumption of the compressor (P_{comp}) according to equations (1) and (2), where $\dot{m}_{H_2O}$ corresponds to the water flow and ΔT_{sink} corresponds to the temperature difference between output and input of the heat sink. The temperature dependence of the specific heat capacity of water $c_{p,H_2O}(T)$ was considered according to [58]. The electrical power consumption of the control system of the heat pump system (approx. 110 W) and the water pumps in the hydraulic circuits (between 0.25 and 1.75 kW) are not taken into account in the COP calculation. According to error propagation, the measurement uncertainty is maximum ± 0.2 COP over the entire measurement campaign.

$$COP = \dot{Q}_{sink} / P_{comp} = \left(\dot{m}_{H_2O} \cdot c_{p,H_2O}(T) \cdot \Delta T_{sink}\right) / P_{comp} \quad (1)$$

$$\eta_{2nd} = COP / COP_{Carnot} \quad \text{with} \quad COP_{Carnot} = T_{sink,out} / \left(T_{sink,out} - T_{source,in}\right) \quad (2)$$

Starting from a reference point (Ref) at W60/W110, a parameter study was carried out to measure the operating characteristics of the heat pump for the two HCFO refrigerants R1224yd(Z) (AMOLEA®1224yd, AGC Chemicals) and R1233zd(E) (Solstice®zd from Honeywell). The influence of the external temperature lift between heat source and heat sink ($\Delta T_{lft} = T_{sink,out} - T_{source,in}$) on the COP and 2nd Law efficiency was investigated. The inlet temperature of the heat source was varied between 30 and 80 °C and the sink temperature between 70 and 150 °C.

The refrigerant change in the HTHP for the drop-in test from R1233zd(E) to R1224yd(Z) was carried out professionally. First, the old refrigerant was extracted with an evacuation station, then an oil change was carried out. The circuit was evacuated overnight to minimize residual moisture in the system. Then the tightness was checked and the system was filled with new refrigerant via the suction line in steps of about 200 g using a scale. In order to determine the optimum filling quantity, the heat pump was put into operation at the reference point W60/W110 during the filling process and the COP was checked as a function of the filling quantity. To accelerate the filling process, the refrigerant gas cylinder was slightly heated from the outside.

5. Experimental test results

Figure 3 (A to F) summarizes the main results of the parameter studies with the refrigerants R1224yd(Z) and R1233zd(E). Figure 3 (A) and (B) show the experimentally measured COP data of the HTHP laboratory plant as a function of the investigated heat sink temperature ($T_{sink,out}$) at different temperature lifts (ΔT_{lft}); in (A) for R1224yd(Z) and in (B) for R1224yd(Z) compared to R1233zd(E) in the IHX cycle. As expected, the COP increases with a smaller temperature lift. At the reference point W60/W110 a COP of 3.2 and 3.0 was reached for R1224yd(Z) and R1233zd(E), respectively.

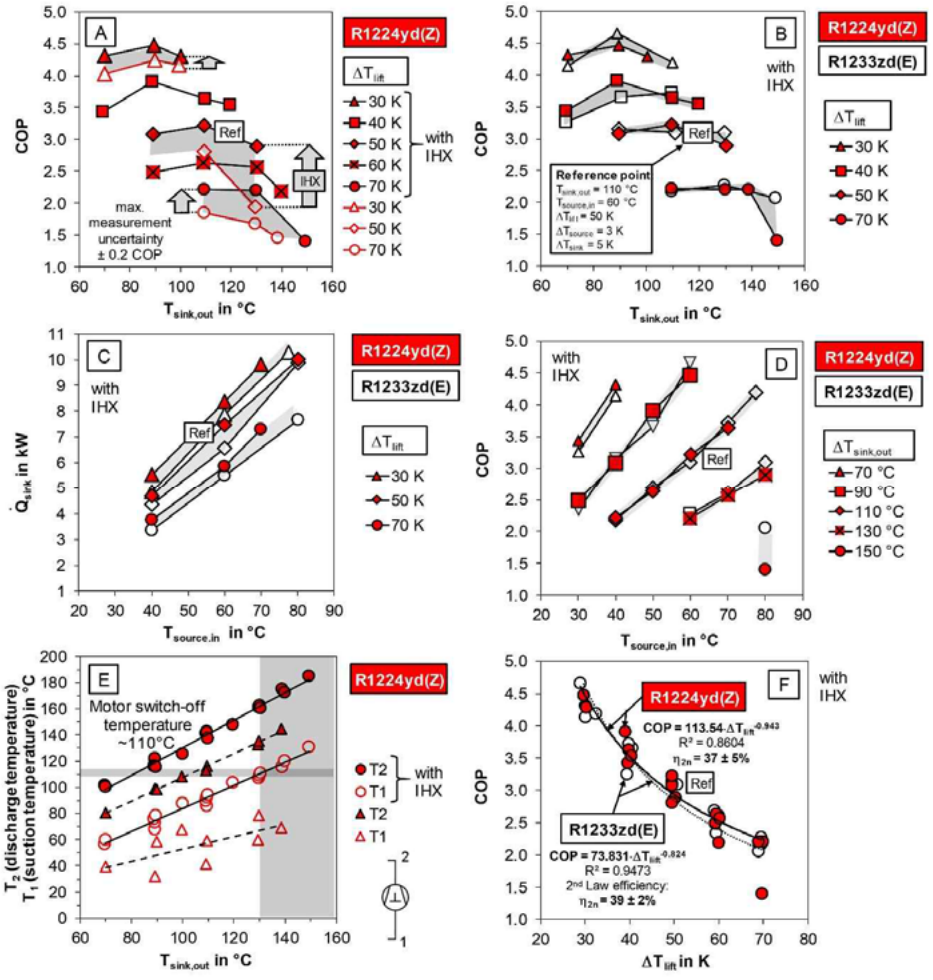

Fig. 3. Experimental test results with R1224yd(Z) and R1233zd(E) in the laboratory HTHP.
(A) Influence of the IHX integration on the COP at different temperature lifts with R1224yd(Z),
(B) Comparison of R1224yd(Z) and R1233zd(E) COPs as a function of heat sink temperature and temperature lift in the IHX HP cycle,
(C) Comparison of R1224yd(Z) and R1233zd(E) heating capacity with IHX cycle at 30, 50 and 70 K temperature lift,
(D) Comparison of R1224yd(Z) and R1233zd(E) COPs as a function of heat source and sink temperature with IHX cycle,
(E) Discharge and hot gas temperature in function of sink temperature with R1224yd(Z),
(F) COP fit curves of the measurement data with 2nd Law efficiency and IHX cycle

The slightly decreasing COP curves at higher sink temperatures are a result of the smaller enthalpy of vaporization for condensation near the critical temperature and the increasing heat loss of the system due to natural convection and radiation. Depending on the temperature, heat losses of about 35 ± 12% are estimated from the energy balance of the heat pump ($\dot{Q}_{bs} \approx \dot{Q}_{source} + P_{com\,p} - \dot{Q}_{sink}$). This means that there is potential for optimisation in insulation (especially at the compressor) and room for efficiency increase.

Overall, the measured COP data of R1224yd(Z) are comparable with R1233zd(E). The deviations lie within the measurement uncertainty of ± 0.2 COP. At operating point W80/W150, near the critical temperature of 155.5 °C of R1224yd(Z), the COP decreased due to the narrowing of the two-phase region (see p-h diagram in Figure 1). The maximum sink temperature tested in this study was 150 °C. R1233zd(E) achieves potentially higher condensation temperatures due to the higher critical temperature of 165.6°C compared to 155.5°C of R1224yd(Z).

Figure 3 (A) with R1224yd(Z) shows that the integration of the IHX into the heat pump circuit leads to a significant increase in COP over the entire operating map. Compared to the basic cycle (0% IHX), the suction gas in the IHX is additionally superheated and the liquid refrigerant is subcooled more strongly. When the IHX is added, both the suction gas (T_1) and hot gas temperatures (T_2) (see Figure 3, E) as well as the heating capacity increase. At the operating point W60/W110, the COP increased by about 15 % (from 2.8 to 3.2) with IHX addition, at W80/W130 even by 48 % (COP from 1.9 to 2.9) compared to the basic cycle. This is in line with earlier work [59] where R1233zd(E) showed an average efficiency increase of 11% and 19% under the same conditions.

Figure 3 (C) compares the heating capacity ($\dot{Q}_{sink}$) of the two HCFO refrigerants in the IHX cycle as a function of the heat source temperature ($T_{source,in}$) at 30, 50 and 70 K temperature lift. The heating capacity increases steadily with higher source temperature according to the Carnot relation. Under (Ref)-conditions the heating capacity with R1224yd(Z) is about 6.6 kW, with R1233zd(E) about 7.5 kW and at operating point W80/W110 about 10 kW. At this point, the HTHP laboratory system reaches its experimental capacity limits. The data show that the heating capacity of R1224yd(Z) is on average 9% higher than that of R1233zd(E). This is consistent with simulation studies [60], where for R1224yd(Z) also about 8% higher VHC values were calculated than for R1233zd(E) at W60/W110. Theoretical results confirm that R1224yd(Z) and R1233zd(E) lead to similar COP as R245fa. The VHCs are 7 to 15% lower than with R245fa. For R1233zd(E) a compressor with a slightly larger displacement volume would be required to achieve similar heating performance as R1224yd(Z). Depending on the refrigerant, a compromise must be found between COP and VHC.

Figure 3 (D) shows the COP data as a function of the heat source and sink temperature. The increase in efficiency at higher source temperatures is obvious. The COP data of R1224yd(Z) are comparable with R1233zd(E). In addition, a greater temperature glide on the heat sink from 5 to 25 K (at W60/W110) has further increased the COP by 9%, which is advantageous for processes with low return temperatures. Heat transfer in the condenser improved with increasing temperature glide.

Figure 3 (E) shows the discharge gas and suction gas temperatures in function of the sink temperature with R1224yd(Z). The measured suction gas temperatures in the basic cycle without IHX were clearly below the motor switch-off temperature of approx. 110 °C (grey line). In the IHX cycle the suction gas temperature exceeded the motor limit temperature at approx. 130 °C and higher. However, short-term tests over several minutes at 150 °C were possible.

Figure 3 (F) shows the determined COP data of the experiments as a function of the respective temperature lift. As expected, the COP values decrease with a higher temperature lift according to the Carnot relationship and follow a fit curve ($COP = A \cdot \Delta T_{lift}^{B}$)) with a 2nd Law efficiency of 39 ± 2% for R1233zd(E) and 37 ± 5% for R1224yd(Z) in the IHX cycle. These values are comparable with results with R1336mzz(Z) (34 ± 3%) in the same HTHP plant [20,24], as well as in another HTHP laboratory setup of Helminger et al. [61] with R1336mzz(Z).

Finally, but still important, the neutralization number of the synthetic POE oils was determined after approx. 100 operating hours in the HTHP after the refrigerant tests by titration according to DIN 51558-1 in mg KOH/g oil. The neutralisation number indicates the content of acid components in the lubricant and is a measure of ageing. Strong acidification of the oil is undesirable. Fresh oil was also measured for comparison. Visual inspections revealed a slightly yellowish discoloration of the oils after operation in the HTHP. The neutralisation number for fresh POE oil was 0.04, for R1233zd(E) 0.06 and for R1224yd(Z) 0.25. This is well below the warning value of 0.5 for HTHP applications assumed by the oil supplier Fuchs. The data shows that the POE-based oil (Reniso Triton SE 170) is suitable for use with HCFO refrigerants. However, long-term tests were not the aim of this study. At best, even more viscous POE oils (SE 220) and the addition of thermal stabilizers would have to be tested. Temperature-resistant compressors and stable lubricating oils are decisive components for the further development and commercialization of HTHP.

6. Conclusions

The two HCFO refrigerants R1224yd(Z) and R1233zd(E) were successfully tested in a single-stage laboratory scale HTHP with basic and IHX cycle. Operation of the HTHP was demonstrated at heat source inlet temperatures of 30 to 80 °C and heat sink outlet temperatures of 70 to 150 °C at 30 to 70 K temperature lift. The temperature levels simulate possible industrial applications of waste heat recovery, steam generation or drying. The laboratory plant was built with standard components.

A COP of 3.2 and 3.1 for R1224yd(Z) and R1233zd(E) was measured at the operating point W60/W110 (50 K temperature lift). Due to the higher critical temperature, R1233zd(E) was more efficient at 150 °C than R1224yd(Z). Otherwise, the differences were within the measurement uncertainty of ± 0.2 COP.

By connecting an IHX to the circuit and thus subcooling the refrigerant more strongly, the COP increased by 15 to 48% with R1224yd(Z) compared to the basic cycle. The IHX additionally superheats the suction gas and subcools the liquid refrigerant more. A further COP increase of around 9% was achieved by a higher temperature glide on the heat sink from 5 K to 25 K, which is advantageous for industrial processes with low return temperatures, such as steam generation or drying processes.

At a heat sink outlet temperature of 130 °C and higher, the motor switch-off temperature of about 110 °C was exceeded. The limit of the compressor's temperature resistance was reached. Short-term tests up to 150 °C were nevertheless possible.

The drop-in test also showed that the heating capacity of R1224yd(Z) was on average 9% higher than that of R1233zd(E), which in practice requires slightly larger compressors to achieve a comparable heating capacity. At operating point W80/W110, a heating capacity of up to 10 kW was achieved. At this point, the HTHP laboratory system reaches its experimental capacity limits.

Overall, the experimental results of the two HCFO refrigerants R1224yd(Z) and R1233zd(E) with the POE oil are promising for use in HTHP. Both refrigerants are characterized by a very low global warming potential, non-flammability (safety group A1), stability with polymers and metals, miscibility with POE oils, negligible decomposition products in the atmosphere, and good thermodynamic efficiency. The refrigerants therefore have a high potential for future use as refrigerants in HTHP applications as drop-in replacement refrigerants for R245fa, which is affected by a phase-down due to the stricter F-gas regulations.

In the future, the HTHP developed will make it possible to test other alternative HFO and HCFO refrigerants with stabilizing additives, HFCs such as R245fa or R365mfc for direct comparison or other oils based on polyol ester or polyalkylene glycol. Further efficiency gains could be achieved by reducing heat losses at high temperatures through better insulation of components and piping.

Abstract

Demand Response and use of residential buildings for peak shaving and load balancing has been proposed as a popular method towards providing security and increasing efficiency for the electrical grids. Use of heat pumps to shift peaks of electricity and thermal demands is one of the possibilities available for this purpose. This is only possible through the use of advanced control algorithms which are capable of interfacing with the thermal and electric devices available at the residences. However, usage of devices like heat pumps for load shifting and/or peak shaving would imply discomfort for the tenants in the residential building. Thus, demand response only becomes an attractive option to the residential user if there are financial incentives available to them. This is only possible in present-day by providing end-users with access to the ancillary markets. The paper studies the implementation of a control framework (using Model Predictive Control and Machine Learning) on a group of buildings with water-water heat pumps. The paper looks at the practical roadblocks that limit the implementation of advanced control algorithms on heat pumps. The paper, then, looks at solutions towards these roadblocks and the hardware and software that is required to ensure successful implementation of demand response for heat pumps. The paper then looks at the data requirements for creating grey-box models of the heat pumps within a Model Predictive Control Framework such that end-users can actively participate in the ancillary market. Finally, the paper discusses possible changes to the ancillary market for better integration of thermal devices for demand response and changes to redress the difficulties in using heat pump use for demand response.

1. Introduction

Distributed Energy Resources (DER) like solar panels and wind turbines have forced a re-think on not only the structure of the grid but also the grid code which exists in today's top-down grid architecture. Demand Response (DR) has often been touted as a great solution to many of the problems faced by the electricity grid. Demand Response has been defined by the Department of Energy (DoE) of USA[1] as, "Changes in electric usage by end-use customers from their normal consumption patterns in response to changes in the price of electricity over time, or to incentive payments designed to induce lower electricity use at times of high wholesale market prices or when system reliability is jeopardized". This definition of DR has been taken as the guideline and the motivation for the rest of the paper. End-use customers, at present, do not have an active role in the electric grid. They are treated as consumers, who only consume and do not have much leeway in changing their consumption patterns. They are as a result, not given an active role in the market and pay fixed tariffs to the consumers.

E-mail address: ramanunni.menon@protonmail.com.

With nearly 45% of the total energy consumption coming from the end-users and buildings, and with 50% of that coming from thermal energy consumption, there is definitely a role that end-users and end-user buildings can play in demand response [2]. Recent papers and concepts like the microgrid [3] and the EnergyHub [4] are concepts that have put forward the idea of the prosumer who not only consumes but also produces and participates in improving the efficiency and efficacy of the grid, by playing an active role in the electricity market. Prosumers are able to produce electricity through Combined Heat and Power (CHP) systems and storage devices like batteries, and are able to consume in a flexible manner through the use of P2H (Power-to-Heat) devices which have controllable consumptions. The heat is stored either in the building mass or in thermal storages used for space heating and Domestic Hot Water (DHW) needs.

1.1. Heat Pumps in Europe

Thermal demand satisfaction is a vital part of energy consumption in buildings in Europe. Heat pumps are one of the technologies, albeit not the predominant one, in use for thermal demand satisfaction in Europe. Most countries use a mix of boilers, electric heating and heat pumps for satisfaction for all their space heating and DHW purposes. European Heat Pump Association (EHPA) estimates that there are over 12 million heat pumps installed across the European countries for heating, accounting for around 12% of the heating market alone [5]. The heat pump installation rates vary between the countries, with countries like France, Italy and Sweden having high penetration, while others like Hungary and Lithuania having extremely low heat pump penetration. EurObserv'er estimates that a total of around 34.4 million heat pumps have been installed in total in Europe for both heating and cooling purposes combined [6].

Heat pumps are being given huge emphasis within DR strategies as they are one of a small number of P2H (Power to Heat) devices able to utilize electrical power and provide thermal power. Thus, they offer a powerful option to shifting and changing a large portion of the energy consumption in buildings, while also making it possible to actively participate in the electricity market.

DR strategies and algorithms developed for thermal systems have typically looked at electric heaters. This is as they are easier to control and model. When algorithms have looked at heat pumps, the typical approach has been to either model them akin to batteries or to use physical models that rarely account for the limitations of controlling the heat pumps remotely and their non-linear behavior.

With this in mind, the aim of this paper is to look at how model predictive control maybe implemented in heat pumps currently existing in the building stock and understand the data requirements, the current roadblocks preventing implementation of DR using heat pumps, and propose solutions towards alleviating these issues. The paper is structured as follows for that purpose: Section 2 details on the implementation of Model Predictive Control (MPC) for heat pumps, through application within a site in Switzerland and the preliminary findings and problems faced when implementing the algorithm on actual buildings. Section 3 identifies the roadblocks that present-day heat pumps create, preventing DR implementation for end-users. Section 4 and 5, identify proposals and potential solutions towards alleviating said roadblocks, followed by a Conclusion and References.

2. Model Predictive Control for heat pumps

Model Predictive Control (MPC) is an often-used optimization method found in recent scientific literature, for forecast and management of building thermal and electric power demand satisfaction. It has also been used for maintaining thermal comfort and minimizing the cost associated with electricity and gas that is spent by the consumer. Some implementations of MPC and the associated theory can be seen in [7], [8], [9], [10].

Model Predictive Control utilizes a Receding Horizon (RH) principle. For the MPC implementation in this paper, we have used a finite time horizon of 24 hours. The optimization utilizes a certain (typically between 15 minutes and one hour) time step depending on the use case. The MPC is used to minimize the energetic costs and discomfort of tenants in these buildings. The objective function is structured such that usage of energy demand is optimized for each of the buildings. More details on the MPC implementation and associated data requirements can be found in the subsequent sections.

2.1. Naters

The block of buildings modelled are based on data collected from a group of 12 buildings of a pilot site in Naters, Switzerland. Each of the buildings at the site are used for either residential or mixed purposes. They were either constructed or renovated between the periods of 1960 and 2015. The buildings have been fitted

with heat pumps and thermal storages of different capacities (as deemed appropriate for building requirements) such that their respective thermal needs can be satisfied. The net capacity of the installed heat pumps come to around 700 kW_{th} peak output when working together in a concerted manner (very rare).

Their electricity and thermal demands vary daily depending on the inter- and intra-seasonal weather fluctuations and user consumptions. The heat pumps are all water-water heat pumps (WWHPs) which utilize a Low-Temperature Heating (LTHN, Anergy) Network as the heat source. The building mass is heated using either radiators and/or through floor heating. The temperatures of the LTH network stay relatively fixed between 9-11°C throughout the year. The water volume within the DHW (Domestic Hot Water) tank is kept constant by refilling from the bottom using clean water at 15°C. When hot DHW is required, the 15°C water is heated up by heat transfer through a plate heat exchanger and fed into the DHW tank. The DHW tank is heated to 60°C once every day to prevent legionella growth and associated health problems. The schematic of the heating systems installed can be seen in Figure 1.

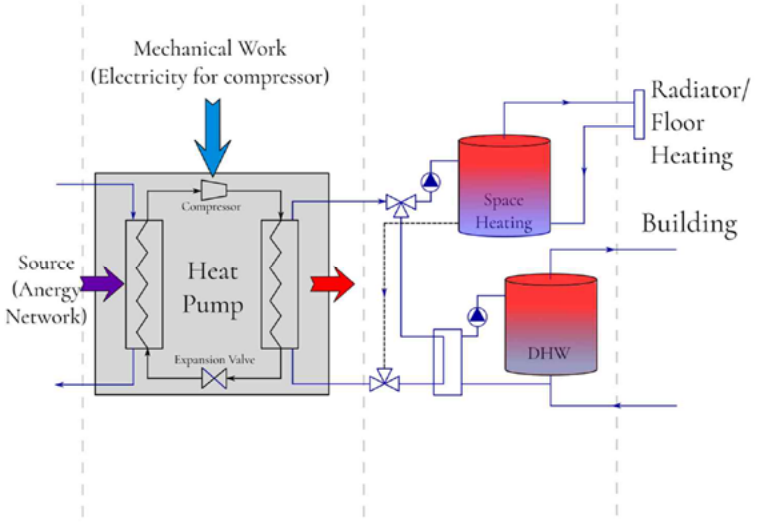

Fig. 1. Conventional Heat Pump set-up in European end-user buildings

2.2. Cluster Manager and Model Predictive Control Implementation

The MPC for the buildings at Naters was implemented in a centralized manner. The MPC is designed to be run by a Cluster Manager (CM). The Cluster Manager is an entity created for the purpose of the EU H2020 (Horizon 2020) research project, Sim4blocks. This entity is charged with the responsibility of monitoring and controlling the heat pumps and other systems within the building stock while, simultaneously, interacting with the aggregators/market. This entity was also created to allow for aggregation of multiple systems to satisfy and/or surmount the high entry barriers to the electricity market. Currently, there are very few end-users who qualify the prerequisites of the existing market. The Cluster Manager agglomerating on behalf of the end-users, is seen as a entity created to surmount these barriers, while also acting as the responsible entity ensuring that the devices are safe from damage due to over-use or being operated under sub-par component conditions. The algorithm was solved such that the end-user buildings can provide ancillary services in the electricity market.

The MPC models are created such that it maximizes the data available from the buildings. As a result, the MPC uses simple two/three node models for the building. The building parameters used are based on the information available from the building construction data and the architectural standards. The models for the storage tanks for space heating and domestic water purposes are single node models. This is a departure from previous work where 3-5 nodes for the storage tanks were chosen, based on the need for stratification or full mixing. This was abandoned as thermal storages in existing buildings only have one sensor (or at best two) measuring the temperature within, making it difficult to create good representations of the stratifications within the tank. Also, single node models are easier to solve.

The equations listed here are mostly generic representations describing an MPC. As can be seen from the equations 1a, 1b, and 1c, the objective function consists of minimization of operating costs and the penalty costs associated with discomfort for the users in the building. The equations 2 represents the forecasted states of the state with reference to the present state and control variables and equation 3 represents the constraints imposed on the systems. The actual models are variations of the equations used in [11] and [12].

$$min \sum_{k=0}^{T} J(x_k, u_k) \tag{1a}$$

$$\sum_{k=0}^{T} J(x_k, u_k) = \sum_{k=0}^{T} l(x_k, u_k) + V(x_T) \tag{1b}$$

$$\sum_{k=0}^{T} J(x_k, u_k) = \sum_{i=0}^{12} \sum_{k=0}^{T} OPC + Penalty \tag{1c}$$

$$x_{k+1} = f_k(x_k, u_k) = Ax_k + Bu_k \tag{2}$$

$$G(x_k, u_k) \leq 0 \tag{3}$$

$$x(0) = x_0, k = 1, 2, 3, \ldots . T - 1 \tag{4}$$

$$u_k \in \{0, 1\} \tag{5}$$

The equations of the state at any starting time is represented as shown in equation 4 and equation 5 highlights that the control variable is a binary variable. Thus, the problem is solved as a Mixed-Integer Linear Programming Problem (MILP).

However, what is different from the conventional heat pump models are the additional constraints that have been imposed on the problem and the post-processing that is required for transforming the MPC results to ensure that the strategy is implemented for each of the buildings.

Conventional heat pump internal logic units use dead-band controls on the temperatures within the storage tanks and the distribution systems to prevent lack of DHW and heat for space heating during winters and use specific programs for heating that change from season to season. These dead-band limits were added to the MPC problem as constraints, as they reflect the actual HP heating ability versus what is theoretically possible. In addition, it is important to know the program that the heat pump is running on (whether it is for both space heating and DHW, or just DHW; whether it is running on a Winter/Summer program etc.) as that will change these dead band values. These factors were also added to the MPC as constraints. In addition, the problem constraints were varied depending on the building end-users' subjective comforts (based on assumptions on internal temperature constraints and historic data observations) and their space heating systems as well.

However, adding these constraints have a direct impact on the tractability, convergence rates and convergence time required for solving the problems. The addition of these constraints was observed to increase the convergence times from a few seconds for each timestep to anything from a few minutes to the maximum allowed 15 minutes to solve (15 mins as the electricity balance markets use 15 minutes as actuation time limit). The 15-minute time limit and the additional constraints make the problem difficult to solve in time, for a site with HPs. As a result, it makes it difficult to be part of the bidding process that is mandatory for participation in the electricity markets.

Other factors and problems associated with such an MPC implementation on HPs is mentioned in detail in the next section.

3. Problems with Heat Pump integration for Demand Response

Heat Pumps have always proven to be difficult devices to use towards DR applications. Heat Pumps are non-linear in behavior and as a result, making linear models which provide time-series of the electric power consumption and thermal power output within time constraints imposed by electricity markets has always been difficult.

This is made, even more difficult by certain practices in the industry, practices seen in installation and the existing internal logic within heat pumps.

These can be broadly divided to five main categories: (1) Installation issues, (2) Monitoring and sensor issues, (3) Standards and communication issues, (4) Feedback of states within installed systems issues and finally, (5) Management system/algorithm design and market issues.

3.1. Installation Issues

For most existing buildings, heat pump installation is performed by certified installers. The existing certification framework is managed by each HP manufacturer (e.g. Each company have a set number of configurations for certain types of buildings and the installer must conform to these configurations). On paper, this seems like a good idea. As building standards change, all that the HP manufacturers need to do is to upgrade the HP installation configurations and train the installers to install accordingly.

However, the reality is that, many a times, the peculiarity of the location of the building, the orientation of the building to the cardinal directions and as a result the sun, and geometrical peculiarities of a building over or underestimates the thermal demands of a building. There are also situations where the blueprint of the thermal installation will still conform to the certified configurations, however, the actual location of the thermal sensor (e.g., for measuring the outdoor temperature or the temperature within the storage tank) will be different from what it says on the schematic owing to space and architectural limitations.

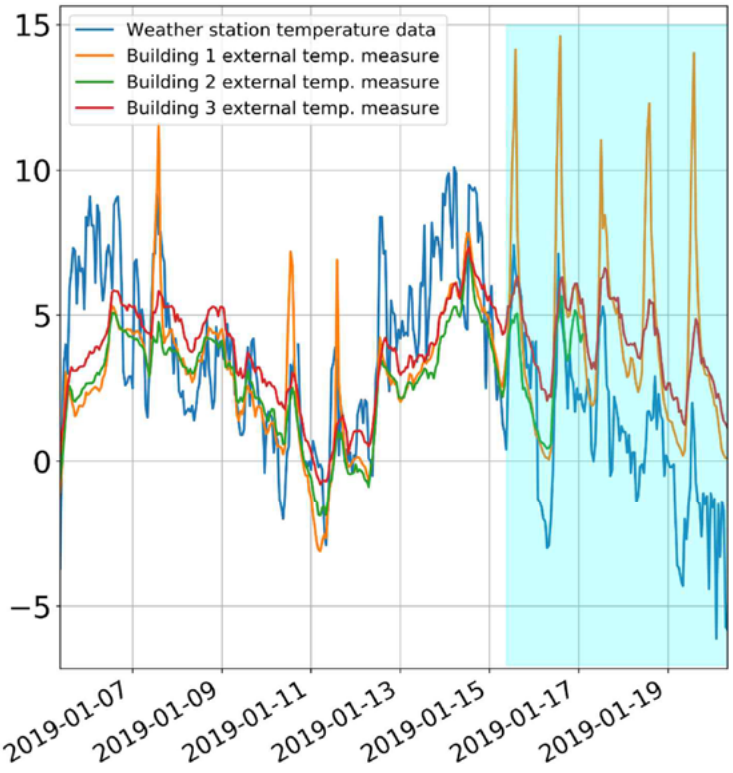

Fig.2. The comparison of the external temperature readings between three buildings at Naters and the weather station data. In the area, highlighted in cyan, one can observe the huge spikes in external temperature reading registered by the heat pumps for one of buildings because of exposure of the external temperature sensor to solar irradiation.

This might seem trivial as a problem, however, during the project, such a faulty installation was seen to measure outdoor temperatures above 20°C during winter days in Naters where the external temperature was measured to be sub-zero. This has drastic effects on the heating done by the heat pumps.

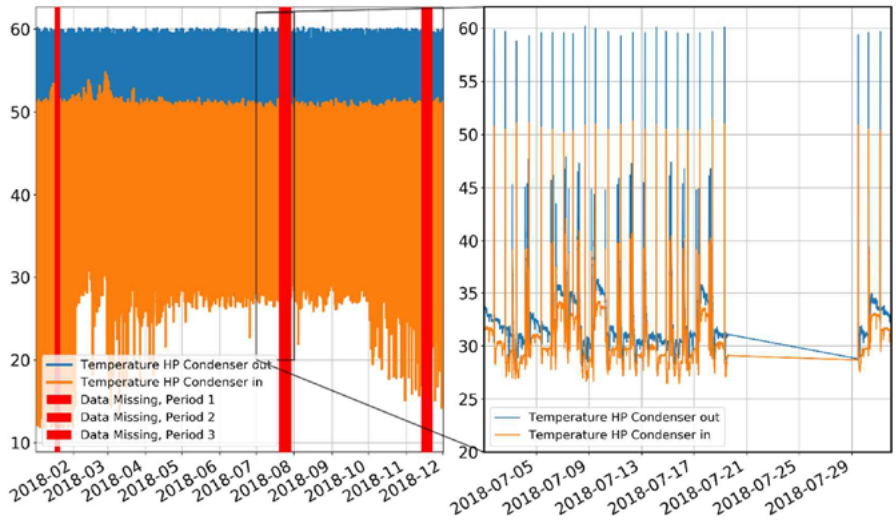

Fig. 3. The temperature of the water that goes into the condenser and comes out of the condenser collected over a year for a building in Naters highlighting the inconsistencies in monitoring

3.2. Monitoring Issues

Monitoring issues are a problem that is only partially attributable to the heat pumps and the manufacturers. However, this is a vital aspect when it comes to functioning alongside the new smart devices and an essential factor that will decide on whether HPs will be able to participate in the electricity market.

Monitoring and monitoring problems are a direct by-product of the participation of devices in the various markets and coming-of-age of the Internet-of-Things (IoT) paradigm. A fundamental marker that signifies the successful participation of any system within the electricity market is the proof of implementation of promised behavior. This is only possible through continuous monitoring.

However, as things stand, heat pumps and many of the thermal and electrical devices that exist in buildings are not prepared for the IoT paradigm and are not fit for continuous monitoring. This maybe owing to implementation of proprietary standards or siloed standards that are industry-standard in certain sectors, but are virtually unknown in IT and other sectors. This issue with monitoring reliability was continuously noticed in the Sim4blocks project, as can be seen in Figure 3, where the temperature of the water going into and coming out of the HP condenser dropped for long periods (49 days in 2018) during a year owing to hardware and software problems of the monitoring framework.

Another factor that plagues the monitoring quality is the calibration of the sensors. This has also been found to be inconsistent and there seems to be a lack of consensus on the general number of sensors that need to be present to get a concrete and consistent quantification of the state of charge in thermal storages and within the building mass. Quite often, due to financial reasons, the bare minimum was installed as standard. In the case of thermal storages, quite often the presence of only a single sensor within the storage tanks and installation errors rendered the monitored data meaningless. The presence of erroneous sensor readings can make certain algorithms ineffective, especially when storages only have one reading per tank (as can be seen in the highlighted blue and red bands in Figure 4).

For MPC implementation, this remains one of the most important issues that needs to be tackled, an MPC is only as good as the model you can make from the data you collect. The more reliable the data is, and the better the frequency of data collected, the better the MPC will perform.

3.3. Standards and communication Issues

The monitoring issues in the previous sub-section is partially owing to the sudden burst of IoT to the fore and the resulting impact of the sudden interconnectivity of systems that were previously not connected. Many standards in different fields were instituted separately in each sector over time. This historical separation has meant that there are still many standards and protocols in use in different sectors that remain industry standards, but, don't translate well in the age of the IoT and for use with DR. Proprietary standards are the biggest obstacle in preventing devices like HPs from being used for DR, followed by lack of conversion interfaces of the proprietary standards to interoperable standards like ModBus. The need for removal of vertical silos of standards to be replaced by OneM2M and ETSI standards for successful participation of devices have been highlighted by [13], [14] and [15].

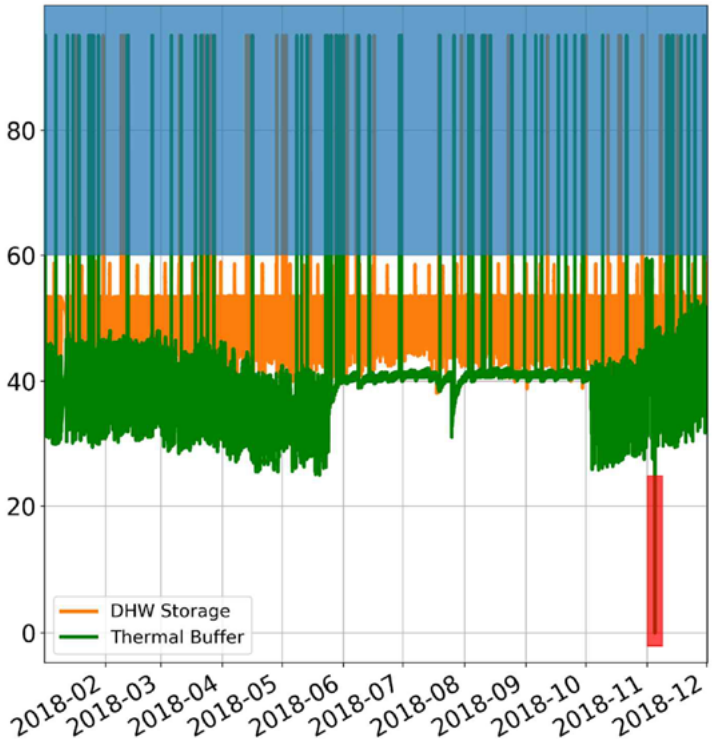

Fig. 4. Faulty water Temperature in the thermal storages (registering 95°C and 0°C, area highlighted in blue and red respectively) in one of the buildings in Naters

Of the existing HP manufacturers, most offer interfaces that can convert the internal logic and standards to ModBus or BACNet signals. This is the first step in the right direction. However, quite a few manufacturers provide this facility solely for monitoring and not towards reading and writing of variables remotely for control purposes. In addition, even number of monitored values available varies from company to company. Of the 12 buildings at Naters, only 8 buildings are equipped with HPs which can be controlled remotely for DR purposes. The other 4 have heat pumps which provide data of very low quality and only for reading purposes.

Presently, most HP manufacturers are more interested in integrating new protocols only for the latest batch of Heat Pumps (HPs). However, this leaves a large swathe of already existing Heat Pumps installed in the existing building stock that are unable to communicate optimally. As many of these devices won't be replaced overnight, it becomes vital to come up with strategies for these heat pumps in addition to the new HPs.

The removal of the standard and communication issues will also have a direct impact on the monitoring issues and thus, the removal of a large obstacle towards participation of HPs in the electricity market for DR and other services.

3.4. Issues concerning feedback over states within installed systems

The class of issues concerning long-term feedback are a result of the previous three issues mentioned working together. However, this is important for estimation of the quality of the heat supply within the buildings by the heat pumps over a year. Quite often, the installed systems behave properly for a certain season/period of time, but perform woefully during other periods of the year. This effect is presented even if the installer adheres to the certified configurations and conforms to the best monitoring standards. This can only be studied and ameliorated through consistent observation over long periods of time.

Currently, this is not performed at all. The only occasions when corrections are made are when the users within the building complain of exorbitant bills or of over/under-heated living spaces.

Conducting long-term monitoring and correction based on data feedback may be too expensive or not possible for manufacturers and/or installers. However, this may be of interest and of value to third-party entities that may also be interested in providing demand response as a service to the end-users.

Providing such services would not only save money spent in maintenance or upgrade in the long-run, but also, provide valuable input on the building's feasibility to participating in DR without losing money in the market by being an active part from the get-go.

3.5. Management system/algorithm design and market issues

All markets currently in existence, have clearly demarcated rules and constraints for participation. However, these rules and constraints were drawn up with the electrical devices in mind. Thermal devices with higher inertia struggle to keep up with the time constraints imposed.

This is often made better through the presence of efficient control and management systems with algorithms that aid further. However, all of the algorithms and control systems that are designed to-date, either follow rules or models (regardless of whether they are white, grey or black). In addition, each algorithm have different data requirements.

These control/management systems are presently unable to provide a solution that fits all buildings and all users. This means, that the best systems need to be equipped to be flexible and adapt to the buildings, the devices and users within. This is only possible through more data, better monitoring, better and more open communication standards. What would also be required is the presence of controllable variables that are readable and writable.

At present, the existing Heat Pumps are woefully under-equipped to handle anything other than scenario-based management systems leaving them either unable to participate in the market or only in a very limited manner.

4. Proposed Solutions for Heat Pump participation for DR and MPC

The following are the proposed solutions to facilitate heat pump participation for DR (in particular for MPC):

- Better standardization across the heat pumps, vis a vis, use of non-proprietary/universal/open-source protocols for communication and control.
- Improvement on variables that can be written by management systems preferably with a range, rather than discrete options.
- Understanding of minimum number of sensors required for reliable data monitoring and algorithm implementation.
- Better standardization on the location of sensor installation and the calibration of sensors, where installed and feedback on the state of the systems and modification of the systems for optimal functioning.
- Third-party certification of the building installation over multiple and sustained periods of time.

With what we have seen from the previous sections, it is fairly obvious that the first thing to address in the heat pumps would be improved access to data within the systems. At the moment, the data access and the use of vertical standards within the devices isolate the heat pumps and the larger thermal distribution system from being accessed and controlled in a reasonable manner. In addition, use of proprietary control and communication protocols leave very little room for the system to be controlled remotely. Use of ETSI, oneM2M and other horizontal layers of standards that aid monitoring and control would greatly aid heat pump participation in markets.

Once, participation is possible, the second aspect that needs to be tackled is the quality of the data that is being collected and the consistency of monitoring of the devices to see whether the installations are performing to the mark that they were built and installed for. There needs to be a framework to study the behavior of the systems over a set period of time and make changes to the system if need be, so that they work as they are listed and not under sub-par conditions.

Finally, there needs to be concerted effort and collaboration between the market monitors, heat pump manufacturers, installers and the designers of the latest machine learning and control algorithms to come up with the software and hardware necessary, which are flexible enough to adapt depending on the needs of the markets and the needs of the users in the buildings. This will also inform the market policy makers as to how relax or tighten the rules to make it easier for HPs to participate.

5. Proposed Changes to ancillary market to aid thermal device participation

The following are the proposed solutions to improve thermal device participation within the ancillary markets:

- Relaxation of certain actuation constraints of devices, while tightening monitoring constraints
- Encouragement of auto-consumption with systems such as solar panels and batteries that are locally available.
- Creation of blocks of periods where thermal devices have priority/advantage (like during night)
- Lowering of base entry size within balance markets and certain ancillary markets
- Continued liberalization of the market to introduce third-party entities that control aggregated end-user buildings

Thermal devices like heat pumps, unlike electrical devices, have high inertia. This is owing to the vast building mass within each building: within the concrete, the air in the buildings and the insulation that reduces loss of heat to the atmosphere. The flow of heat through the distribution system and the dynamics of the thermal transfer from the source to the sink and then to the storage tanks within the buildings and finally to the distribution system and to the buildings themselves take time.

This is very different from the electric systems which have low inertia and consume and/or produce electricity within seconds. This puts thermal devices on the back foot from the outset.

As things stand, the ancillary and balance markets in Switzerland [16], even the slowest market constraints require the systems to have proof of actuation from 30 seconds to within a minute and be satisfying the power promised within 5 minutes. This is an exceedingly difficult proposition for thermal devices and is a high barrier for consistent HP participation in the market.

So, the active role of thermal systems within an electricity market is only possible if there is a rethink on the rules of participation within the market. Another option would be allowing for the thermal devices to be used to offset electrical devices like PV and batteries.

During nights and certain periods of the day, it might also be possible to prioritize use of thermal devices to offset electricity produced elsewhere in the grid such that they heat the storage tanks and the building mass in advance.

Finally, participation of third-party entities who can control many disparate systems, various thermal devices and in a geographically-wide area, while being able to disaggregate their actuation signals successfully would greatly improve the ability of thermal devices to participate in the market. This would require liberalization of the market to allow for such actors such as aggregators and the cluster manager described in the previous sections.

6. Conclusion

This paper hopes to shine some light on how to better utilize heat pumps within end-user buildings, with a priority on the existing building block, rather than the newly constructed buildings. This is of vital importance as the yearly retrofit/upgrade rate of the existing building stock has been found to be less than 2% throughout Europe.

The authors realize that the conclusions and the proposals that have been made are based solely from a small subset of the heat pump installations in the residential and mixed-use building sectors. This may not reflect the rest of the heat pump installations in Europe or the world. However, based on the similarities seen between the different heat pumps and the similar problems faced by the different pilot sites within the

Sim4blocks project and also from conversations with partners and other players in the industry, the authors believe that the suggestions made could be used as a good baseline to improve the participation of thermal devices, especially Heat Pumps in the electricity market, especially for Demand Response.

Further analysis of the ongoing MPC experiments within the Sim4blocks project and the resulting data will only strengthen the observations made here and shed further light on the ability and shortcomings of MPC for DR with HPs. It will also reinforce the need for more sensors, reliable monitoring data and more tests in other real pilot sites located in actual communities situated in various countries.

This paper is a distillation of the lessons learnt on the value of good sensors, the quality, reliability and type of data, the standardization of communication and monitoring protocols which will be required to ensure successful and optimal thermal device participation in electricity markets. It also shows a possible direction to the evolution of the markets and the grid when used with modern algorithms and management systems.

In addition, the authors hope to highlight the great need for concerted effort between engineers, scientists and policy makers across different fields to ensure successful evolution of the present electrical and thermal systems to create more efficient and greener grid, cities and future.

Acknowledgements

This project has received funding from the European Union's Horizon 2020 research innovation program under grant agreement No. 695965. The authors would also like to thank the partners of the Sim4Blocks project for their invaluable support and help without which this paper would not have been possible.

Single Source "Solar Thermal" Heat Pump for Residential Heat Supply: Performance with an Array of Unglazed PVT Collectors

Christian Schmidt, Arim Schäfer *, Korbinian Kramer

Fraunhofer-Institute for Solar Energy Systems ISE, Freiburg 79110, Germany

Abstract

This work deals with the results of experimental measurements of a novel solar heat pump based heating supply concept for residential heat supply. The constructed load case aims at supplying heat for a single-family house with a moderate heat demand of 45 kWh per m² and year. An system design case was measured comprising an array of rear insulated uncovered photovoltaic thermal (PVT) collectors, a brine/water heat pump with deactivated resistance heaters and extended temperature range on the evaporator side, and a two-zone combi storage. The main innovation is to operate the PVT array as the sole heat source for the heat pump and accordingly with extended collector loop temperatures below the freezing point. Performance analysis was carried out on two characteristic cold winter test days. Measurement results show that the present system configuration is able to cover the heat demand comprising domestic hot water and space heating. Analysis of the cold winter test days reveal that insignificant icing occurred on the surface of the collectors. Temperature comfort levels were reached. Improper system design was detected, discussed and several concrete optimization potential measures were identified.

1. Introduction to solar thermal heat pump systems

1.1 System Concepts

In residential heating systems comprising domestic hot water preparation, solar thermal collectors are usually combined with a fossil back up. Replacing the fossil boiler with a heat pump provides the possibility to boost the renewable share of these heating systems. In such a solar and heat pump (SHP) system, solar thermal collectors and the heat pump supply energy for space heating and/or hot water independently of the source(s) of the heat pump. Heating systems with this kind of operation mode were defined as "parallel" within the work of the Task 44/Annex 38 "Solar and Heat Pump" of the Solar Heating and Cooling program of the International Energy Agency (T44A38). In the "serial" configuration the solar thermal collector acts as a source of the heat pump, either exclusively or additionally (Hadorn, 2015). In general, in SHP systems, both, parallel and serial operation modes can be realized within one system (Fig. 1, left). The SHP system investigated in this work is

E-mail address: arim.schaefer@ise.fraunhofer.de.

a combined parallel/serial solar thermal heat pump system (Fig. 1, right) with an array of unglazed PVT collectors.

1.2 Market barriers

The T44A38 market research conducted in 2011/2012 found 135 solar thermal heat pump system configurations offered by different suppliers and manufacturers (Ruschenburg, Herkel et al., 2013). Results of T44A38 have shown that there are promising systems in terms of energy performance in both, serial and parallel (and regenerative) configurations (Hadorn, 2015). For illustration purposes, Fig. 2 shows the operating temperatures of the main components, solar part and heat pump with either air or ground source, of said SHP configurations ("state of the art"). It can be seen that in (regenerative and) serial SHP configurations, controller and system design rule out operation temperatures below zero degrees in the solar loop.

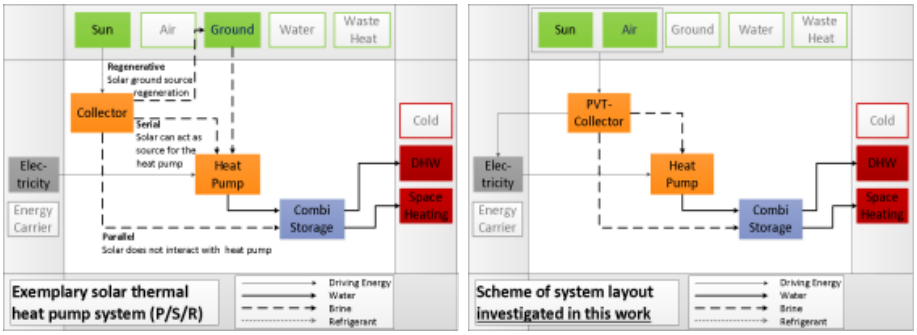

Fig. 1: The left scheme shows an exemplary parallel/serial solar thermal heat pump system according to T44A38 visualization scheme with costly energy sources on the left bar, free energy sources on the top bar, and useful energy sinks on the right bar. The right scheme shows the combined parallel/serial solar thermal heat pump system investigated in this work. Similar to the example on the left, this system has access to two heat sources via the PVT collector array.

Manufacturers may shy away from the risk of formation of ice. On the one hand, the performance of unglazed solar collectors under operating conditions below the frost point was investigated in the past i.e. in (Massmeyer and Posorski, 1982) or more recently in (Bunea, Perers et al., 2015), but studies with operation of entire systems are still rare. Hence, a second heat source is required to cover the remaining (high) heat demand during cold weather periods. A consequence is that the utilization ratio of the solar array is greatly reduced by limiting the operating temperatures of the collector field above the freezing point (i.e. < 2 °C). As a result, the solar fraction of these systems would be in a similarly (low) range as for conventional solar thermal combi systems with fossil back up heater.

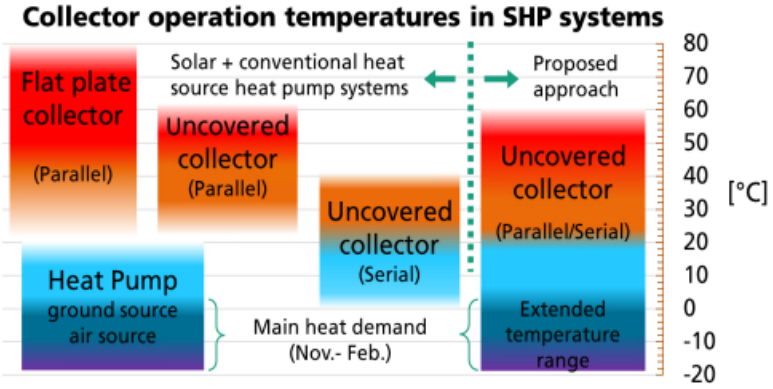

Fig. 2: Most SHP configurations investigated within T44A38 (i.e. market study) do not substitute a conventional heat source. Hence, solar does not cover the main heat load: This design approach limits the solar utilization ratio, thus leading to low fractional energy savings.

Whereas improved system performance can be achieved, the additional investment cost for the solar thermal part (solar collector array, hydraulics and pump group, installation and initial operation, etc.) forms a market barrier: Considering the extra cost of the "optional solar thermal add-on" and its limited saving potential, investors might question its meaningfulness. To date, solar thermal and heat pump systems – if at all – play a niche role in the national heat pump markets. In order to improve the cost efficiency solar thermal heat pump systems, it seems in the nature of the case to substantially increase the utilization ratio of the solar part by extending its temperature operation range below zero degrees Celsius, hence, making the conventional heat pump heat source and cost for its activation obsolete (Fig. 2, "Proposed approach").

2. Single source SHP systems

2.1 Solar thermal and PVT: Previous developments

Only six out of 135 configurations of said T44A38 market study can be called single source SHP systems employing an array of solar collectors as sole source of the heat pump (Table 1). All systems but one use unglazed solar collectors to operate below ambient temperatures. The majority of systems allow for operation below the frost point. All but two systems rely on smaller or larger source side storages, mostly using water as a phase change material, which results in additional cost. None of the systems use PVT collectors. On the one hand, PVT collectors in T44A38 system configurations are only employed as additional low-temperature heat and electricity source for space heating and DHW or to regenerate a heat pump source (ground probe or brine storage). On the other hand, the prospect of a heat pump heating system with a single component PVT collector as heat and electricity generator for the heat pump seems attractive.

Table 1: Overview of collector types, operation temperatures and storage types of all identified single source solar thermal "only" heat pump system configurations of T44A38 market study. Only systems providing space heating and domestic hot water (DHW) are listed. For comparison, the system investigated in this work is shown at the end.

#	Available modes	Collector type	Collector array operated		Storage on heat pump ... side	
			as ambient heat exchanger	below freezing point	source	sink
1	Parallel/ Serial	Flat plate	Presumably not	-	wet sand (large, outdoor)	DHW
2	Serial	Absorber	yes	yes	-	DHW
3	Serial	Absorber	yes	?	ice (large, outdoor)	DHW
4	Serial	Absorber	yes	yes	ice (320 l)	Combi storage
5	Serial	Absorber	yes	yes	-	DHW
6	Serial	Flat plate with integrated fan	yes	yes	ice (320 l)	Combi storage
This work	Parallel/ Serial	PVT	yes	yes	-	Combi storage

While in R&D, the heat supply concept of PVT collectors applied as sole heat source for a heat pump gained increased interest (Zhang, Zhao et al., 2012), especially for DHW applications (Wang, Guo et al., 2017), efficient application in combined space heating and DHW still seems to pose a challenge. To date, the authors are aware of only one single source PVT heat pump system configuration for space heating application which is about to enter the market (Leibfried, 2018).

2.2 Objectives of the study

The objective of this study was therefore to check the principal meaningfulness and furthermore the potential of the single source PVT heat pump as a heat supply concept for residential buildings.

1. Is the array of PVT collectors able to sufficiently supply heat for the heat pump during cold weather periods, including extreme cold and snowfall?
2. To what extent can icing be expected due to the continuous low-temperature operation?

3. Which optimization potential can be derived?
4. How to integrate the electric benefit of PVT into established performance figures?

3. Experimental setup

3.1 Single source PVT heat pump system configuration

A parallel/serial solar thermal heat pump system with an array of PVT collectors, power inverter, combi storage, heat pump, and hydraulics was installed at the system test rig at Fraunhofer ISE in Freiburg, Germany and put into operation in December 2017 (Fig. 3). The main system components are described in further detail in Table 2.

Fig. 3: Investigated single source SHP system with an array of PVT collectors in two rows totaling 20 collectors installed on top of the system test stand at Fraunhofer ISE (left). The photo on the right shows the installed combi storage and the heat pump including a hydraulic unit. The power inverter is installed as well (not shown in the photo).

Table 2: Description of the main components of the measured solar thermal heat pump system.

Component	Subcomponent	Description
Solar PVT array 31,4 m² 5,2 kWp,	Collector type	The array consists of 20 rear-insulated uncovered and therefore infrared and wind-dependent PVT collectors (“2Power HM 1000, 1Power 260 Mono Black”). Rated power is 260Wp (PV), area is 1,57m².
	Electric side	The modules are connected to an SMA inverter, which is connected to the grid. The inverter is powered only by the PV array.
	Thermal side	The array is subdivided into four arrays with five modules each. The hydraulic connectors of the modules are connected according to the Tichelmann system; hence all collectors are flowed through in parallel.
	Control	The parallel mode is set as first priority. Charging is triggered if the temperature of the solar array is above the lower storage tank temperature. Serial mode is triggered by heat pump control settings based on heat demand.
Heat pump P_{rated}: 5,1 kW	Type	Brine-water heat pump with extended temperature operation range on the source side from -20 °C to +30°C.
	Heating rods	Resistance heaters (backup) on source/sink side deactivated during measurements.
	Control	Storage tank temperatures trigger the serial heat pump operation using the solar array. After parallel mode, serial mode is second priority: The heat pump should provide temperatures above 48°C in the DHW section of the combi storage. If this criterion is fulfilled, the space heating section of the combi storage is charged. The required temperature depends on the ambient temperature.
Storage	Type	850 liter combi storage provided with a permeable partition plate to avoid temperature mixing of space heating and domestic hot water zones. Inner outlets in the space heating zone are provided with diffusors (cf. Fig. 4).

3.2 Description of load emulation and measurement equipment

Fig. 4 shows the experimental setup of this work comprising the solar thermal heat pump system (equipment

under test), with its main thermal components and hydraulics as well as the interface to the test rig. In total, almost 60 sensors were installed, of which 41 were calibrated for the characterizing measurements, the remaining form part of the equipment under test. Table 3 and Fig. 4 refer to (and show) selected sensors relevant to this work only: Table 3 shows the applied sensor types and accuracies; Fig. 4 shows the denominations of the sensors used in result diagrams (Fig. 5) in chapter 4.

Table 3: Properties of selected sensors used for the measurements and presented in this work.

Sensor	Manufacturer	Type	Accuracy
Temperature (fluid)	TMH	PT 100	0,1 K
Flow Rate	Krohne/Siemens	magnetic inductive (Optiflux 5000/ Sitrans FM MAG 1100)	0,5 %
Solar radiation	Kipp&Zonen	CMP 11	2 %
Relative humidity	B&B Thermo-Technik GmbH	HA-ANA-10V	2 %
Electricity (summer test day only)	EMU	Allrounder 3/75	1 %

Fig. 4 shows the load side on the right side of the dashed line, comprising a space heating loop (radiator) and domestic hot water loop with a freshwater station (heat exchanger and shower head symbol). In both cases, hot water tapping from the combi storage is realized by directly connected hydraulic loops with eccentric worm pumps. Details of the volume flow control specifications are given in Table 4.

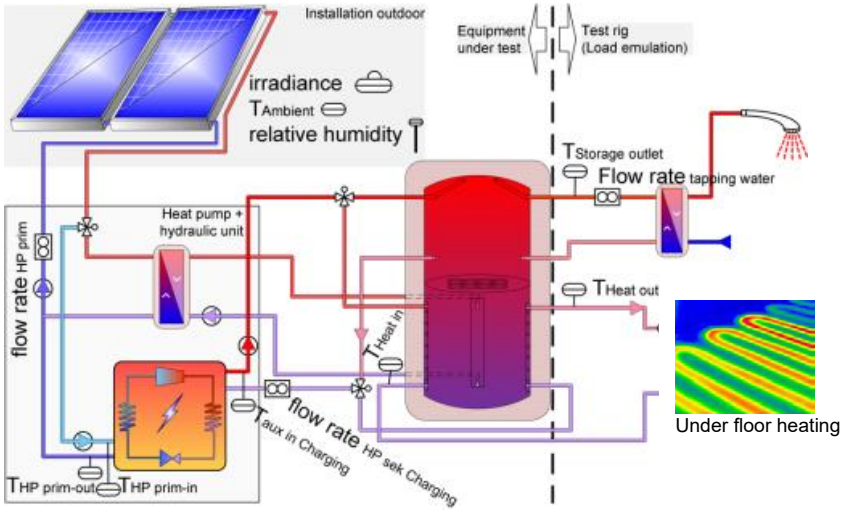

Fig. 4: Experimental setup of this work comprising the solar thermal heat pump system, with its main thermal components and hydraulics, interface to the test rig and sensor positions. The electric side of the solar array is connected to a power inverter (not shown). Sensor denominations given in this illustration are used in Fig. 5 of the next chapter.

Table 4: Set up for the domestic hot water (DHW) and space heating heat loads.

Type	Load description
DHW load:	7,7 kWh at 45 °C carried out in 23 draw offs (shower, small draw offs, dishwashing, bathtub). The load profile is equal for every day and based on the EU tapping cycle "M" with 23 draw-offs, ~5,8kWh (Ecodesign Regulation 814/2013, 2013). The following T44A38 modifications according to (Haller, Dott et al., 2013) were adopted: • Since a daily 3,6 kWh "bathtub" draw off was added to the EU tapping cycle, the energy demand for the other draw-offs was reduced (Total: 7,7kWh instead of 9,4kWh). • Required draw off temperatures were set to 45 °C.

	Deviations from the T44A38: • The bathtub draw-off is every day (not every 7th day) • The dishwasher draw-off is as well at 45 °C (instead of 55 °C) The temperature loss of the freshwater station was assumed 3 K. Hence, the heat pump control was set to provide temperatures of least 48°C in the DHW zone of the combi storage.
Heating load:	65 kWh "Winter peak case" for winter and spring test days based on SFH45 building with underfloor heating (ΔT = 4K) in the climate of Strasbourg. A maximum heating load "winter load case" was defined for all test days except summer. The load is based on T44A38 simulation results for an "SFH 45" building with an underfloor heating in the climate of Strasbourg (45 kWh/m²a) and a heated area of 140m². Based on simulated monthly values given in (Dott, Haller et al., 2013), the mean daily heat demand for the coldest months December and January was obtained (51 kWh/d and 54 kWh/d). Since there are positive (and negative) deviations from these mean values throughout these months, an increased daily space heat load of 65kWh was chosen for said winter load case. The temperature of the space heating zone of the combi storage (hence, indirectly $T_{Heat\ out}$) is controlled dynamically by a heating curve dependent on ambient temperature, as usual in heating systems. The heat load of 65 kWh is achieved as follows: Underfloor heating loops are often operated without night setback because of their inertia; accordingly, the eccentric worm pump operates 24 h with a (constant) volume flow of 10 l/min. Assuming a temperature difference of 4K between $T_{Heat\ out}$ and $T_{Heat\ in}$, ~65kWh is discharged from the combi storage within 24h. $T_{Heat\ in}$ was set dynamically to $T_{Heat\ out}$ - 4 K with a minimum temperature admitted by the thermostat at 20°C.

3.3 Test days

In response to the questions raised in section 2.2 (Objectives of the study), characteristic test days were selected from the measurement period and analyzed accordingly. Refer to the next chapter for test day description and system performance analysis.

4. Results: Performance analysis on test days and optimization potential

4.1 Presentation of measurement results on test days

Result diagram description: Result diagrams of all test days are shown in Fig. 5. The characteristic operating behavior of the system is shown by pairs of diagrams showing the key sensor values of the charging (left) and discharging (right) side of the combi storage. Discharging is carried out via the domestic hot water and/or the space heating loop. Refer to Fig. 4 of the previous chapter for sensor positions. Irradiance and ambient temperature are shown on the left side.

Load side - DHW tapping emulation: 23 draw offs were performed on every test day, with the desired characteristics. Energy quantities as provided by the test rig are presented (Table 5). DHW tapping was carried out as intended: The targeted energy load of 7,7kWh was either met or slightly surpassed presumably due to a temperature level above 48°C in the DHW zone of the combi storage on test days spring and summer.

Load side - space heating load emulation: Due to inappropriate control settings of the thermostat, which in turn lead to temperature differences lower than 4K between $T_{Heat\ out}$ and $T_{Heat\ in}$, the targeted "winter peak case" heat demand of 65 kWh was met only on the second winter test day (03th of March), caused by the control of the test rig. Nevertheless, heat demand is still appropriate: 57.2 kWh is still above the mean heat demand of December (51kWh/d) and January (54kWh/d, cf. Tab 4, "heating load").

Table 5: Measured heat loads for DHW and space heating for given test days. Measurements were carried out in 2018.

Unit [kWh]	1st winter day 28th Feb.	2nd winter day 03th Mar.	Spring day 09th Apr.	Summer day 19th Aug.
DHW: Total	7.6	7.5	8.1	9.1
DHW: Tapping, shower	4.1	4.0	4.6	5.4
DHW: Bathtub	3.6	3.6	3.6	3.7
Space heating: Total	**57.2**	**66.9**	55.7	0.0

General remarks regarding the system behavior – combi storage charge: Charging is carried out either via the heat pump (serial mode) or via the solar plate heat exchanger (parallel mode). In serial mode, the heat pump is

charging the DHW and space heating zone of the combi storage alternately (cf. $T_{aux\text{-}in\ -\ charging}$). Depending on the heat demand, this occurs continuously, as on the 2nd winter test day, or with interruptions when the combi storage is fully charged (cf. spring test day from ca. 07:30). During these periods, it can be seen that the heat pump control "checks" the source temperature level three times per hour, sending a volume flow of about one minute to the source side pump. On the summer test day, the occurrence of the parallel mode can be observed, starting at about 11:30 (cf. flow $rate_{solar\ -\ charging}$, $T_{HP\ prim\text{-}in\ =\ sol\ out}$ $T_{HP\ prim\text{-}out\ =\ sol\ in}$).

General remarks regarding the system behavior – combi storage discharge: Regarding the achieved temperatures of the space heating temperatures, the two winter test days are relevant only (Refer to the following section 4.2). Regarding the achieved DHW temperatures, a general problem can be observed which concerns the heat pump charging behavior: DHW temperature comfort level ($T_{Minimum\ demand}$ = 48°C) is generally met for all draw offs apart from the bathtub where discharge temperatures always drop to about 43 - 44 °C. That this is a storage tank specific issue can be seen on the summer day, where the combi storage is fully charged by the solar array in parallel mode. The heat demand for the entire bathtub is met without any temperature drop. Further malfunctions due to bad control/system layout are discussed in chapter 4.4, Tab 5.

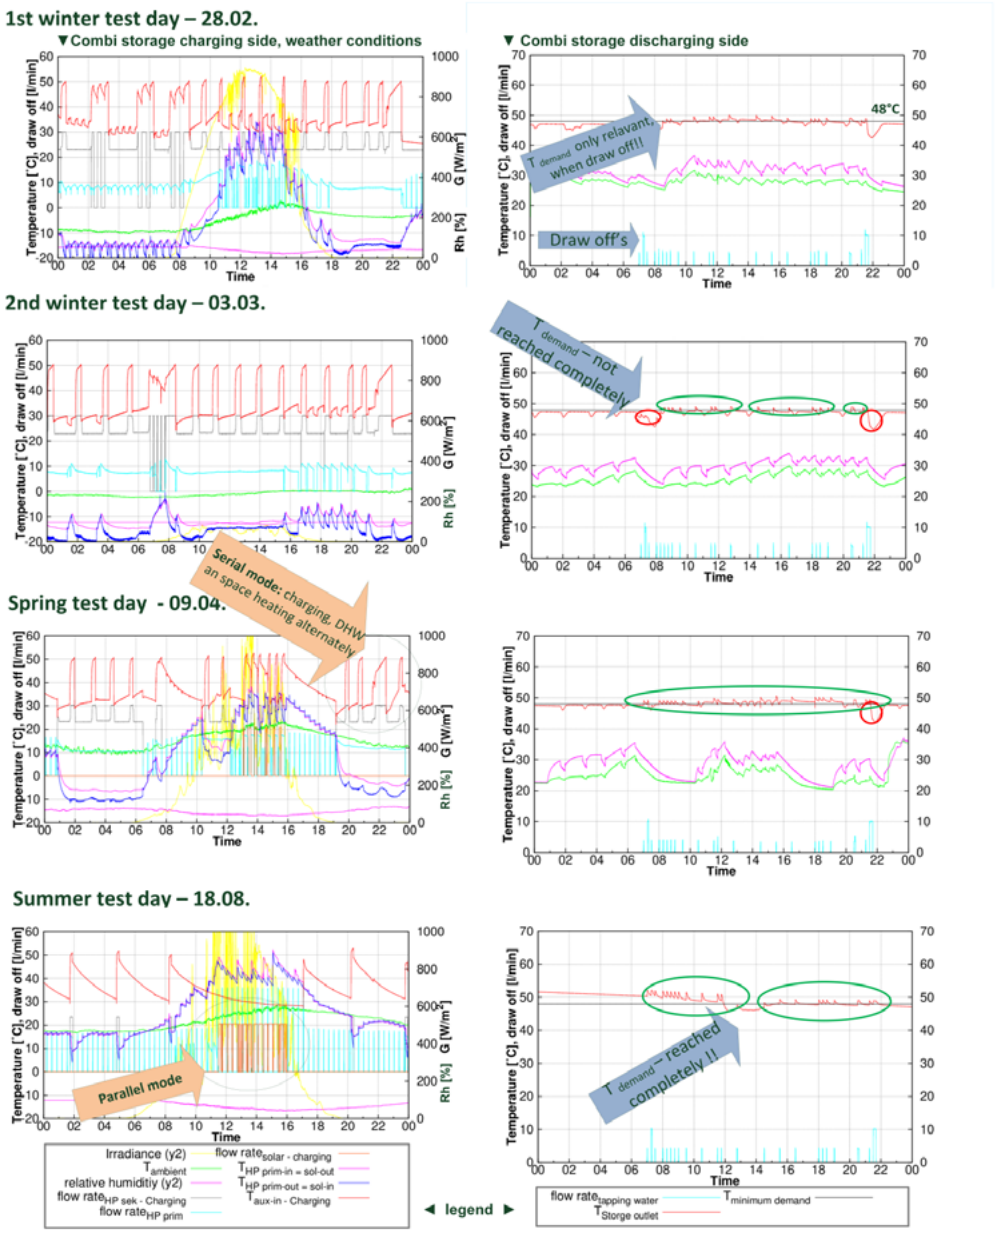

Fig. 5: Diagrams of the following test days: Winter (1st: 28.02.18 and 2nd: 03.03.18), Spring (09.04.18) and Summer (18.08.18). Diagrams on the left show the charging side of the combi storage, diagrams on the right show the discharging side of the combi storage. Legend applies to all diagrams above. Refer to Fig. 4 for positions of the sensors within the system.

4.2 Performance under cold weather conditions

This section deals with the question, whether the array of PVT collectors is able to sufficiently supply heat for the heat pump during cold weather periods, including extreme cold, snowfall, and icing. In response, system performance on two typical winter situations is analyzed.

- 1st winter day (28.02.) Clear sky day/night with ambient temperature ranging from -5 °C to -10 °C. 27th and 28th of February 2018 were the coldest days of the entire winter period 2017/2018 in Freiburg (Fig. 5,6).
- 2nd winter day (03.03.) Cloudy day/night with an ambient temperature between -2°C to 1°C (Fig. 5,7).

Icing: Fig. 6 shows the maximum level of ice formation at 04:53 the early hours of the 1st winter test day. The layer of ice is in places and superficially only (< 1 mm). Similar behavior was observed during measurements of other cold days, as well as in the climate chamber (Schmidt, Schäfer et al., 2018). **"Ice-production" on the module surfaces did not exceed 1cm of thickness (precipitation) on the front side during the entire system measurement phase (Dec. '17 to Aug. '18). No slipping of ice could be detected (tilt angle of 35°).** The comparably low ice formation can be explained due to the low flow of humidity being transported to the surface of the PVT collectors by means of natural convection. In contrast, icing occurs usually in external air units, where humidity is permanently supplied by means of a forced air flow to the compact heat exchanger of the external unit. In consequence, significant amounts of icing on the PVT collector array should only be expected if transport of humidity is assured in large quantities (i.e. precipitation). It could also be observed, that surface ice would melt within a few minutes under direct solar irradiation.

Fig. 6: Maximal observed ice cover on the surface of the solar array in the clear sky night from 27th/28th of February with a thickness approximately below one millimeter (left). On the coldest two days of the winter 2017/2018, the solar array reached operation temperatures above 20 °C from noon to the early afternoon.

The layer of snow on the solar array on the 2nd winter test day (Fig. 7) originates from snowfall on the previous day. It persisted for the entire test day on the solar array due to: low irradiance, the cooled PVT collectors operating as ambient heat exchanger and ambient air temperatures close to the freezing point. As explained below, such a layer of snow still allows for ambient heat exchange with the collector fluid. Measurements on absorbers under comparable conditions (Bunea, Perers et al., 2015) revealed that heat exchange can be increased due to the "naturally" increased collector surface**. The heat pump allows for manual reversing the heat pump cycle to heat the collector with energy by cooling the space heating zone of the combi storage. The mechanism was successfully tested on a layer of snow (+5 cm) on the solar array**: The layer of snow started melting on the side touching the collector array and slipped afterwards to the test rig floor.

Fig. 7: The solar array was covered with a layer of snow with a thickness of ~2 cm on the solar array for the period of 24h of the first winter test day (03.03.). The photos show the first row of the solar array in the morning (07:02) and in the evening (17:41).

System performance on the 1st winter day (cf. Fig. 5): On the second coldest day of the winter period 2017/2018, a space heat demand of 57.2 kWh is covered. Mean temperatures of the space heating loop ($T_{heat\ in}$ + $T_{heat\ out}$)/2 range from 26°C to 33°C. DHW energy demand is met as well; comfort levels are met with exceptions in the morning and in the evening (cf. section 4.2, last paragraph and section 4.5, Table 6, Area "DHW").

Throughout the day, the heat pump is operating most of the time in serial mode (cf. flow $rate_{HP\ Sek\ –\ Charging}$). Due to the cold ambient temperatures, when the evaporator outlet temperature $T_{HP\ prim\text{-}out}$ reaches -20 °C, the heat pump switches to frost protection mode and combi storage charging is interrupted. This occurs frequently from midnight to about 8am in the morning. During this time, it can be seen how space heating loop temperatures decline gradually. Interestingly, during the sunny day, mean evaporator temperatures ($T_{HP\ prim\text{-}in}$ + $T_{HP\ prim\text{-}out}$)/2 increasing along with the sunrise to peak values above 20 °C between 12:00 and 15:00 and decreasing back to low night time values after sunset. Hence, on clear sky days, the single source heat pump can play out its advantage by means of high source temperatures compared to air or ground source heat pumps.

System performance on the 2nd winter day (cf. Fig. 5): On this cloudy winter day, where a layer of snow covers the solar array, a space heat demand of 66.9 kWh is covered. Mean temperatures of the space heating loop ($T_{heat\ in}$ + $T_{heat\ out}$)/2 range from ca. 26°C to 30°C. DHW energy demand is met as well; comfort levels are met with exceptions due to an unknown charging interruption of the heat pump between ca. 7:45 to 8:45 (see also section 4.2, last paragraph and section 4.5, Table 6, Area "DHW").

Likewise, to the first winter day, the heat pump is operating most of the time in serial mode (cf. flow $rate_{HP\ Sek\ –\ Charging}$), charging DHW and space heating zone alternately (cf. $T_{aux\text{-}in\ –\ charging}$). Mean evaporator temperatures ($T_{HP\ prim\text{-}in}$ + $T_{HP\ prim\text{-}out}$)/2 are below -10°C during the whole day reaching minimum values at night time between -15° and -18°C. Apart from two frost protection cycles (at about 01:15 and 03:15), the solar array provides low-temperature energy to the heat pump at all times.

Assessment of system performance under cold weather conditions: Heat demand was met completely. The heat was delivered at the required temperature levels for space heating and with few limitations for domestic hot water.

4.3 Performance indicators used in the project (SPF or AZ)

Measurements in summer, autumn and winter where continued. The test days where repetitive days like mentioned before. The heating demand was adapted to the demand developed in IEA TASK44A38 (Summer: no heating; spring/autumn: 35 kWh/d; winter: 55 kWh/d). The daily DHW draw offs where
8 kWh/d split in the 23 taps based on Erp.

Representative test days where used to determine (daily) performance indicators.

Fig. 8 is based on IEA TASK44A38. The boundaries for the different AZ-values are shown.

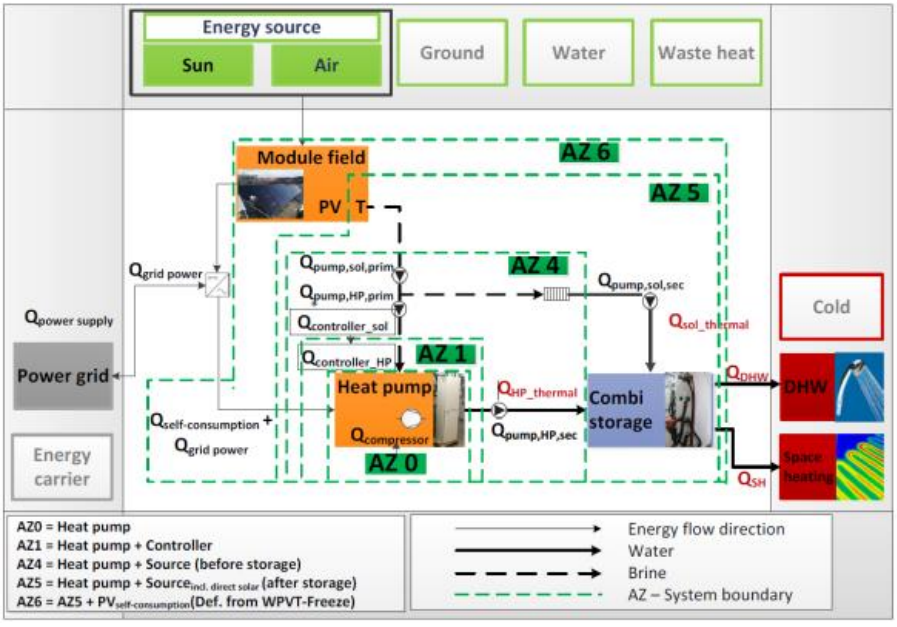

Fig. 8: Boundaries for the performance indicators based on T44A38.

AZ0 – AZ5 are known performance indicators. AZ6 is introduced to show the performance indicator by considering the PV- self consumption.

	Date:	18.08.2018	24.08.2018	27.10.2018	06.11.2018	03.11.2018	24.01.2019	29.01.2019	
Day type	Characteristics of the day	Summer-sunny	Summer-cloudy	Autumn-Rain	Autumn-cloudy	Autumn-sunny	Winter-cold	Winter - sunny	Seasonal Performance Factor
Load	Domestic hot water [kwh]	9.1	9.1	8.3	8.0	8.4	8.5	8.5	(ISE-internal Extrapolation - Weighting of reference/test days)

Fig. 9: Performance indicators, with boundary conditions (daily and a yearly, projected based).

Fig. 9 shows the daily performance indicators with it's boundary conditions. Theses values are based on real

measurements. The last column shows the seasonal performance indictors. The base for this are the test days shown in the table, extrapolated to reach a rough first estimation.

4.4 Optimization potential

The realized system has optimization potential. The main points are the following:

- Storage tank design not satisfying. The ErP "bathtub" tapping could also be reached completely by a better use of the buffer volume (readiness volume) for the DHW.
- A controller concept with focus on higher amount of PV self consumption could increase the seasonal performance factors
- PVT modules without back insulation for higher use of latent heat and thermal convection could increase the energy coming from the PVT source

4.5 Key performance indicators according IEA TASK60

Within the IEA TASK60 (PVT systems) Subtask D, key performance indicators are under development. The report of this Subtask D was supposed to be published in January 2020. All formulas with description will be content of this report. A presentation of the Subtask D leader Daniel Zehnhäuser showed a list of KPI's, which are wished "at least". The following chapters show the application of these KPI's, based the measurements on the PVT-heat pump system of project WPVT-Freeze.

4.5.1 Area-specific thermal yield

(listed in the presentation; but no defined calculation method in the Subtask D report)

$$Area\ specific\ yield = \frac{Q\ thermal\ taken\ from\ PVT - field}{Areagross\ (31{,}4\ m^2)} = 312\ \frac{kWh}{m^2 a}$$

Aspects of the PVT-module-field:

- System controlling was not optimized on using solar
- Thermal absorber is glued on the back side of the PV
  -> solar is absorbed by PV and heat conduction to absorber could be optimized
- Back side insulation of the module causes less use of environmental energy
  -> later PVT prototype in the project is without back side insulation

4.5.2 Thermal utilization ratios

$$\omega_{PVT,\,th}^{gross} = \frac{Q_{PVT}}{\int G_{col}\,dt \cdot A_{PVT}^{gross}}$$ Equation 3 (Report – Subtask D)

$$Thermal\ utilisation\ ratio = \frac{Q\ thermal\ taken\ from\ PVT - field}{Qsolar\ *\ area\ gross\ (31{,}4\ m^2)} = 0{,}28$$

Aspect:

- $Q_{thermal}$ contains heat taken from sun and environment

4.5.3 Average of the collector mean fluid temperature

$$\overline{\vartheta_m} = \frac{\int_{\substack{collector\ field \\ in\ operation}} dt\ \vartheta_m}{\int_{\substack{collector\ field \\ in\ operation}} dt} = 0.4\ °C\ \ (mean\ value\ /year)$$ **Equation 11** (Report – Subtask D)

Aspects:

- Main service time of heat pump during space heating season
- Main heat source of this PVT-application is using environmental energy
  -> low surrounding temperatures during winter

4.5.4 **Solar thermal fraction**

$$f_{sol,th}^{total} = \frac{Q_{PVT,*}}{Q_{*,primary}+Q_{PVT,secondary}} = 1 \quad (has\ to\ be\ 1)$$ **Equation 18** (Report – Subtask D)

Expl.: Thermal energy PVT / (Energy delivered to heat pump + Energy delivered directly to the storage)

$$f_{sol,th}^{secondary} = \frac{Q_{PVT,secondary}}{Q_{H\,P,*}+Q_{PVT,secondary}} = 0.1$$ **Equation 19** (Report – Subtask D)

Expl.: Thermal energy PVT (direct charge of storage tank) /
(Heat pump energy delivered to storage tank+ Thermal energy PVT, direct charge of storage tank)

Aspects:

- The calculation according to TASK60 seems to focus on multi source systems (see Eq. 18)
- Main heat source of this PVT-application is using environmental energy -> low surrounding temperatures during winter (low value of 0,1 considers only solar)

4.5.5 Performance Factor – heat pump system

$$SPF_{SHP+}^{(total)} = \left[\frac{Q_{HS}}{E_{*,HS}}\right]_{SHP+} = \frac{used\ heat}{electricity\ for\ heat\ pump} = 2.4$$ Equation 28 (Report – Subtask D)

Remark: See also chapter 4.3 (it corresponds to AZ5=2.4)

4.5.6 Performance Factor – heat pump system incl. grid

$$SPF_{SHP+}^{(Grid)} = \left[\frac{Q_{HS}}{E_{Grid,HS}}\right]_{SHP+} = \frac{used\ heat}{electricity\ for\ heat\ pump - PV\ self\ consumption} = 3.2$$

Equation 28 (Report – Subtask D)

Remark: See also chapter 4.3 (it corresponds to AZ6 = 3.2)

4.5.1 Investment cost per square meter

$$i_0^{PVT} = \frac{[I_0]_{PVT}}{A_{gross}^{PVT}} = 378\ €/m^2$$ Equation 48 (Report – Subtask D)

The following costs are considered:

(PVT-modules, inverter, controller, piping and mounting equipment, solar fluid)

4.5.2 Levelized Cost of Heat

$$LCoH = \frac{\left[\sum_{t=1}^{T=25}(I_t+OM_t-RV_t)\cdot(1+r)^{-t}\right]_{HS}}{\sum_{t=1}^{T=25}Q_{HS,t}\cdot(1+r)^{-t}}$$ Equation 44 (Report – Subtask D)

	PVT incl. PV self-consumption **incl. PV costs**	Thermal system (PV-system deducted)
I_0 = Investment costs	31 985 €	21 985 €
C_t= O&M costs	320 €	220 €

T = Service years	25	25
E_t = DHW and heating energy [kwh/a]	8483	8483
AZ6 (SPF) (3.2) or AZ5 (SPF)(2.4)	3.2	2.4
LCoH	28 ct/kWh	25 ct/kWh

Remark: System is not yet optimized, not energetically and not yet on use of PV self-consumption.

Example values for other technologies (based on internet research – whole system costs):

Heat pump deep bore	31 ct / kWh
Heat pump - air heat	24 ct / kWh
Heat pump - surface collector	23 ct / kWh
Oil central heating - calorific value	26 ct / kWh
Oil central heating calorific value	25 ct / kwh
Gas central heating calorific value	18 ct / kWh
Gas central heating calorific value	17 ct / kWh
Firewood central heating	15 ct / kWh
District heating wholesale customer tariff	17 ct / kWh
Central pellet heating	23 ct / kWh
Direct electrical heating	22 ct / kWh

4.5.3 Saved fuel and grid electricity cost

(according to chapter 2.5 of report – Subtask D)

Costs based on calculation, if the whole energy demand would have to be supplied by oil.

Saved **fuel** costs = **9.00 €/a m²** module area
= **282.65 €/a** system

Calculation basis:

saved energy/avoided primary energy	4 948.5	kWh/a	system
	157.6	kWh/a m²	module area
heating oil - calorific value	11.8	kWh/l	
saved fuel	419.4	l/ a	system
	13.4	l/m² a	module area
price for heating oil	67.40	€ /100l	

Saved cost for **electricity** = **47.28 €/a m²** module area
= **1 484.55 €/a** system

(whole energy demand supplied by electricity – 0.30 €/ kwh)

4.5.4 Avoided primary energy depletion

(according to chapter 2.3.5 of report – Subtask D)

Avoided primary energy (based on oil) = **157.6 kwh/a m²** module area
= **4 948.5 kwh/a** system

4.5.5 Avoided global warming impact

(according to chapter 2.4.2 of report – Subtask D)

Avoided primary energy depletion = **44.1 kg CO_2/a m²** module area
= **1 385.6 kg CO_2/a** system

Calculation basis:

saved energy/avoided primary energy	4 948.5 kWh/a system
	157.6 kWh/a m² module area
Example values:	1 litre heating oil ≙ 3.17 kg CO_2
	or 1 kwh ≙ 0.28 kg CO_2

5. Conclusion

Up to date, combined solar thermal heat pump (SHP) systems form a niche in the heat pump markets. The hypothesis is raised that an ineffective integration of the solar collector array forms a market barrier due to increased cost but little-added value, because solar thermal collectors are inactive during the cold periods of a year when heat demand is large. While such inactivity is inevitable in a conventional solar thermal system with a fossil backup heater, the solar array of a SHP system should be active, operating as heat exchanger to ambient during low irradiation conditions and night time. Hence, in order to exploit the full saving potential in SHP systems, it is suggested to substitute other conventional heat pump sources entirely by the solar thermal array. To date, such single source SHP systems typically rely on solar absorbers. The objective of this work was to check the principal meaningfulness and potential of an array of photovoltaic thermal (PVT) collectors in a single source SHP system configuration with a residential heat demand: On the one hand, a PVT collector can provide electricity for the heat pump. On the other hand, the thermal performance is lower compared to a solar thermal absorber.

Results suggest that the single source SHP with PVT collector array is a promising heat supply concept for residential buildings. An extreme case with an array of rear-insulated PVT collectors was investigated. A brine/water heat pump with extended temperature range on the evaporator side and deactivated resistance heaters as well as two-zone combi storage form the other components of the SHP system configuration. The analysis of cold winter test days reveals that insignificant icing occurred on the surface of the collectors and heat demand was met completely. Temperature comfort levels were also met for space heating and with few limitations for domestic hot water delivery. Improper system design was detected and discussed and concrete optimization potential measures identified. The most obvious measure is to replace the solar array with rear non-insulated PVT collectors. A significant temperature increase of source temperatures can be expected. The main aspects are:

- Wider source temperature range down to – 20°C incl. condensation and ice has a big potential
- **PVT Single Source Heat Pump concepts can work!**
- New system concept was designed by project partner PA-ID
- Position of backup heater on the demand side of the fresh water station is recommended
- 2-3 mm max. ice thickness on the front of the PVT-modules during test period
- Key performance indicators for the system where calculated according IEA TASK60 formulas

13th IEA Heat Pump Conference
April 26-29, 2021 Jeju, Korea

A study on the heat pump system for removing white plume of cooling tower and recovering water vapor

Chulwoo Roh*, Gilbong Lee, Beomjoon Lee, Eun Seok Wang, Young-Jin Baik, Hyung-ki Shin, Jongjae Cho, Junhyun Cho, Bongsu Choi

Korea Institute of Energy Research, Yusung-gu Gajengro 152, Daejeon, South Korea

Abstract

A study on the system applying a heat pump technology to remove the white plume from a cooling tower and recover the water vapor is carried out. The proposed system firstly cools the discharged humid air stream (38 ℃, RH 95%) from a cooling tower by using a cool outside air and secondly cools the humid air stream by the evaporator of the heat pump system to recover water vapor. The recovered water is re-supplied to the cooling tower's water basin. The thermal energy absorbed in the evaporator is released to the condenser of the heat pump system. The condenser is located at the final stage of the cooling tower to heat the air stream discharging into the atmosphere. The final discharging air stream is cooled by the cold outside air as soon as it is released, but the probability of white plume generation is significantly low, owing to the thermal buffer which is provided by the condenser of the heat pump.

1. Introduction

A Cooling tower is an important facility in various industrial fields such as power generation and air conditioning that can supply a heat sink at 28~32 ℃ by using the latent heat of water evaporation [1]. The cooling tower discharges heat energy into the atmosphere by evaporating the fresh water under forced direct-contacted convection. The humid air which is discharged from the upper part of the cooling tower in fall or winter generates the form of cloud, usually called white plume. The white plume from a cooling tower can pose several issues. It may affect visibility and safety as well as public perception [2]. Even though the cooling tower plume is made up of water vapor, a community may perceive it as unwanted or smoke-related. This may affect the use of nearby land or decrease property values.

Another issue about recent cooling tower technology is related to the huge consumption of fresh water for cooling. The water consumption in cooling towers may lead to lower efficiency of facilities and a decrease in industrial production in certain seasons especially when drought occurs. Large inland power plants with cooling towers generating electricity by using water supplies in large quantities should pay high attention to water saving in drought season.

Water conservation is highly related to energy conservation. It takes a considerable quantity of water to generate electricity [3]. Likewise, it takes a considerable amount of energy to produce fresh water and to treat wastewater. This article discusses a water-saving modification using a heat pump in the upper part of the cooling tower. The heat pump condenses the water vapor discharged from the cooling tower for the recovery of fresh water and heats the final discharging flow to reduce white plume.

2. System schematic and experimental results

2.1. System schematics

Fig. 1 shows a schematic diagram of the heat pump dehumidification system for a cooling tower. The humid air flow at DB (dry-bulb) 36 °C – RH (relative humidity) 95% is generated in a duct system by using a thermo-hygrostat and additional humidifiers. The air flow rate was 1000 CMH. The heat pump system makes hot and cold water circulating for heat exchangers. In order to simplify the system configuration and to consider the actual installation conditions of the cooling tower, the cold and hot water stream are separately circulated. For better performance, it is necessary to adopt a method of direct heat exchange of the refrigerant with the humid air, so further studies are currently underway. The temperatures of the cold water and hot water were 24 °C and 61 °C, respectively.

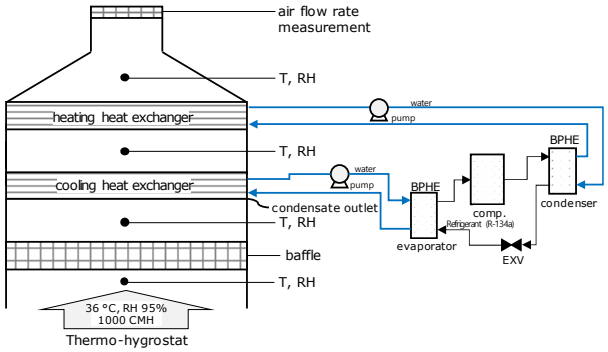

Fig. 1. Schematic of the cooling tower test system with a heat pump dehumidifier

2.2. Experimental Results

Table 1 presents the experimental results of the targeted system. Approximately 18% of water vapor was recovered by the heat pump system from the humid air flow. The final air flow was heated by the heat pump condenser to DB 52 °C and RH 34%. This final state of the air flow does not cause white plume even under the conditions of the outside DB 0 °C and RH 95%.

Table 1. Performance results of the heat pump system for a cooling tower discharging flow

Evaporator inlet	Evaporator outlet	Water recovery	Condenser outlet	Heat pump capacity	Power consumption of heat pump
DB 36 °C RH 98%	DB 33 °C RH 95%	30 g·kg$_{DA}^{-1}$ (-18.1%)	DB 52 °C RH 34%	Evaporator: 3.2kW Condenser: 4.5kW	1.46kW

Energy is required to condense the water vapor in the air. The energy recovered by the heat pump as water vapor condenses into the water can be used to abate the white plume as in this study, or it can be used for the purpose of supplying hot water for district heating. In order to apply the recovered heat from the water vapor for the district heating system, it is necessary to consider the cost-effectiveness of the electric power consumption of the heat pump system versus the fuel cost to operate a separate peak boiler in a conventional district heating system.

It is difficult to secure economical effectiveness in recovering the water vapor by the heat pump system to simply reduce the water usage cost. The presented approach should be recognized as a disaster response technology that can cope with serious water depletion, desertification or frequent occurrence of drought. In terms of socioeconomic costs of whit plume problem in cooling towers, the presented technology must ensure compatibility in the operation of public infrastructure.

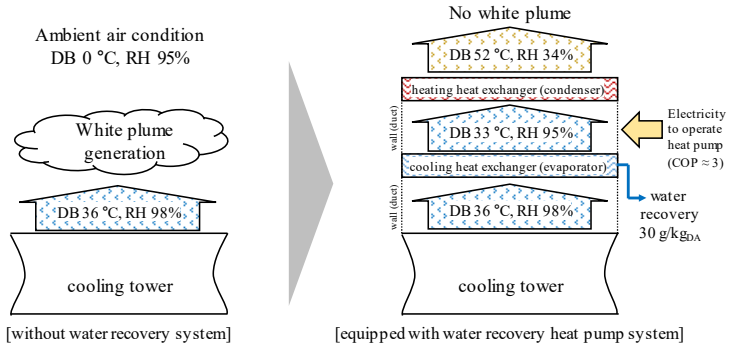

Fig. 2. Schematic of the heat pump system to remove white plume from cooling tower outlet

2.3. Economic Analysis

The power plant that produced 100MW of electricity with 40% efficiency generates 150MW of heat. Assuming a capacity factor of 80% and the plant is cooled by evaporating 15 °C of water, the annual cooling water requirement is estimated at 1.44 million tons. South Korea's industrial water cost is approximately $0.34 per ton. Assuming the additional flow rate for the drain of the cooling tower is 80% of the absolute coolant requirement, the annual cooling water cost is expected to be $927,280. There is sewage fee for drainage of the cooling tower, which is $0.487 per ton of water. Sewage rate of cooling tower is estimated by $563,000 annually. Therefore, annual cooling water usage costs are estimated to be $149 million, taking into account sewage rates. However, this figure is an absolute small cost of $0.002, calculated as the cost of cooling tower in power generation costs per kWh.

From an operator's point of view, unless there is an absolute shortage of water, there seems to be a lack of factors to try to reduce the use of cooling tower with additional investment. It may be better to have an infrastructure with high externalities that can draw water to prepare for an emergency case. This aspect suggests that various technical options should be considered from a policy perspective.

3. Conclusions

In this study, we propose a dehumidification system using a heat pump to recover water by condensing from the humid air discharged from a cooling tower. The experimental results are as follow.

1. As the heat pump system operates in the condition of COP 3 for the cooling tower exhaust air flow (DB 36 °C, RH 95%), 28.5% of water was condensed and recovered from the incoming air-water mass flux.
2. The latent heat which is absorbed from the heat pump's evaporator was utilized for producing hot water by the heat pump, so the final exhaust humid air flow can be in a state of DB 51 °C and RH 31%.
3. The proposed approach can effectively recover water by condensation and prevent a white plume in cold air conditions, but consumes energy required for driving the heat pump. A follow-up study will be conducted to ensure optimum performance of the heat pump in response to various cooling tower exhaust flow and ambient conditions.

Abstract

Theoretical considerations indicate enhanced system performance of household appliances when using zeotropic mixtures compared to R134a. This paper describes the experimental investigation of the performance behavior of a rolling piston compressor used in a heat pump tumble dryer and operated with a zeotropic zeotropic blend.

The experimental investigations demonstrate the change in operation conditions and compressor performance of the substitute refrigerant in comparison with the hydrofluorocarbon R134a. The compressor is tested on a compressor test rig according to DIN EN 13771-1 to measure and determine power consumption, cooling resp. condensing capacity, pressure ratio and cycle temperatures. The measured data of the reference setup with R134a and the substitute setup with a hydrocarbon refrigerant mixture will be compared with each other for a better understanding of their influences under different operation conditions.

Keywords: Rolling Piston Compressor; Compressor Performance;Liquid Slugging; Zeotropic Refrigerant Blend; Drop-in Refrigerant

1. Introduction

The Kigali Amendment to the Montreal Protocol [1] entering into force on January 1, 2019 regulates the global phase down of hydrofluorocarbons (HFC) with a high global warming potential. It confirms the European F-Gas Regulation from 2015 that already controls the phase down of fluorinated substances, e.g. refrigerants, based on their global warming potential (GWP). Consequently, hydrofluorocarbons (HFCs), for instance R134a, are limited in their availability and alternative solutions need to be investigated. Such solutions can include the development of new refrigeration systems designed to the specifics of the chosen low GWP refrigerant or retrofitting an existing system to said low GWP refrigerant. The latter is widely favored in terms of investment cost. The difficulty in retrofitting is to match the thermo-physical properties of one refrigerant with an entirely different substance not compromising the efficiency.

Having identified a refrigerant matching the boundary conditions, refrigeration cycle calculations follow to assess the system performance. However, the effects and consequences of a refrigerant change have to be tested in real systems. The influences of geometry or the compatibility with the lubricant and the behavior in the existing components are parameters difficult to appraise analytically. Therefore, an experimental investigation is necessary to achieve a deeper understanding e.g. of the effects on the compressor performance of an alternative solution.

A series of measurements on a test rig according to the DIN EN 13771-1 was carried out using a commercial rolling piston compressor designed for household heat pump applications. This paper presents the results of the performance measurements of the reference set-up with R134a and the substitute refrigerant blend of RE170 and R290. Three test conditions were examined corresponding to the operating range of the compressor.

2. Experimental Method

2.1. Experimental Setup

The present test rig setup is designed for performance tests of small capacity refrigerant-compressors in accordance with the ASHRAE standard 23.1 [2], resp. DIN EN 13771-1 [3]. Based on a standard vapor compression cycle the test bench includes a calorimeter evaporator and a flow meter to determine the refrigerant mass flow rate. Besides the main components like the compressor, the condenser, and an electronic expansion device, the cycle is additionally equipped with an oil separator, a filter dryer, sight glasses, and an accumulator (see Fig. 1). The compressor and the condenser are each integrated in the circuit with a detachable screw connection ensuring the adaption of the test bench to varying compressor capacities. Additionally, a small 12 V-fan installed next to the compressor may optionally cool it with ambient air to prevent too high discharge temperatures.

There are five measuring points for temperature and pressure, one of them monitoring the state of the secondary fluid in the calorimeter. The numbering of the locations refers to the designated point of state of the refrigerant in the cycle. All temperature sensors are PT100 resistance thermometers with class A accuracy [4]. The pressure transducers have a measurement inaccuracy of ±0.1 %FS. Table 1 lists the measuring range of the installed pressure sensors, which is necessary to calculate the absolute value of the uncertainty. A power meter separately plots the electrical input power of the compressor and the resistance heating element of the calorimeter. Finally, the mass flow rate and the ambient temperature complete the set of measured data.

In this specific study, the compressor mounted onto the test bench is a rolling piston compressor with the following characteristics:

- displacement of 7.8 cm³/rev,
- 2 pole induction motor, grid frequency of 50 Hz,
- voltage range of 187 to 264 V.

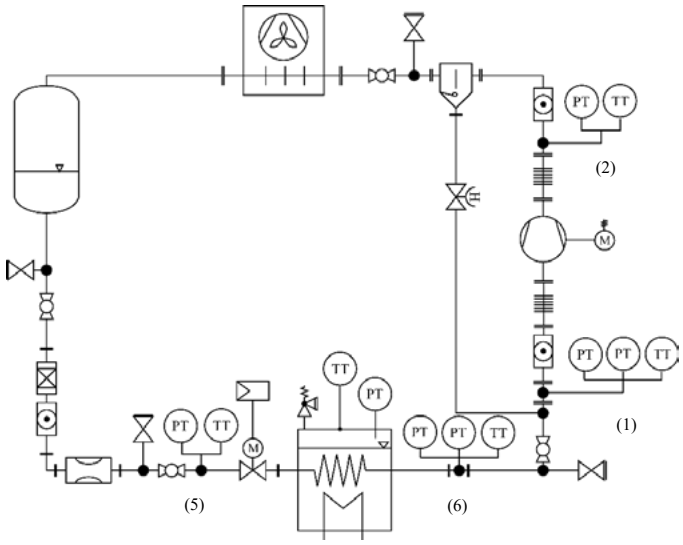

Fig. 1. Process and instrumentation chart of the test bench

Table 1. Installed Pressure Transducers

Measuring point	Range	Output
discharge line (2), inlet of the expansion device (5)	0 … 25 bar	4 … 20 mA
outlet of the evaporator (6), inlet of the compressor (1)	0 … 16 bar and 0 … 3 bar	4 … 20 mA
inner volume of calorimeter	0 … 25 bar	4 … 20 mA

Besides the pressure range of the sensors, the design of the evaporator calorimeter limits the operation range of the test bench. The maximum heat input capacity is 2 kW that is equivalent to the maximum cooling capacity. Secondly, the opening pressure of the safety relief valve is 20 bar, which leads to a maximum calorimeter temperature of 67.48 °C with liquid R134a as a secondary fluid.

2.2. Test Conditions

This paper investigates a rolling piston compressor used in a heat pump tumble dryer application. The objective is to compare the nowadays-used R134a with the substitute refrigerant blend RE170/ R290 at certain operating conditions. Besides the performance data supplied by the manufacturer, American and European standard rating conditions were considered to identify consistent parameters for the tests. The American AHRI standard 540, table 1, [4, p. 5] defines rating conditions for positive displacement refrigerant compressors. Next, the DIN EN 12900, table 5, [5, p. 10] states rating conditions of performance data as well but differing from the AHRI conditions. However, both standards distinguish three refrigeration appliances:

- "H" – high evaporation temperature,
- "M" – medium evaporation temperature,
- "L" – low evaporation temperature.

Figure 2 shows the manufacturer's data on the compressor operating pressure range with R134a. Considering those limits, the number of possible rating conditions decreases eminently leaving four rating conditions.

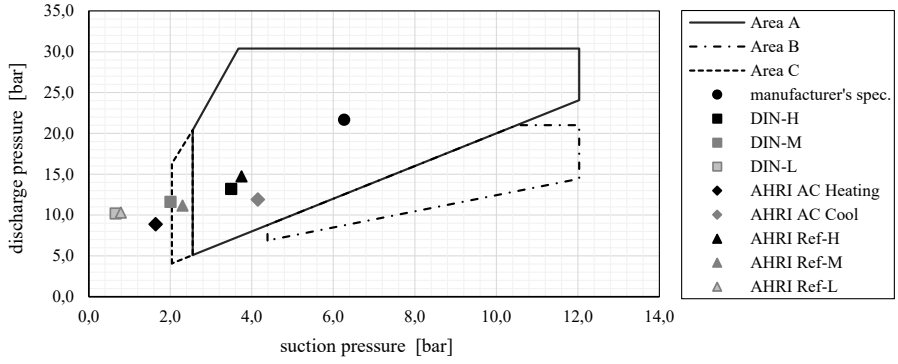

Fig. 2. Compressor operating range for R134a (Area A: normal operating zone; Area B: High density flow zone - running time less than 3 minutes; Area C: Low pressure zone - running time less than 3 minutes) with possible rating conditions

Out of the four points within area A, the "AHRI AC Cool" condition is neglected in the tests because it refers to an air-conditioning application not corresponding to the compressor's appliance. Since an adjustment of the refrigerant subcooling temperature and the ambient temperature is not possible with the described set-up of the test bench, those parameters are not specified in the rating conditions. Instead of the "AHRI Ref-H" point, the manufacturer defines a condition called "ASHRAE" condition. This state has similar temperature levels but different superheating which is included in the experimental investigation. Each test condition has a distinctive feature giving it merit for testing. The manufacturer specification refers to a heat pump application. The "DIN-H"-condition derives from a refrigeration appliance and the "ASHRAE"-condition adds a large superheating to similar refrigeration characteristics. The test conditions retained for the comparison of the two refrigerants are given in Table 2.

Table 2. Performance rating conditions for the rolling piston compressor in accordance with the manufacturer's data

	Suction dew point T_0 [°C]	Discharge dew point T_C [°C]	Suction gas T_1 [°C]
manufacturer's specification	23	71	35
ASHRAE	7.2	54.5	35
DIN-H	5	50	20

2.3. Experimental proceeding

The preparation for the test consists of evacuating the circuit and charging the cycle with refrigerant and the compatible oil (Table 3). The charged mass is measured indirectly by weighing the refrigerant bottle. Uncertainties result from the non- measurable liquid level of the receiver (see Table 3).

Table 3. Tested refrigerants, their charged amounts and the corresponding compressor oil

Refrigerant	Composition [%w]	refrigerant charge	Oil charge
R134a	100	434.8±20 g	prefilled, POE VG65
RE170/R290	69.86/30.14	383.8±20 g	200 ml of POE VG 100

The DIN test procedure [3] stipulates the recording of the measured data once the cycle reaches steady state. Therefore, the expansion device and the calorimeter heat input are adjusted according to the set temperature and the pressure at the suction side of the compressor. The condenser fan speed, respectively the swept air-volume flow, is the regulating variable for the compressor discharge pressure. When using a flow meter to determine the mass flow rate one must ensure that the minimum subcooling of the refrigerant is $\Delta T_{C,sc} = 3\,K$. Increasing or decreasing tendencies larger than 50% of the allowed deviation of the test parameter, as listed in Table 4, indicate that no steady state has been reached. The minimum duration of data recording is 15 minutes and at least one set of measurements per minute is required. Having established steady state conditions, several consecutive measurements of 15 minutes each are recorded. The same test is repeated in another session.

Table 4. Permitted deviation of measured values for the duration of a test series

Measured parameter	allowed deviation
pressure (absolute)	±1%
temperature	±3.0 K
calorimeter heat input	±1% of cooling capacity

2.4. Evaluation of the Data

The general processing of the acquired data for this experimental investigation follows the European standard on compressor rating [3]. If the measurement meets the criteria of the steady state, the mean values of the logged parameters are the basis for the calculation. Due to the diversion between the experimental data and the ideal rating condition, the consideration of corrective factors is vital for an objective comparison of the rated compressor performance. In addition to the COP, the isentropic efficiency is also determined using this test procedure.

The described data evaluation applies on the average values of a 15-minute-measurement. The first step is to determine the refrigerant mass flow rate. Therefore, the present test rig is equipped with the evaporator calorimeter (method A) and a refrigerant flow meter (method E), thus representing two standard methods [3] indicated in Fig. 3.

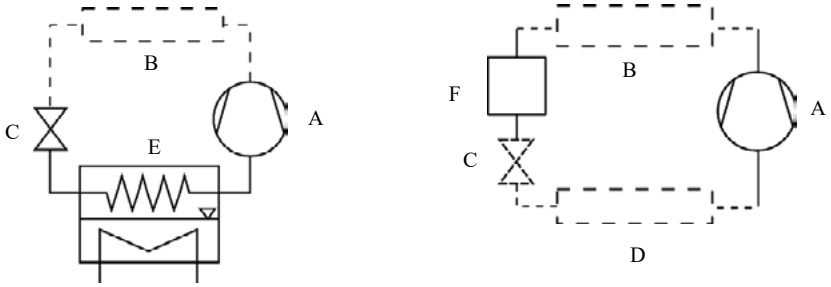

Fig. 3. Schematic of DIN 13771-1 test methods A (left) and E (right): A – compressor; B – condenser; C – expansion device; D – evaporator; E – evaporator calorimeter with heat source; F – mass flow meter

According to method A, the mass flow rate $\dot{m}_A$ is calculated using a calorimeter energy balance (1) considering the calorimeter heat loss F, the electrical input power of the heater $\dot{Q}_n$, the saturation temperature

of the secondary fluid t_s'' and the enthalpy difference of the inlet (h_6) and outlet (h_5) state. The measured refrigerant mass flow $\dot{m}_E$ is assumed to be oil-free due to the installed oil separator (2). Subsequently, the average of those two values is referred to as the actual mass flow rate $\dot{m}_a$ (3). The multiplication with a corrective factor regarding the ratio of the actual density at the compressor inlet $v_{1,a}$ and the ideal density v_1 leads to the refrigerant mass flow at the specified rating conditions (4).

$$\dot{m}_A = \frac{\dot{Q}_n + F*(t_{amb} - t''_s)}{h_6 - h_5} \quad (1)$$

$$\dot{m}_E = \dot{m}_{flow\ meter} \quad (2)$$

$$\dot{m}_a = \frac{1}{2}(\dot{m}_A + \dot{m}_E) \quad (3)$$

$$\dot{m} = \dot{m}_a * \frac{v_{1a}}{v_1} \quad (4)$$

The compressor's cooling capacity $\dot{Q}$ is obtained by multiplying the mass flow with the enthalpy difference between the ideal state at the compressor inlet h_1 and the boiling point enthalpy h_{f2} at the ideal compressor discharge pressure.

$$\dot{Q} = \dot{m} * (h_1 - h_{f2}) \quad (5)$$

The calculation of the power consumption at the ideal rating condition regards the ratio of the isentropic compressor power P_i at the specified rating conditions (6) and the isentropic power at the measured conditions P_{ia} (7). This ratio multiplied with the measured compressor power consumption P_a equals the input power at the specified rating conditions P.

$$P_i = \dot{m} * (h_{i1-2} - h_1) \quad (2)$$

$$P_{ia} = \dot{m}_a * (h_{i1-2a} - h_{1a}) \quad (7)$$

$$P = \frac{P_i}{P_{ia}} * P_a \quad (8)$$

Finally, the characteristic values are determined putting the previously calculated figures into relation.

$$COP_R = \frac{\dot{Q}}{P} \quad (9)$$

$$\eta_i = \frac{P_{ia}}{P_a} \quad (10)$$

The evaluation of a 15-minute-measurement solely gives a momentary impression. The average of the consecutive measurements and the results of the repetition experiment performed on another day as well as the corresponding standard deviation of each parameter represent the performance characteristics categorised by the refrigerant and the test condition.

3. Results and Discussion

The investigation of the compressor performance consists of three aspects. First, the difference between the two refrigerants at the theoretical nominal rating condition is examined, second the values calculated from the measured data are investigated and finally the compressor performance with regard to the refrigerant substitution is discussed.

3.1. Nominal Conditions

The experimental investigation comprises three operating points defined by the suction pressure dew point temperature, the discharge pressure dew point temperature, and the actual suction gas temperature as described above. Applying two refrigerants calls for a closer examination of the fluids properties regarding the specific refrigeration capacity, the specific volume of the compressor inlet state, and the pressure ratio assuming an ideal refrigeration cycle.

Fig. 3 (left) illustrates the specific refrigeration capacity of both refrigerants at the three operating points. Generally, the refrigerant mixture of RE170 and R290 possesses a distinctively larger specific refrigeration capacity than R134a. It indicates that less refrigerant mass flow is required to obtain the same cooling capacity. The large superheat of the "ASHRAE"-condition leads to a slight increase of capacity while the high dew point temperatures of the manufacturer's condition significantly decreases the specific refrigeration capacity. The latter observation is rather unsurprising as the latent heat decreases with rising temperature, respectively pressure.

As a rule, the volumetric refrigeration capacity (see Fig. 4, right) is an indicator for the compressor size. The mixture of RE170 and R290 exhibits a slightly larger volumetric capacity, indicating that an adjustment of the compressor size is necessary for future endeavours. Overall, the prospective reduction of the refrigerant mass flow due to the increased specific refrigeration capacity in combination with comparable volumetric refrigeration capacity leads to the conclusion that using the zeotropic blend reduces the refrigerant charge maintaining the compressor size or rather the compressor model. This observation corresponds to the actual refrigerant charge of the test bench in Table 3 and further supports the substitution of R134a.

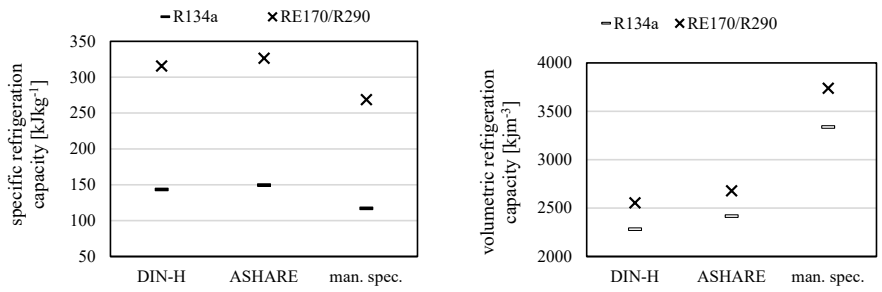

Fig. 4. Specific refrigeration capacity (left) and volumetric refrigeration capacity (right) of R134 and RE170/ R290 at the specified rating conditions

The last nominal parameter to discuss in terms of compressor performance is the pressure ratio depicted in Fig. 5. This value mainly influences the required compression work and gives an idea of the discharge temperature too. Ideally calculated according to the specified rating conditions, the pressure ratios of the two refrigerants are in a similar range supporting a substitution. Yet, it even suggests a slightly lower work input in the case of the zeotropic blend. Still, there are more influencing factors to the power consumption like the mass flow rate, the pressure ratio, and internal friction that should be analysed.

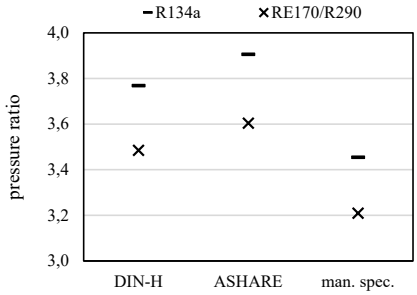

Fig. 5. Ideal pressure ratio of R134 and the mixture RE170/R290 at the specified rating conditions

3.2. Experimental Data

The evaluation of the experimental raw data follows the calculation described in section 2.4. All discussion points of the experimental results refer to the average value over the number of consecutive measurements at the same nominal conditions performed on one day and their repetition on another day. The standard mean error is shown to depict the deviation within the measured or calculated figure.

In general, the rating consists of the refrigerating capacity, the power input and the refrigerant mass flow rate. However, this paper refrains from discussing the refrigeration capacity, as it is the product of the ideal refrigeration capacity and the determined refrigerant mass flow rate. Boundary conditions not specified upfront or different from the standard condition must be stated as well (see Table 5).

The boundary conditions such as the ambient and the subcooled refrigerant temperature affect the compressor performance comparability but cannot be influenced at the present state of the test bench. The experiments were performed during the summertime causing fluctuating and, in some cases, elevated ambient temperatures. As it solely matters in terms of the compressor-shell cooling and the condenser fan speed, the latter being of low importance to the compressor performance, the relatively small divergence is negligible. The subcooled temperature of the refrigerant-mixture tends to be around 2 K cooler than the baseline refrigerant tracing back to the temperature glide of the refrigerant blend. As stated before, the subcooled state is a boundary condition that influences the calculation of the mass flow rate (1). There is no direct link to the rating of the compressor power due to the mentioned corrective factors.

Table 5. Boundary conditions for the performed compressor test

Test condition		DIN-H		ASHRAE		manufacturer's specification	
Refrigerant		R134a	RE170/R290	R134a	RE170/R290	R134a	RE170/R290
ambient temperature T_{amb}	[°C]	26.04±0.34	24.84±0.36	27.19±1.45	25.0±0.31	28.77±0.99	25.11±0.09
subcooled refrigerant T_5	[°C]	45.41±0.29	43.90±0.33	50.03±0.07	48.22±0.33	66.50±0.13	64.94±0.06

The discussion of the experimental data regards the determined mass flow rate as depicted in Fig. 5 (left diagram) and the standard mean error shown in Table 6. It supports the suggestion of a reduced mass flow of the alternative refrigerant. Given the fact that the compressor runs at a constant speed thus having a constant suction volume flow, the mass flow determined from the measured data according to equations (1) to (4) of the zeotropic mixture is on average 47 % lower than the one of R134a. In terms of the comparability of this value with other testing facilities, one must bear in mind that the mass flow rate is highly dependent on the expansion device and its inlet state. The measured mass flow rate of the test bench is the result of the valve lift and the expansion device's inlet state resp. the subcooled temperature, the priority of the valve lift being the setting of the suction pressure. Consequently, the measured flow rate might differ for other test benches for other subcooled temperatures. The examination of the product of the mass flow rate and the previously compared specific refrigeration capacity of both refrigerants combined lead to an on average 17.7 % higher refrigeration capacity with the zeotropic blend.

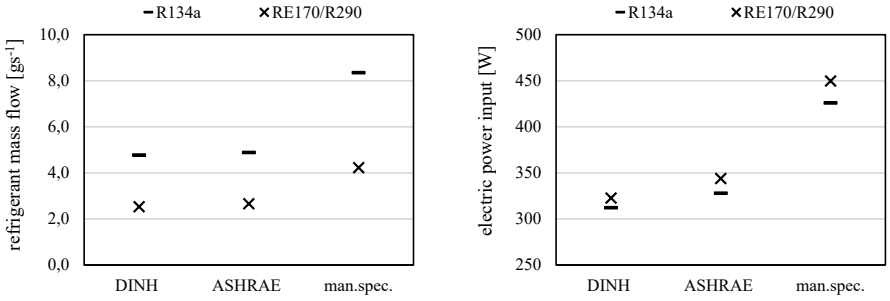

Fig. 6. Calculated refrigerant mass flow rate and electric power input at the specified rating conditions

Table 6. Relative standard mean error of averaged results in percentage [%]

Test condition	DIN-H		ASHRAE		manufacturer's specification	
Refrigerant	R134a	RE170/R290	R134a	RE170/R290	R134a	RE170/R290
power consumption	0.80	1.00	1.17	0.55	0.26	0.38
mass flow rate	1.42	0.46	0.98	0.09	1.24	0.59

In spite of the favorable pressure ratio and mass flow rate as stated before, the power consumption of the compressor (see Fig. 6, right diagram) in the case of the zeotropic mixture is on average elevated by 4.6 %. However, the trend for both refrigerants at the specified test conditions is the same. The refrigeration conditions "DIN-H" and "ASHRAE" have comparable pressure levels while the suction gas temperature is considerably higher for the latter condition. As a result, the power consumption increases while the mass flow rate remains rather constant. This observation testifies that a large superheating of the refrigerant is not beneficial to the compressor power consumption. The analysis of some compressor characteristics such as the discharge temperature, the oil sump temperature, and the isentropic efficiency in Fig. 7 helps to understand the mechanism behind this difference in the compressor input power for both refrigerants. The actual compressor input power is subject to thermal and mechanical losses. While thermal losses of the refrigerant gas affect the isentropic efficiency, friction causes the compressor material temperature to be elevated thus decreasing the heat loss of the compressed gas to the compressor shell. This chain of cause and effect helps to understand the observations made in Fig. 7. The left diagram reveals a higher isentropic efficiency at all operating conditions using RE170/ R290 compared to R134a. Meanwhile, the oil sump temperature of R134a is considerably below the one occurring during the tests with the refrigerant blend as the discharge temperature ranges among the same high values. The rather large thermal gradient over the shell of the compressor respectively the oil sump and the compressed gas supports the low isentropic efficiency. In return, the oil sump temperature of the tests with RE170/ R290 is close to the measured discharge temperature resulting in small to no thermal losses of the compressed gas. However, the elevated oil sump temperature indicates friction of the mechanical parts. Given the fact that the described behavior can be observed throughout all operating conditions it is the evidence that the lubricant is not favorable for the compressor although it was selected for the refrigerant blend due to the higher solubility.

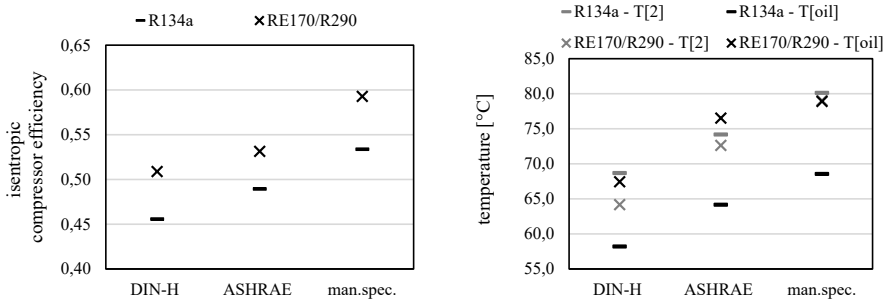

Fig. 7. Compressor characteristics – calculated isentropic efficiency based on measured values (left), refrigerant discharge temperature and oil sump temperature (right)

Finally, all evaluated data at the reference rating conditions come together when discussing the rated coefficient of performance COP_R depicted in Fig. 8. Despite the elevated power consumption of the compressor with the refrigerant blend, its coefficient of performance is greater than of the base line refrigerant at the three tested rating conditions. On the other hand, the results of the R134a tests reveal an upward trend throughout the rating conditions. Given the fact that the compressor is designed for the heat pump application, the observation of the highest COP using R134a-at the manufacturer's condition is not surprising. However, the COP of the substitute refrigerant is on average 12.6 % higher than the baseline.

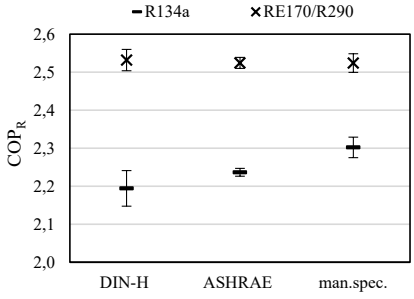

Fig. 8. Rated coefficient of performance at the specified rating conditions

4. Conclusion

In comparison to the high GWP refrigerant R134a, the tested natural refrigerant blend of RE170 and R290 shows favorable results e.g. the COP is significantly higher and the volumetric cooling capacity is in the same level of magnitude. Under this precondition, the experimental outcome supports the substitute refrigerant blend. The reduction of the charge and the increased performance at three different rating conditions are the core findings. The standard mean deviation proves the repeatability of the tests with respect to the stated boundary conditions like the ambient temperature. However, the increase of input power testing the alternative refrigerant raises interest for further optimization of the lubrication.

To conclude, the performed compressor tests reveal the potential of the natural refrigerant blend RE170/ R290 directly substituting R134a. It has merit to regard it for future cycle designs because the adaption of the compressor size, the heat exchangers or, the expansion device might affect the cycle efficiency positively. Further, the general acceptance of the natural yet flammable refrigerants must grow respecting the appropriate security measures since these refrigerants are inevitable for sustainable solutions.

Nomenclature

symbols		*Unit*	**subscripts**

Abstract

Conventional refrigerants, e.g. R-410A have high global warming potentials (GWP) > 1800. They are being phased out to protect the environment. The candidates to replace R-410A include R-32, R-452B, R-454B and R-466A for heat pump applications. These candidates are intended for drop-in replacement, i.e. having minimum modifications on existing systems. The paper investigates the low GWP refrigerants drop-in application via system simulations using a well-regarded, hardware-based heat pump model. A baseline heat pump having all fin-and-tube heat exchangers and a two-speed compressor was used. Cross-comparisons were made under rated conditions of ambient temperatures, compressor speeds, indoor air flow rates, respectively for cooling and heating operations. The seasonal performance indices, i.e. SEER and HSPF are presented.

1. Introduction

The earth continues to see a record increase in temperatures and extreme weather conditions that is largely driven by anthropogenic emissions of warming gases such as carbon dioxide and other more potent greenhouse gases such as refrigerants. The cooperation of 188 countries in the 21st Conference of the Parties in Paris 2015 (COP21) resulted in an agreement aimed to achieve universal agreement on climate, with the aim of keeping global warming below 2°C by the end of the century. A global phasedown of hydrofluorocarbons (HFCs) can prevent 0.5°C of warming by 2100.

To replace HCFC and HFC refrigerants in existing air conditioner/heat pump equipment, selections of alternative lower GWP refrigerants are subject to a few key factors. The candidates are expected to have similar volumetric capacity, so that available compressors would provide similar cooling capacity, and equal or higher energy efficiency. In addition, a selected refrigerant should accommodate the same or wider working envelope, i.e. an adequately high refrigerant critical temperature for high ambient operation. Similar or moderately higher compressor discharge temperature levels are also important, to prevent the need to change compressor lubricant and maintain good reliability.

Potential low GWP refrigerants for R-410A used in the study are introduced in Tables 1. The R-410A replacements are mostly blends containing R-32 and an HFO (Hydrofluoroolefins) of R-1234yf, as well as a pure refrigerant of R-32. They have approximately 70% lower GWPs than R-410A. On the other hand, the compositions of R-32 and R-1234yf cause minor flammability and are classified as A2L. It should be noted that R-466A is an A1 refrigerant, i.e. non-flammable. These refrigerant blends have negligible temperature glides. All the alternatives have higher critical temperatures than R-410A, making them more suitable for high condensing temperature operation.

Table 1. Alternative Low GWP Replacements for R-410A

Refrigerant	GWP AR4[a]	GWP AR5[b]	Safety Class	Temperature glide [K]	Critical T [C]
R-410A[c]	2088	1924	A1	0.1	71.34
R-32	675	677	A2L	0.0	78.12
R-452B[d]	698	676	A2L	1.3	79.68
R-454B[e]	466	467	A2L	1.5	77.0
R-466A[f]	733	733	A1	1.5	83.8

a. IPCC 2007.
b. IPCC 2013.
c. R-410A has mass-based compositions of R-32 (0.5)/R-125 (0.5).
d. R-452B has mass-based compositions of R-32 (0.67)/R-125 (0.07)/R-1234yf (0.26).
e. R-454B has mass-based compositions of R-32 (0.689)/R-1234yf (0.311).
f. R-466A has mass-based compositions of R-32 (0.49) / R-125 (0.115) / R-13I (0.395).

2. Refrigerant Properties

The temperature-enthalpy diagram of a refrigerant illustrates two critical properties: the span between the saturated liquid line and saturated vapor line (i.e. latent heat of vaporization per unit mass of refrigerant) and the critical temperature (working range). Volumetric vaporization heat, i.e. latent heat × vapor density at an average saturation temperature of dew point and bubble point, indicates the evaporating capacity per unit volumetric flow rate. Refrigerants with smaller volumetric vaporization heat have reduced cooling capacities at a fixed compressor displacement volume.

Figure 1 illustrates the temperature-enthalpy diagram of R-410A and its alternative refrigerants. All the R-410A alternatives (except R-466A) have wider domes and higher critical temperatures, indicating that they are better refrigerants for high ambient operations. Figure 2 shows the volumetric vaporization heat versus the average saturation temperature. R-32 has noticeably larger vaporization heat than R-410A, and R-466A is slightly larger. R-452B and R-454B have similar vaporization heat, which are slightly lower than R-410A. When approaching to the critical temperature, all the refrigerants' vaporization heat drops.

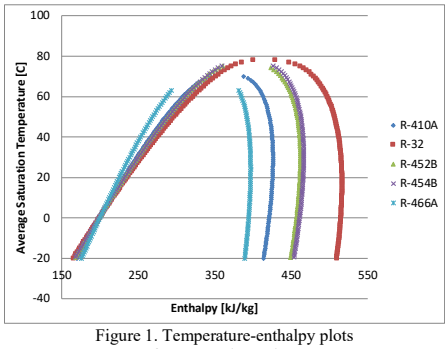

Figure 1. Temperature-enthalpy plots of R-410A alternatives.

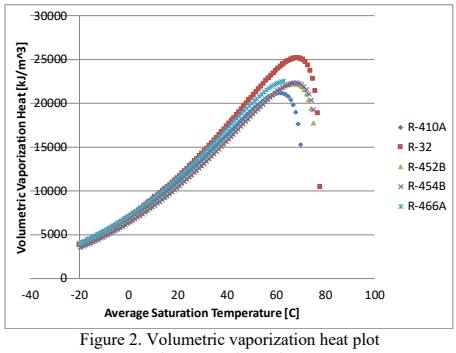

Figure 2. Volumetric vaporization heat plot of R-410A alternatives.

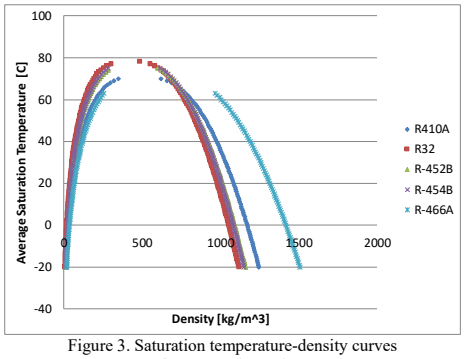

Figure 3. Saturation temperature-density curves of R-410A alternatives.

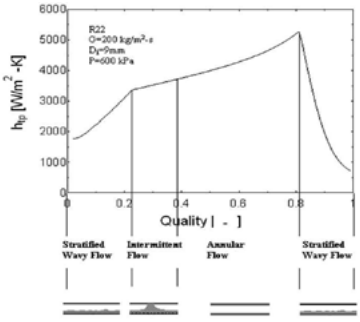

Figure 4: Local flow boiling coefficient predicted with the Thome (2002) [1] flow-pattern-dependent evaporation model.

Figure 3 shows curves of saturation temperature versus density of the R-410A alternatives. Most of the R-410A alternatives, except R-466A, have lower suction vapor density and lesser refrigerant mass flow rate if using a fixed compressor displacement volume.

At an average saturation temperature, a refrigerant with a lower volumetric vaporization heat results in smaller cooling capacity during a drop-in replacement. The saturation temperature is also impacted by the heat transfer performance and refrigerant pressure drop of the refrigerant. Lower saturation temperature leads to smaller cooling capacity if using the same compressor. And thus, whether an alternative low GWP refrigerant leads to higher or lower capacity depends on the trade-off between its volumetric vaporization heat and the resultant suction saturation temperature impacted by its heat transfer characteristics.

3. Model Description

A public-domain HVAC equipment modeling and design tool (HPDM, Shen 2016 [2]) was used to model a baseline heat pump. Some features of the HPDM, related to this study, are introduced below:

Compressor model:

AHRI 10-coefficient compressor maps (ANSI/AHRI 540-99, 2010 [3]) are used to calculate mass flow rate and power consumption, and enable calculation of the refrigerant-side vs. air-side energy balance from inlet to outlet by inputting a compressor shell loss ratio relative to the power input. It also considers the actual suction state to correct the map mass flow prediction.

We obtained the original compressor maps, developed for R-410A. For modeling the alternative refrigerants, it is assumed that the compressor would maintain the same volumetric and isentropic efficiencies at the same suction and discharge pressures. Thus, the efficiencies were reduced from the original R-410A map as a function of the suction and discharge pressures. The volumetric efficiency is defined in Equation 1, and isentropic efficiency is shown in Equation 2.

$$m_r = Volume_{displacement} \times Speed_{rotation} \times Density_{suction} \times \eta_{vol} \quad (1)$$

$$Power = m_r \times (H_{discharge,s} - H_{suction}) / \eta_{isentropic} \quad (2)$$

Where $\boldsymbol{m_r}$ is compressor mass flow rate; $\boldsymbol{Power}$ is compressor power; $\boldsymbol{\eta_{vol}}$ is compressor volumetric efficiency; $\boldsymbol{\eta_{isentropic}}$ is compressor isentropic efficiency; $\boldsymbol{H_{suction}}$ is compressor suction enthalpy; $\boldsymbol{H_{discharge,s}}$ is the enthalpy obtained at the compressor discharge pressure and suction entropy. The approach converting the compressor map of a baseline refrigerant to be used by its drop-in replacements has been extensively validated in Shen et al. (2018) [4].

Heat Exchanger Models:

Segment-to-segment fin-&-tube condenser: It uses a segment-to-segment modelling approach, which divides a single tube to numerous mini segments; each tube segment has individual air side and refrigerant side entering states and considers possible phase transition. An ε-NTU approach is used for heat transfer calculations within each segment. Air-side fin is simplified as an equivalent annular fin. Both refrigerant and air-side heat transfer and pressure drop are considered. The coil model can simulate arbitrary tube and fin geometries and circuitries, any refrigerant side entering and exit states, maldistribution, and accept two-dimensional air side temperature, humidity and velocity local inputs; the tube circuitry and 2-D boundary conditions are provided by an input file.

Segment-to-segment fin-&-tube evaporator: In addition to the functionalities of the segment-to-segment fin-tube condenser, the evaporator model is capable of simulating the dehumidification process. The method of Braun et al. (1989) [5] is used to simulate cases of water condensing on an evaporating coil, where the

driving potential for heat and mass transfer is the difference between enthalpies of the inlet air and saturated air at the refrigerant temperature. As noted, the segment-to-segment modelling approach can reveal the glide of a zeotropic refrigerant, since the temperature increment is accounted by each individual segment along the refrigerant flow path.

Through an extensive literature survey, we identified heat transfer and pressure drop correlations suitable for modeling and optimizing air conditioners and heat pumps, to assess various low GWP refrigerants. The correlations are listed in Table 2.

Table 2. Selected correlations for two-phase heat transfer and pressure drop

Application	Correlation
Fin-&-tube heat exchanger (FTC) -Evaporation heat transfer	Thome (2002) [1]
FTC-Condensation heat transfer	Cavallini et al. (2006) [6]
FTC-Evaporation pressure drop	Kedzierski and Choi (1999) [7]
FTC-Condensation pressure drop	Kedzierski and Choi (1999) [7]

The two-phase heat transfer correlations developed by Thome (2002) [1] and Cavallini (2006) [6] account for local flow patterns, considering refrigerant properties. The idea of the flow-pattern dependent evaporation model is to first estimate the wetted surface inside a horizontal smooth tube using a flow map prediction. The model covers stratified flow, stratified-wavy, annular-wavy, intermittent, annular flow, annular flow with partial dryout, and mist flow in evaporation. The general expression for local evaporating heat transfer coefficient is of the form,

$$h_{tp} = \frac{\theta_{dry} h_v + (2\pi - \theta_{dry}) h_{wet}}{2\pi} \tag{3}$$

$$h_{wet} = (h_{nb}^3 + h_{cb}^3)^{1/3} \tag{4}$$

In Equation 3, θ_{dry} is the dry angle corresponding to the dry circumference of the tube, which is determined from the flow pattern and void fraction. The void fraction model for this correlation is Rouhani (1970). h_{wet} is the heat transfer coefficient at the wet circumference of the tube, which is composed of a nucleate boiling term h_{nb} and a convective boiling term h_{cb}. h_v is the heat transfer coefficient at the dry circumference of the tube.

The local evaporation heat transfer coefficient calculated with the Thome (2002) [1] correlation is shown in Figure 4. The Thome (2002) correlation reasonably predicts degradation of heat transfer coefficient at high quality due to dry out of the liquid film, while most of the other correlations are not able to do this. This model can also reveal the effect of heat flux.

The condensation correlation of Cavallini (2006) [6] is given in Equation 5,

$$h_{tp} = \frac{\theta_{film} h_f + (2\pi - \theta_{film}) h_c}{2\pi} \tag{5}$$

θ_{film} is the falling film angle around the perimeter of the tube, which is dependent on the local flow pattern and void fraction. h_f is the Nusselt film condensing coefficient, and h_c is the convective condensation heat transfer coefficient. The Cavallini (2006) [6] condensation model also starts with the flow pattern prediction.

It is reported that azeotropic refrigerant mixtures have the same heat transfer performance as pure refrigerants. Thus, pure refrigerant correlations are able to work for an azeotropic refrigerant mixture such as R-410A. However, zeotropic refrigerant mixtures with large temperature glides, have different behaviors.

Heat transfer correlations developed for pure refrigerants must be corrected if they are to be used for zeotropic refrigerants. Stephan et al. (1992) proposed a correction method for condensation as well as evaporation. In this method, the mixture heat transfer coefficient h_m is defined as,

$$h_m = [1/h_f + (\delta Q_{SV} / \delta Q_T)/h_g]^{-1} \tag{6}$$

where h_f is the heat transfer coefficient computed from a pure refrigerant heat transfer model and h_g is the heat transfer coefficient of the vapor phase, which can be calculated with the Dittus-Boelter equation. $\delta Q_{SV} / \delta Q_T$ is the ratio between the sensible heat transfer and the total heat transfer. Bell and Ghaly (1973)

suggested that if the total isobaric temperature glide is around 7-8 °C, then the ratio could be approximated as,

$$(\delta Q_{SV} / \delta Q_T) \approx x Cp_g (\Delta T / \Delta h_m) \quad (7)$$

Where ΔT is the temperature glide, Δh_m is the enthalpy of latent heat of the mixture, x is the quality, and Cp_g is the vapor specific heat.

We adopted air side heat transfer correlations specific to individual fin types, respectively for dry and wet surface. Dittus-Boelter correlations was adopted to modelled single-phase refrigerant tube side heat transfer.

Expansion Devices:

The compressor suction superheat degree and condenser subcooling degree or system charge are explicitly specified. As such, the expansion device is not solved here – a simple assumption of constant enthalpy process is assumed.

Fans and Blowers:

The air flow rate and power consumption were direct inputs from the laboratory measurements for the model calibrations.

Refrigerant Lines:

Temperature changes and pressure drops of suction, discharge and liquid lines were specified using the measured data from the experiments.

Refrigerant Properties:

We programmed interface functions to call REFPROP 10.0 (Lemmon, 2018) [7] directly; our models accept all the refrigerant types in the REFPROP 10.0 database, and also we can simulate a new refrigerant by making the refrigerant definition file according to the REFPROP 10.0 format, or look-up tables.

4. Baseline Heat Pump and Rating Conditions

The DOE/ORNL heat pump design model (HPDM) was used for analytical evaluations for a baseline heat pump having a two-speed compressor. The two-state heat pump has the total cooling capacity of 5-ton/17.6 kW at 35°C ambient temperature/26.7°C indoor dry bulb temperature (DB) and 19.4°C indoor wet bulb temperature (WB). The high and low speeds of the scroll compressor provide 100%/67% capacity. The indoor and outdoor heat exchangers are described in Table 3. For the system modeling, the condenser exit subcooling degree was set at 10 R (5.6 K) for cooling mode and 20 R (11.2 K) for heating mode; the evaporator exit was assumed to have a constant superheat degree of 10 R (5.6 K).

Table 3: Parameters of Indoor and Outdoor Units

Parameters (heating mode)	Indoor Fin-&-Tube Coil	Outdoor Fin-&-Tube Coil
Face area, ft2 (m2)	3.30 (0.307)	22.3 (2.07)
Total Tube Number	84	64
Number of rows	3 (cross counter-flow)	2 (cross counter-flow)
Number of parallel circuits	9	6
Fin density, fins/ft (fins/m)	168 (551)	264 (866)
	Indoor Blower (High/Low[1])	Outdoor Fan
Flow Rate, cfm (m3/s)	1670/1380 (0.790/0.653)	3500 (1.652)
Power [W]	322/203	300

1. The indoor blower has two speed levels, corresponding to the compressor low/high speeds respectively.

Following the AHRI 210/240 standard [9] to rate a two-speed heat pump. In cooling mode, the heat pump should provide performance indices at 35°C, 27.8°C ambient temperature and indoor condition of 26.7°C DB/19.4°C WB. In heating mode, the heat pump should be rated at the indoor dry bulb temperature of 21.1°C. At the low speed, the ambient temperature should vary at 16.7°C DB/13.6°C WB, 8.3°C DB/ 6.1°C WB, 1.7°C DB / 0.6°C WB and -8.3°C DB / -9.4°C WB. The high speed should be rated at 8.3°C DB/ 6.1°C WB, 1.7°C DB / 0.6°C WB and -8.3°C DB / -9.4°C WB.

Since HPDM is a steady-state system model, it doesn't predict cyclic performance and frost/defrost penalty. We adopted a typical degradation coefficient of 0.1 for the high speed, and 0.15 for the low speed. AHRI 210/240 quantifies frosting/defrost loss at the outdoor condition of 1.7°C DB / 0.6°C WB. If no frost effect is

correlated by an analytical model, the standard recommends a 98% factor to scale the power consumption and a 91% factor to scale the heating capacity. AHRI 210/240 assumes no frost formation at the ambient temperature above 8.3°C DB/ 6.1°C WB and below -8.3°C DB / -9.4°C WB. At other ambient conditions, the performances are interpolated between 8.3°C DB/ 6.1°C WB, 1.7°C DB / 0.6°C WB; and interpolated between 1.7°C DB / 0.6°C WB and -8.3°C DB / -9.4°C WB. For the ambient conditions below -8.3°C DB / -9.4°C WB, the results are extrapolated based on the predicted results at 8.3°C DB/ 6.1°C WB and -8.3°C DB / -9.4°C WB.

5. Cooling Performance

Table 4 below presents predicted cooling performances of the heat pump using R-410A at the low (_L) and high speed (_H) levels, including cooling capacities [kW], cooling COPs [W/W], compressor discharge temperature [F] and compressor isentropic efficiency reduced from the compressor map in the form of Equation 2. The two-speed scroll compressor uses the full displacement volume at 100% capacity. At 67% capacity, only part of the scroll is utilized, which causes more loss factors. As a result, the compressor efficiency of the low speed is roughly 7% lower than the high speed.

Table 4: Predicted Cooling Performance Indices Using R-410A

Outdoor Condition	Capacity [kW]	COP [W/W]	Compressor Disc T [F]	Isentropic efficiency
35C_H	17.6	3.7	164.1	74%
27.7C_H	18.7	4.5	147.4	73%
35C_L	13.0	3.9	158.7	67%
27.7C_L	13.9	4.8	140.5	67%

Figure 5 show cooling capacity increments of the alterative refrigerant in comparison to R-410A, dropping into the same equipment. Corresponding to the vaporization plots in Figure 2, R-32 and R-466A result in 4% to 6% higher cooling capacities at all the conditions. On the other hand, R-452B and R-454B lead to approximately 2% smaller capacities. Figure 6 show increments in cooling COPs. With the same heat exchangers, larger capacity tends to cause higher condensing temperature and lower evaporating temperature, degrading the efficiency. Consequently, R-32 and R-466A have large capacities at the expense of reduced COPs. R-452B and R-454B result in higher COPs. Figure 7 presents compressor discharge temperatures. R-32 have significantly higher discharge temperatures, up to 30R. The other alternative refrigerants lead to minorly high temperatures, up to10R. At the low speed, the discharge temperatures are lower than those at the high speed, because the condensing temperature is reduced at the part-load operation. Figure 8 compares the seasonal cooling COPs, calculated from AHRI 210/240. They differ minorly, ranging from 4.45 to 4.58. R-454B results in the highest COP and R-466A results in the lowest COP.

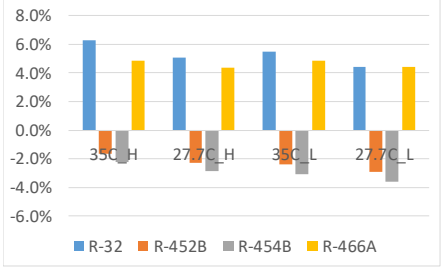

Figure 5. Capacity increments in cooling mode

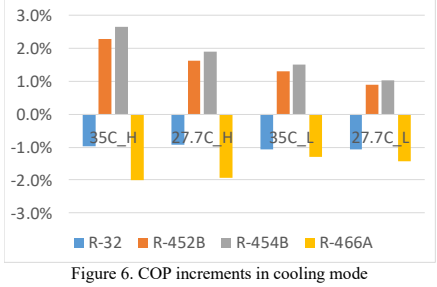

Figure 6. COP increments in cooling mode

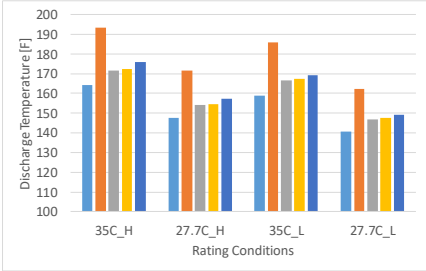

Figure 7. Compressor discharge temperatures in cooling mode

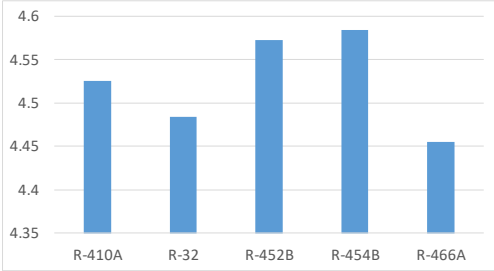

Figure 8. Seasonal cooling COPs

6. Heating Performance

Table 5: Predicted Heating Performance Using R-410A

Outdoor Condition	Capacity [kW]	COP [W/W]	Compressor Disc T [F]	Isentropic efficiency
8.3C_H	17.6	3.9	167.1	72%
1.7C_H	15.0	3.6	166.7	70%
"-8.3C"_H	11.4	3.0	172.8	64%
16.7C_L	15.8	4.5	165.7	66%
8.3C_L	12.8	3.9	165.7	63%
1.7C_L	10.8	3.4	170.1	59%
"-8.3C"_L	7.9	2.6	190.8	50%

Table 5 predicts heating performances using R-410A at the low (_L) and high speed (_H), including heating capacities [kW], heat pump heating COPs [W/W], compressor discharge temperatures [F] and the compressor isentropic efficiencies. Comparing the high speed with the low speed at low ambient temperatures, the efficiency degradation is more pronounced because the loss factors ascend with the compressor pressure ratio. At -8.3°C, the isentropic efficiency decreases from 64% to 50% when the pressure ratio increases from 3.4 to 4.2.

A typical heat pump sized to meet the building cooling load can't satisfy heating load at low ambient temperatures. Figure 9 compares the heat pump capacities as a function of the ambient temperature, versus the building load line of DHR_{min} defined in AHRI 210/240 in the ASHRAE climate zone IV. DHR_{min} indicates a well-insulated building. Even in the adequately insulated home, the heat pump total capacity still can't provide enough heating capacity. The high speed will be called at the ambient temperature below 25°F. Below 15°F, the high-speed operation can't meet the building heating load, and then, supplemental resistance heat will be used.

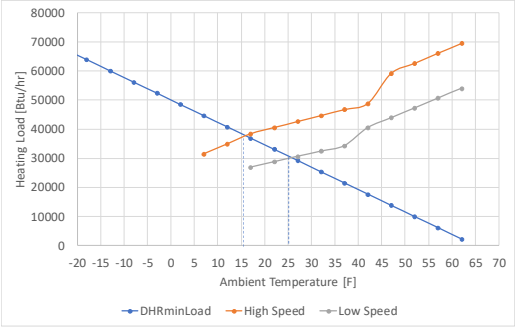

Figure 9: Heat Pump Capacities versus building load line

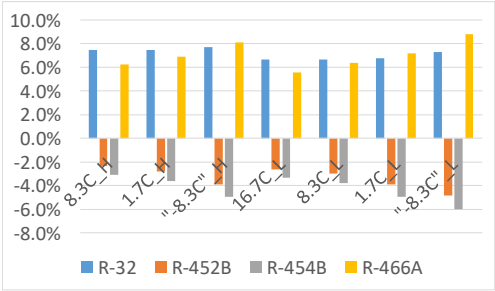

Figure 10. Capacity increments in heating mode

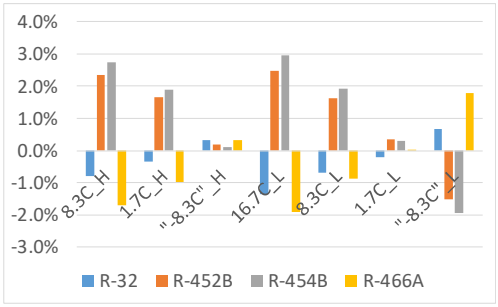

Figure 11. COP increments in heating mode

Figure 10 shows capacity increments of the alterative refrigerants versus R-410A in heating mode. R-32 and R-466A result in 6% to 8% higher heating capacities, which increase with decreasing the ambient temperature. On the other hand, R-452B and R-454B lead to approximately 2% to 6% smaller capacities, which decrease with the ambient temperature. Figure 11 shows increments in the heat pump heating COPs. R-32 and R-466A lead to 2% lower COPs due to the increased heating capacities. R-452B and R-454B lead to 2% higher COPs. Figure 12 presents compressor discharge temperatures. Because of the noticeably lower isentropic efficiency of the low speed at low ambient temperatures, more compressor power is converted to heat the refrigerant vapor than providing more useful pressure energy. Thus, the compressor discharge temperatures at low speed are higher than those at high speed. This is opposite to the trend, shown in Figure 7 regarding the cooling mode.

The discharge temperature increases with the pressure ratio, which tends to be higher in heating mode. Limit of discharge temperature is the major reason preventing heat pump operating below a certain ambient temperature. The higher discharge temperatures of the R-410A replacements would narrow the working envelope. The significantly higher discharge temperatures of R-32 (>210°F at -8.3°C) would require compressor lubricant change for the heat pump application. Figure 13 compares the seasonal heating COP, i.e. HSPF calculated by AHRI 210/240. Larger heating capacity causes degradation in heat pump COP, however, it decreases the supplemental resistance heat use at low ambient temperatures. As a result, the seasonal heating COPs are almost identical, regardless of the variations in heating capacity.

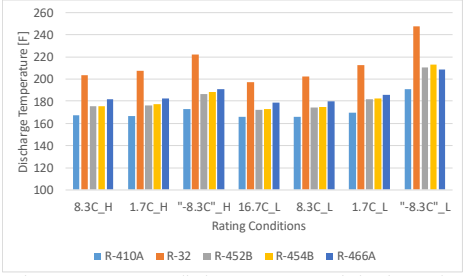

Figure 12. Compressor discharge temperatures in heating mode

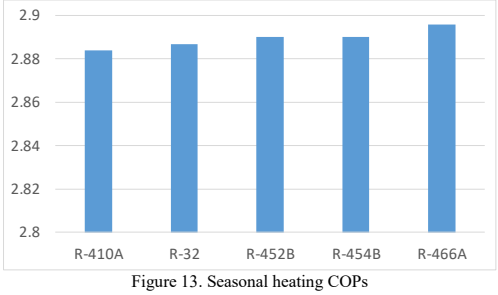

Figure 13. Seasonal heating COPs

7. Summary

This study starts with a hardware-based heat pump system simulation and design model, which adopted fundamental flow-pattern-dependent heat transfer correlations to represent variations in refrigerant properties. A method, to convert a baseline refrigerant compressor map used by alternative refrigerants in the similar pressure range, was developed and validated. Using the advanced analytical tool, we assessed lower GWP refrigerants to replace R-410A, in a drop-in application with respect to a two-speed heat pump. The alternatives include R-32, R-452B, R-454B and R-466A. The performance indices were predicted at the rating conditions of the AHRI 210/240 standard. Additionally, the seasonal cooling efficiency (SEER) and heating efficiency (HSPF) were compared.

In summary,

1) In cooling mode, R-32 and R-466A led to higher capacities, but slightly lower COPs than R-410A. R-452B and R-454B had very similar performance, having slightly lower capacities but higher COPs. R-454B resulted in the highest seasonal COP, and R-466A resulted in the lowest seasonal COP. In general, they differ minorly, ranging from 4.45 to 4.58.
2) In heating mode, R-32 and R-466A led to higher capacities, which degraded the heat pump heating COPs. R-452B and R-454B had slightly lower capacities but higher COPs. Larger heating capacity causes degradation in heat pump COP, but reducing the supplemental resistance heat use at low ambient temperatures. As a result, the seasonal heating COPs are almost identical among these refrigerants.
3) R-32 causes significantly higher discharge temperatures; R-466A, R-452B and R-454B results in moderately higher discharge temperatures. The higher discharge temperatures may narrow the operation envelope, particularly in heating mode. It is necessary to change the compressor lubricant for R-32, to tolerate the high discharge temperature during heating mode or cooling mode at elevated ambient temperature.

Abstract

This study aimed to analyze the mechanism and the basic performances of a heat pump desalination system. As a kind of evaporation method, a heat pump system using cascade cycles of R410A and R134a generates 80℃ of heat to the heat pump condenser and transfers it the plate type heat exchanger. Heat generated by the heat pump is transferred through the plate type heat exchanger and the fin tube type exchanger. Through the 3-way valve installed in the seawater supply system to reduce the heating time, water below set temperature 60℃ is recycled and water above the set temperature is discharged to the storage tank. The hot water discharged into the storage tank is evaporated and passed through the cyclone and the bag filter to the fin tube type heat exchanger by using the vacuum pump, which condenses into fresh water by heat exchange with the low temperature air of the heat pump evaporator. The amount of hot water that can be produced is about 20ℓ/min and the power consumption used for the entire system is estimated to be 9.3 kWh/㎥.

1. Introduction

Currently, more than 40% of the world's population suffers from water shortages. In addition, due to global warming and deepening climate change, uncertainties in water resource use and management are increasing. Korea, which is relatively rich in water resources, is also concerned about the lack of water in mountainous and coastal areas due to climate change [1]. Along with these problems, various measurements are needed for the independence of the building facilities in the island area. While the development of alternative water resources is needed, seawater desalination technology is receiving the most attention, and the reverse osmosis method, which consumes less energy than the conventional evaporation method, is increasing. According to Kim et al. [2], the reverse osmosis system occupies about 90% in the overseas seawater desalination plant market, and 87.5% of seawater desalination facilities in Korea use reverse osmosis. Kesieme at al. analyzed desalination technologies in the context of carbon pricing and found that the cost of desalination schemes increased by introduction of a price for carbon, but RO still remain the lowest cost [3]. However, reverse osmosis also has a limitation in that a pretreatment facility is essential, energy recovery cannot be more than 50%, and maintenance costs are high due to membrane replacement [4]. In addition to maintenance costs and energy aspects, existing seawater desalination systems are difficult to apply to island areas due to their large size. This study aimed to analyze the mechanism for the optimal design of seawater desalination system using heat pump that is a compact facility and can be applied as an independent water supply system for island buildings.

2. Experiment apparatus and method

To study the performance of heat pump desalination system, the experimental apparatus is setup, which consists of a heat pump system, cyclone, bag filter and seawater supply system. The heat pump system is a commercial product of LG Electronics and refrigerant cycle uses R410a and R134a cascade cycles. The seawater supply system consists of a seawater tank, a circulation pump, 3-way valve and check valve, as shown in Fig.1. Heat generated by the heat pump is transferred through the plate type heat exchanger and the fin tube type exchanger. A vacuum pump was installed to adjust the evaporation pressure, and a demister was installed to capture the uncondensed vapors being discharged through the vacuum pump. The blowout air temperature of the heat pump evaporator and the water temperature in seawater tank were measured using a thermocouple wire (T type). The inlet and outlet water temperatures between the heat pump condenser and the plate type heat exchanger and water temperature at 3-way valve were measured by automatic temperature sensor.

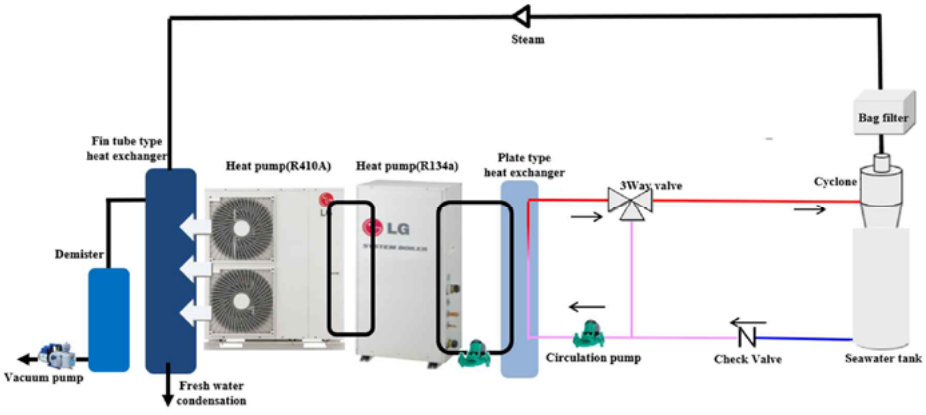

Fig. 1. Schematic diagram of heat pump desalination system

Fig. 2. Photo of the experimental apparatus

3. Results

3.1. Experiment apparatus analysis

Schematic diagram of the heat pump desalination system is shown in Fig.1. A heat pump system using cascade cycles of R410A and R134a generates 80℃ of heat to the heat pump condenser and transfers it the plate type heat exchanger. The seawater circulated in the seawater supply system receives heat from the plate type heat exchanger and is heated to the storage tank. Through the 3-way valve installed in the seawater supply system to reduce the heating time, water below set temperature 60℃ is recycled and water above the set temperature is discharged to the storage tank. The hot water discharged into the storage tank is evaporated and passed through the cyclone and the bag filter to the fin tube type heat exchanger by using the vacuum pump, which condenses into fresh water by heat exchange with the low temperature air of the heat pump evaporator.

3.2. Fluid state inside system

The inlet and outlet water temperature variations between the heat pump condenser and the plate type heat exchanger and water temperature variations at 3-way valve are shown in Fig.2. After the heat pump starts up, the temperature is continuously increased, and 70℃ hot water is passed through the 3-way valve to produce a storage tank.

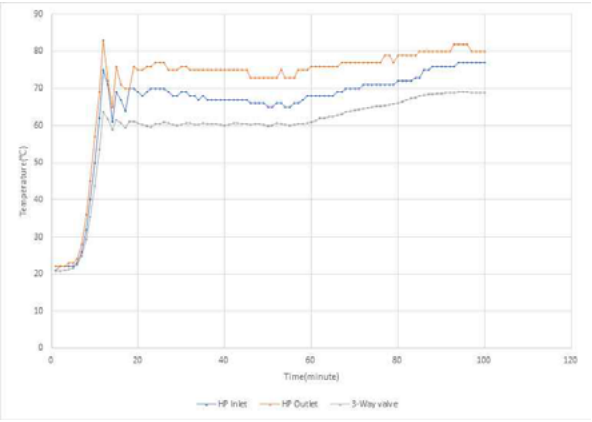

Fig. 2. Temperature variations in each point

3.3. Productivity and Energy consumption

After 90 minutes of a heat pump operation, the amount of hot water produced is about 20ℓ/min and the power consumption used for the entire system is estimated to be 9.3 kWh/㎥. The conditions of the produced hot water are shown in Table 1.

Table 1. Condition of produced hot water

Temperature	Water flow rate	vacuum pressure	Energy consumption
70℃	20ℓ/min(1.2 ㎥/h)	0.3077 atm	9.3 kWh/㎥

.

4. Conclusions

This study aimed to develop a high-efficiency seawater desalination system using heat pump. The heat pump condenser heats seawater and generated steam condenses through heat exchange with the heat pump evaperator. Heat pump cycles were constructed using refrigerants R410A and R134a. The vapor is condensed by removing impurities as it passes through the cyclone and bag filter. The mechanism analysis results are as follows.

1. A heat pump system using cascade cycles of R410A and R134a generates 80℃ of heat to the heat pump condenser and transfers it the plate type heat exchanger. The hot water discharged into the storage tank is evaporated and passed through the cyclone and the bag filter to the fin tube type heat exchanger by using the vacuum pump, which condenses into fresh water by heat exchange with the low temperature air of the heat pump evaporator.
2. By installing 3-way valve, hot water can be produced quickly and it can produce hot water of 70 ℃ continuously.
3. After 90 minutes of a heat pump operation, the amount of hot water produced is about 20ℓ/min and the power consumption used for the entire system is estimated to be 9.3 kWh/㎥.

Experimental results show that energy consumtion of heat pump desalination system for fresh water production is 9.3kW/㎥, which requires more energy than reverse osmosis and large-scale evaporaton plants. But it will increase the efficiency by expanding the scale of heat exchanger and heat storage tank. The price of production water during the short term is expected to be least considering the construction cost, pertreatment cost and facility maintenance cost.

Abstract

A deep reinforcement machine learning algorithm was applied to household inverter air-conditioner precision temperature control. Generally, air-conditioner temperature control aspects rely on the specific technology of the product, cooling room area size, outdoor temperature variation, and indoor building load variation when the set temperature is fixed. In this study, we fixed the test product and room size, and used the given variations of outdoor temperature and indoor building load over the course of one day. Even though the test product showed satisfactory performance at the remote controller set temperature of 26°C without a machine learning algorithm, we experimented with deep reinforcement learning performances to check whether the test product could follow general product performances or surpass the product ability in the precision temperature control by applying only high and low set temperatures alternatively. Training started with no disturbances of constant building cooling load and outdoor temperature. It resulted in reasonably accurate temperature control with the real training environments of Korean and Middle Eastern climates.

1. Introduction

Smart home appliances are a rapidly expanding industry. Korea is one of the leading countries in the smart home market, especially in the home appliance division. Premium air-conditioner and refrigerator products in Korea are now expected to embed smart-phone applications that can monitor energy consumption and be controlled from outside the house. However, there is further scope to improve them by adopting AI technology. Korean manufactured high-quality air-conditioners currently make it possible to perform target cooling by learning the occupant's positioning area and operating commands from the occupant's voice. But until now, these products seem to only borrow existing AI technology of vision and voice recognition from other fields.

Many HVAC (Heating, Ventilation, and Air-Conditioning) studies predict building cooling loads using a time series method and neural networks [1–4], fuzzy logic [5–7], and applying machine learning techniques in central air- conditioning systems [8–13]. However, it is not easy to find machine learning research in the field of household air-conditioners. For the energy usage comparison between inverter and constant speed air-conditioner technology, Yoon et al. [14,15] tested an air-conditioner under the actually varying temperature condition in an accurately controlled test chamber over a prolonged period. Referring to international standards such as ISO or EN, they suggested a one-point environmental test energy efficiency ratio (EER) or a more complicated multi-point interpolated energy efficiency ratio (seasonal EER) for the test of air-conditioner energy performance. These methodologies, however, cannot capture the dynamically improved performances of an AI driven air-conditioner because test chamber environments are statically fixed at each test point. Therefore, Yoon et al. [14,15] suggested a more realistic experiment. They simulated varying outdoor

E-mail address: msyun95@ktl.re.kr

temperature and indoor building load conditions over the course of a day. This approach was analogous with a realistic car fuel economy test under real road load circumstances rather than a fixed high-speed condition.

In our study, a deep reinforcement learning algorithm was applied to a household inverter air-conditioner under an experimentally simulated varying environment (outdoor temperature, indoor building load). The purpose of this study was to check whether the machine learning algorithm could be applied to the household inverter air-conditioner temperature control and surpass the normal usage of the product.

2. Related work and background

Reinforcement learning (RL) is one of the most exciting and also one of the oldest areas of the machine learning discipline [16]. The problem of reinforcement learning is expressed in the Markov decision process (MDP), which is popular in the theory of dynamic programming [17]. Dynamic programming using value iteration or policy iteration evolved into the SARSA (State, Action, Reward, State, Action) on-policy problem, and later, the Q-learning (SARSA off-policy) [18].

A deep neural network (DNN) is an artificial neural network (ANN) consisting of several hidden layers between the input and output layers. One ANN study goes back to the Fukushima's convolution neural network (CNN) paper [19], and DNN is now used in various fields related to vision recognition [20,21]. In addition, language recognition studies use the modified DNN methods, which are RNN (Recursive Neural Network) or LSTM (Long Short-Term Memory) in machine learning [22–24].

In this study, we used the well-known DQN (Deep Q-learning Network) method that uses DNN for the Q-learning [18,25,26].

$$Q(S_t, A_t) \leftarrow Q(S_t, A_t) + \alpha[R_t + \gamma \cdot max_{a'} Q(S_{t+1}, a') - Q(S_t, A_t)] \quad (1)$$

where, (S_t, A_t) is the current state and action, (S_{t+1}, a') is the next state and action, $Q(S_t, A_t)$ is the quality of the agent in (S_t, A_t), R_t is the reward obtained by taking an action A_t from state S_t, and α and γ are the learning rate and the discount factor, respectively. In the iteration i, Q-learning updates by the following loss function

$$L_i(\theta_i) = \left(R_t + \gamma \cdot max_{a'} Q(S_{t+1}, a', \theta_{i-1}) - Q(S_t, A_t, \theta_i)\right)^2 \quad (2)$$

where, θ_i is the parameter of the Q-network at iteration i and θ_{i-1} is the network parameter from the previous iteration.

3. Methodology

3.1. Artificial neural network model

In this study, we used one input layer of 3 nodes, two hidden layers of 24 nodes each, and one output layer of 2 nodes. The input layer consists of three elements of state [$(T_{in}(t) - 26)$, dT_{in}/dt, $T_{dis}(t)$]. Each element represents indoor temperature (T_{in}), indoor temperature derivative (dT_{in}/dt), and air-conditioner discharge temperature ($T_{dis}(t)$) according to ISO 5151 [27] and ASHRAE 116 [28].

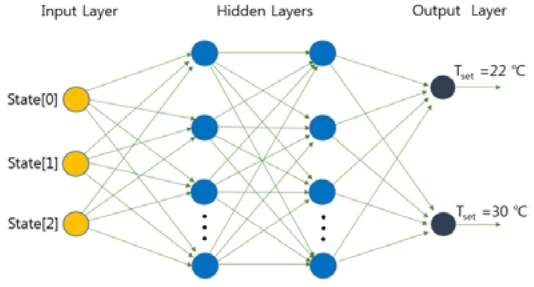

Fig. 1. DNN model for the inverter air-conditioner temperature control

The output layer gives action outputs to the remote controlled air-conditioner with the selected set temperature of each low and high product temperature [22, 30] °C. Even though the real test product has a wider controllable temperature range (16–31°C), we define action states here as two cases of set temperature to simplify the problem definition and reduce the calculation time when the target temperature is 26°C. These input, hidden, and output layers' artificial neural networks are generated by TensorFlow [29].

3.2. Simulation of the test chamber environment

Air-conditioner power consumption depends on indoor-side and outdoor-side environment conditions simultaneously. An indoor unit has an evaporator heat exchanger, and an outdoor unit usually has a condenser heat exchanger and a compressor component. If the outdoor-side temperature rises and the indoor cooling load is high, then the air-conditioner instantaneous power input usually increases. Therefore, international test standards such as ASHRAE and ISO request the exact fixing of the indoor and outdoor environment (temperature or humidity) for the rating test [28,29]. For example, the standard test condition (T1) of summer periods is (DBT/WBT) = 35°C/24°C and 27°C/19°C at each outdoor- and indoor-side chamber, respectively.

For the AI training of the product, we need time-varying real environment conditions rather than fixed-temperature conditions. Here, we assumed a summer situation of a typical region in Korea and the Middle East for the TRNSYS simulation [14,15]. The TRNSYS simulation program was used to obtain indoor building load $q_{build}(t)$ and outdoor temperature variation $T_{out}(t)$. The average temperature and building load variations during a summer's day can be obtained using TRNSYS climate data and analysis. The TRNSYS simulation condition is shown in Table 1.

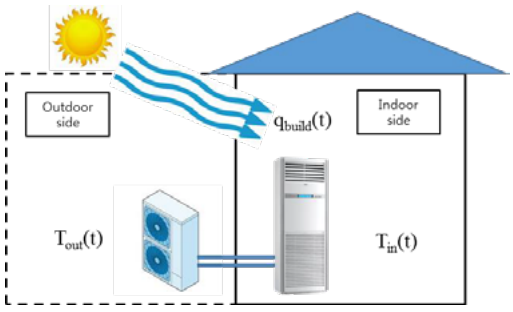

Fig. 2. Environment simulation concept (reproduced from Yoon et al. [14,15])

Table 1. TRNSYS simulation condition in Seoul & Middle East

Input variable	Simulation condition in Seoul	Simulation condition in M.E.
Space (single zone)	10m × 8m × 2.5m	10m × 8m × 2.5m
Window	60% of the southern wall area (15 m^2)	30% of the southern wall area (7.5 m^2)
Floor of space	Located between floors – up and down insulations	Located between floors – up and down insulations
Glass insulation	1.20 W/m^2K	1.720 W/m^2K
Wall insulation	0.21 W/m^2K	0.345 W/m^2K
Room temp. & humidity	26°C & 60%R.H.	26°C & 60%R.H.
Heating & light element	25 W/m^2	25 W/m^2
Persons	4 persons	4 persons
Infiltration	0.4 (1/h)	0.4 (1/h)
Ventilation	0.6 (1/h)	0.6 (1/h)

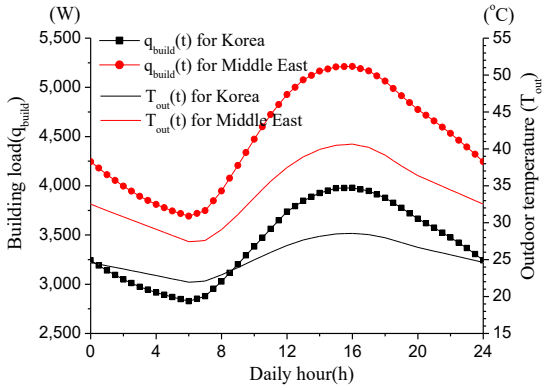

Fig. 3. Environment simulation result

3.3. Air-conditioner selection

A household room air-conditioner is categorized largely by constant speed compressor type and inverter compressor type. This study prepared an inverter compressor split wall mount air-conditioner. A constant speed air-conditioner's compressor turns off and on according to whether the room environment temperature satisfies the remote controller set temperature or not. In contrast, an inverter air-conditioner can control compressor speed to adjust the needed cooling capacity, which varies over time [14,15]. In this study, we simply control the set temperature by using an IR remote controller because each component's control method or signals (e.g., compressor speed, fan speed, expansion valve openness) are usually hidden by the manufacturer.

Even though the thermostat switching method of an inverter air-conditioner differs depending on the technology of each manufacturer, a dead band thermostat is usually used. This means that an air-conditioner starts to change the operation state when a certain activation range of temperature difference is satisfied between the measured room temperature and the product set temperature.

Table 2. Specifications of test air-conditioner

Contents	Name plate values
Air-conditioner type	Split wall mount
Compressor type	Inverter type
Electricity	Single phase, 220 V, 60 Hz
Rated cooling capacity	6 500 W
Rated power input	1 750 W
Max. power input	2 900 W
Min. power input	500 W
Refrigerant	R410a, 2kg

3.4. Deep reinforcement learning algorithm coding

The problem definition is:

- State : $[(T_{in}-26), dT_{in}/dt, T_{dis}]$
- Action : [22°C, 30°C]
- Reward : +1 pt, when T_{in} in the range of (26 ± 0.5)°C
- Penalty : –100 pts, when T_{in} out of (26 ± 0.5)°C

- Each episode ending : when penalty
- Environments during simulation time:
  - Day 1 : constant T_{out} = 28°C, q_{build} = 3,000 W
  - Day 2 : constant T_{out} = 28°C, q_{build} = 3,000 W (repeat one more day)
  - Day 3 : Korean summer climate, as Fig. 3
  - Day 4 : Middle Eastern summer climate, as Fig. 3
- Reset : T_{set} is reset within (26 ± 0.2)°C when each episode ends.

The coding flow is shown in Fig. 4. The basic algorithm is the same as established deep Q-learning, with experience replay [25], but differs by the addition of the training condition, T_{in} = (26 ± 0.5)°C, and reset condition T_{in} = (26 ± 0.2)°C.

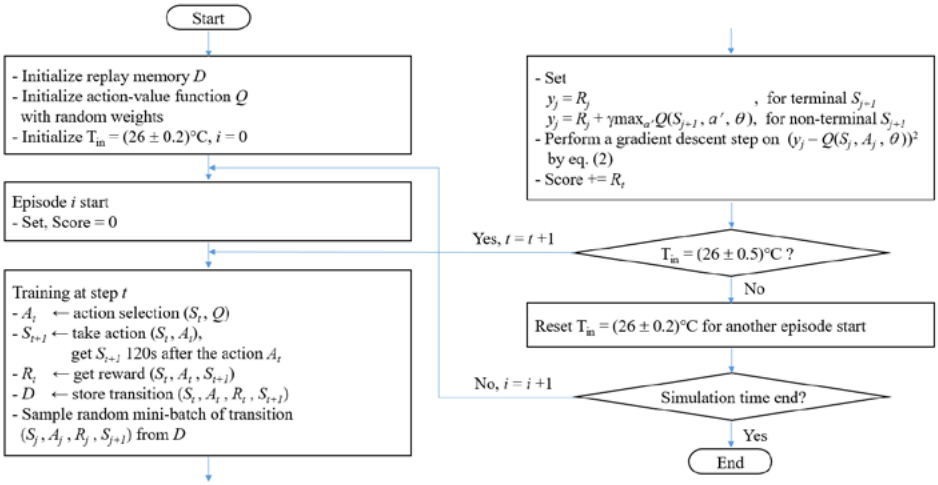

Fig. 4. Deep reinforcement learning coding flow

3.5. Air-conditioner remote control

Our deep reinforcement learning algorithm generates two cases of agent action, which are the remote controller setting temperatures of up and down. One of these action signals is transferred to the Arduino-based IR signal emitter. The IR signal changes the setting temperature of the air-conditioner. Before undertaking the IR operations, we need to record the infrared signals for each setting temperature of the remote controller. These Arduino IR signal-receiving and emission codes are well established in the Arduino-IRremote github library (https://github.com/z3t0/Arduino-IRremote). Figure 5 presents circuit diagrams of the IR signal receiver and emitter.

The block diagram for the experiment set-up is shown in Fig. 6. The test facility has one computer system for the facility environment simulation and data acquisition. The necessary data for the machine learning state inputs are transferred to a second PC. The second PC conducts a machine learning calculation and sends action output to the Arduino IR signal emitter.

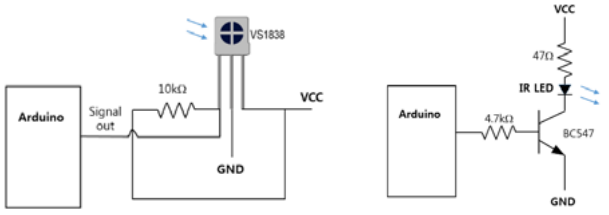

Fig. 5. IR signal receiver (left) and emitter (right) circuit

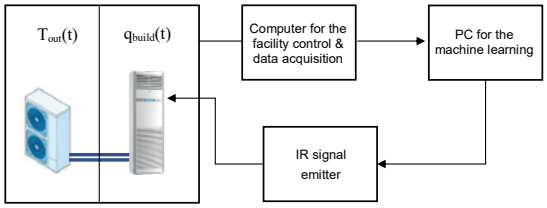

Fig. 6. Block diagram for the experiment set-up

4. Experiments and results

Even without AI, today's commercially available inverter air-conditioner technology is well established and can adjust building cooling demand to the desired room temperature. It offers satisfactory performance for the customer. However, this study aims to show that combining an inverter air-conditioner with RL machine learning can demonstrate better performance, especially in temperature precision control. First, normal usage of an air-conditioner with the fixed set temperature case, T_{set}=26°C, was experimented. Second, a simple thermostat algorithm was applied using computer control. Third, DQN RL training was started with a reward at T_{in}=(26±0.5)°C. Fourth, the same environment as the third case was maintained to check training reliability. Fifth, Korean summer climate environment variation was applied as a disturbance. Sixth, a Middle Eastern climate environment was applied as a harsh condition.

4.1. Without machine learning (normal usage of the product)

The recommended temperature setting for air-conditioners varies from country to country. In Korea, 26°C indoor room temperature is recommended. In order to compare the effect of RL machine learning, here we set the remote controller to 26°C without a machine learning algorithm and checked the indoor room temperature ($T_{in}(t)$) variation pattern under the Korean climate environment of outdoor temperature ($T_{out}(t)$) and building load ($q_{build}(t)$) change over the course of a day.

We introduced an inverter compressor-type air-conditioner to fine tune the indoor temperature, but the results in Fig. 7 are not very precisely controlled. Searching for other papers' results of different household inverter air-conditioner models does not change this fact [14,15]. The reason for this temperature control pattern is that ordinary HVAC products perform dead band control in order to reduce the switching frequency and increase the operating efficiency of the product [30]. During one day (24 h), as shown in Fig. 7, the maximum of T_{in} was 27.46 and the minimum was 25.00°C. Although the remote controller set temperature was fixed at 26°C, room temperature T_{in} oscillates with a deviation of approximately ±1°C.

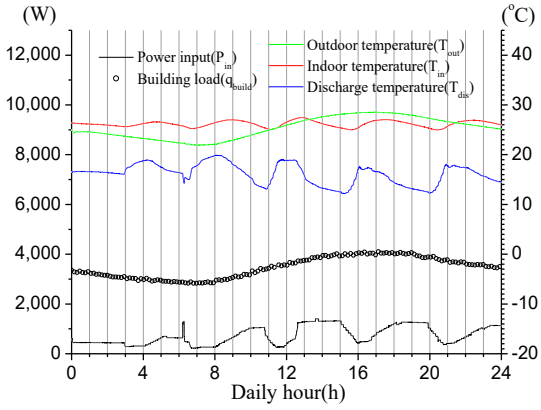

Fig. 7. Normal operation of the air-conditioner with T_{set} = 26°C

4.2. Simple computer thermostat algorithm control

In this case, the behavior of the product was identified by applying a simple thermostat algorithm rather than allowing the product to operate on its own. In Fig. 8(a), if the indoor temperature (T_{in}) was below 26°C, the product was remote controlled by an Arduino LED emitter at the value of 27°C. When T_{in} was over 26°C, the remote control value was set as 26°C. That is, a simple thermostat operation was implemented by computer algorithm. As another case of simple computer thermostat control, in Fig. 8(b), if T_{in} was below 26ºC, the product was remote controlled at the value of 30°C. When T_{in} was over 26°C, the remote control value was set as 22°C immediately.

Compared with Fig. 7, showing the normal operation under the T_{set} = 26°C, Fig. 8(a) of the simple thermostat algorithm shows similar graph patterns with some more fluctuations in indoor temperature (T_{in}), power input (P_{in}), and product discharge temperature (T_{dis}). Peaks in discharge temperature (T_{dis}) near 2, 6, and 10 hours were caused by the abrupt decrease of P_{in}. This abrupt change of P_{in} was due to the T_{set} signal of 27°C. To speculate on the control behavior of the product, we analyzed the point where the 26°C gray baseline meets T_{in}. At the 1.5 hour position, the room temperature (T_{in}) meets the downward 26°C line, and the automatic program changes the T_{set} set point to 27°C, but only slightly reduces power. In practice, the point at which power is drastically reduced is around 1.7 hours where the room temperature is at the local minimum. At 12 and 16 hours, T_{in} declines and meets the 26°C line. But, P_{in} does not decrease abruptly. For this reason, even though we cannot know the exact control design information of the original product, we can infer that the product uses dead band thermostat control.

Figure 8(b) shows the result when we use T_{set} of 22 and 30°C, instead of 26 and 27°C for the simple thermostat control. Because 22 and 30°C of T_{set} are far from our target of 26°C, immediate control is possible regardless of the dead band control of the product. The on and off graph line of the power input (P_{in}) and oscillating indoor temperature (T_{in}) are typical control aspects of a constant speed (or fixed speed) compressor air-conditioner. It is similar with the constant speed air-conditioner result (Fig. 3) of Yoon et al. [14].

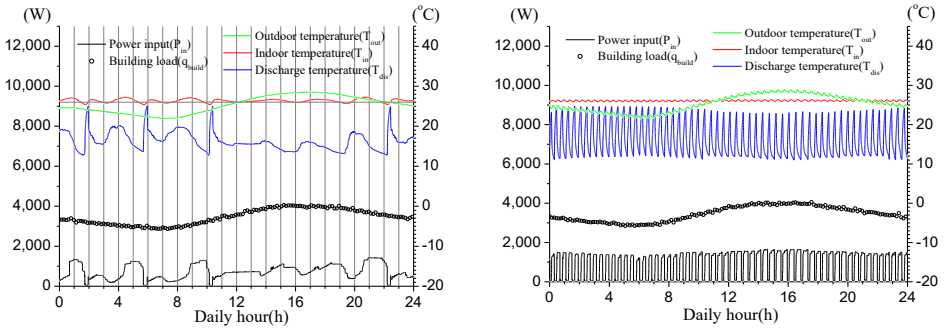

Fig. 8. Simple computer thermostat algorithm of (a) T_{set} = 26°C & 27°C (b) T_{set} = 22°C & 30°C

4.3. With machine learning algorithm (day 1 of RL)

On day 1 of reinforcement learning (RL), the test chamber environment was maintained at a constant outdoor temperature (T_{out}) of 28°C and a building load (q_{build}) of 3 000 W to reduce disturbances, as shown in Fig. 9. Even though the tested air-conditioner is an inverter type, which has typically small adjustment characteristics of power input (fine saw-tooth shape increase or decrease), such as in Figs. 7 and 8(a), in this case, Fig. 9 shows on and off switching characteristics as the indoor temperature was only controlled by the action of T_{set} high (30°C) and low (22°C).

Usually, pure computer RL machine learning such as in Atari games [25,26] takes less than a few hours. But real-world machine learning can take much longer, especially in the thermo-fluid system, which has a slow response time. Fortunately, this real-world air-conditioner RL study "only" took 16 hours to solve the problem. T_{in} in Fig. 9 is stabilized after 16 hours. The graph patterns of air-conditioner discharge temperature (T_{dis}) and power input (P_{in}) are irregular prior to 16 hours, so that sometimes the large time span of power-on duration can be seen (e.g., 9~10 h, 13 h). After 16 hours, P_{in} and T_{dis} show regular graph patterns.

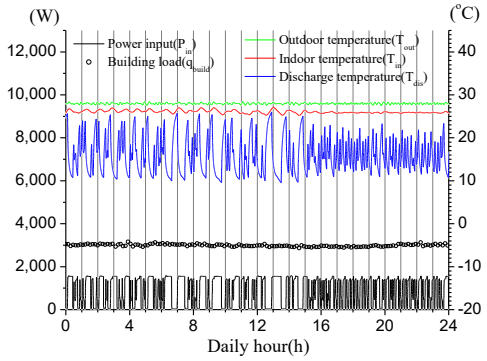

Fig. 9. Day 1 of RL result under the constant environment

An enlarged picture of the indoor temperature (T_{in}) is shown in Fig. 10. The red portions of the graph reflect the region where the reward +1 pt is taken. If T_{in} escapes the (26±0.5)°C range, each episode of training ends. For the restart of the training, the program algorithm forces the temperature down or up to reset T_{in} within (26±0.2)°C. The obtained scores at each episode are shown in Fig. 11. In this study, approximately one episode matches one hour before problem stabilization (16 h). It shows fluctuation from 2 to 25 scores. Even though Fig. 11 has no score information after 17 hours, episode 18 recorded 1,518 pts at the moment near the start time of day 4 (Fig. 15) when the environment changes abruptly to a harsh Middle Eastern climate condition.

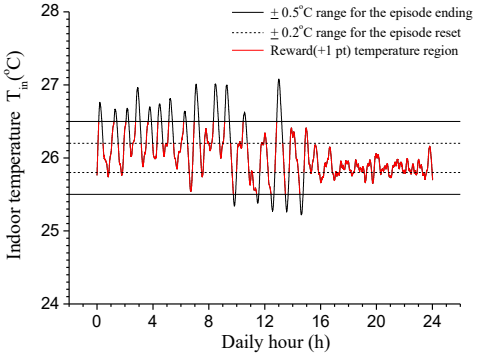

Fig. 10. Enlargement of the indoor temperature (T_{in}) graph during day 1

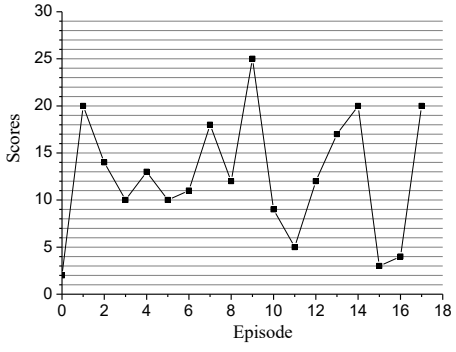

Fig. 11. Scores at each episodes during day 1

4.4. With machine learning algorithm (day 2 of RL)

On day 2 of RL, we repeated the same environment of constant T_{out} (28°C) and q_{build} (3 000 W) as day 1 of RL. Figure 12 shows a very well-trained and stabilized situation, and episode 18 continued during day 2 of RL. One thing to mention here is that throughout this work, there is a slight micro-vibration of the outdoor temperature (T_{out}) as a whole. This phenomenon is caused by the vibration of the condenser heat from the outdoor unit as the air-conditioner is turned on and off. Therefore, the fluctuation time matches between T_{out} and P_{in}. Normally, there are no such temperature interferences because air-conditioners are operated in a steady state on mode when products are tested according to ISO standard.

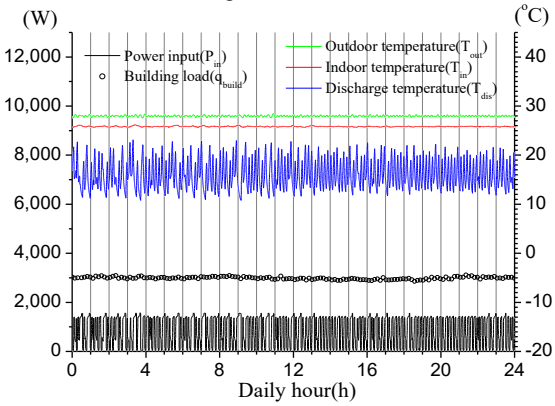

Fig. 12. 2nd day of RL result under the constant environment

4.5. With machine learning algorithm (day 3 of RL)

On day 3 of RL, a Korean summer climate (Fig. 3) was applied to the outdoor temperature ($T_{out}(t)$) and building cooling load ($q_{build}(t)$) as disturbance variations. Some other papers [2–4] have used these kinds of thermal variation as LSTM periodic state inputs, but in this study we did not use them as state inputs. Therefore, $T_{out}(t)$ and $q_{build}(t)$ variables act as unknown disturbances. From Fig. 13, $T_{out}(t)$ and $q_{build}(t)$ have minimum values near 6–7 a.m. and maximum values near 3–4 p.m. Indoor temperature (T_{in}) seems to converge well without change. However, the discharge temperature (T_{dis}) and power input (P_{in}) exhibit some different aspects with the constant environment case of Fig. 12. P_{in} near the maximum variation (3–4 p.m.) shows more on mode time span rather than minimum variation interval (6–7 a.m.). Also by the same reason, T_{dis} records a lower discharge temperature near 3–4 p.m. than 6–7 a.m. This means RL machine learning DNNs are adapted to the environment.

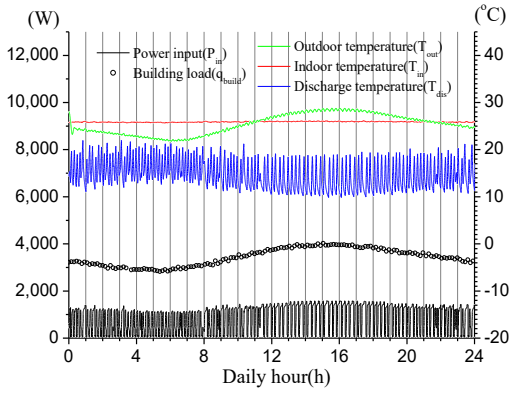

Fig. 13. Day 3 of RL result under Korean summer climate

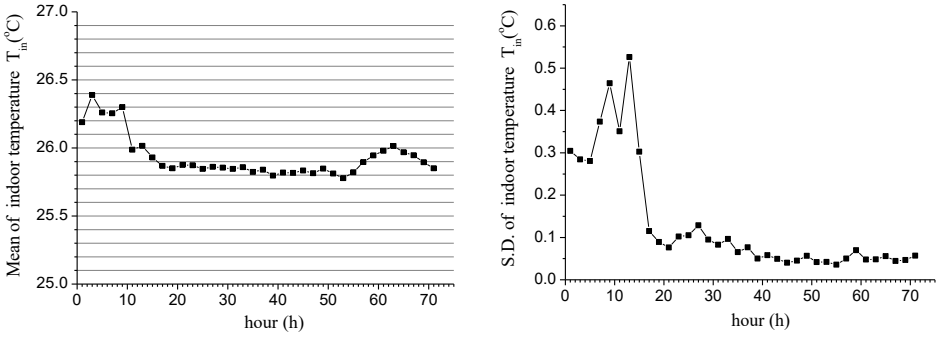

Fig. 14. Mean (left) and S.D. (right) of indoor temperature (T_{in}) during total three days at every 2 hour

The quality of T_{in} data during over the three days of RL was compared in Fig. 14. Because the training was stabilized after 16 hours of day 1, the mean value and standard deviation of T_{in} also show stabilization after 16 hours. However, the mean value shows one high peak at 64 hours (= 2 days and 16 h). This peak is due to environmental variations (T_{out} and q_{build}) during day 3 of RL. In any event, T_{in} exhibits a high accuracy when comparing the RL case of Figs. 12 and 13 with the normal usage (T_{set} = 26°C) case of Fig. 7.

4.6. With machine learning algorithm (day 4 of RL)

In this section, the environmental conditions of the Middle East were applied successively after the Korean environment, since summer temperatures in the Middle East are the harshest on the planet, which can act as big environmental disturbances in this study. In Fig. 15, because the start value of $q_{build}(t)$ abruptly changed from the Korean climate ending $q_{build}(t)$ value 3 250 W to the Middle East start value of 4 250 W, it shows disturbed T_{in} temperature near the start time. Therefore, we obtained a renewal of episode number by 19 at this moment. Episode 18 ended with the score of 1,518 pts at this position.

During the day time, there is a time interval in which power input (P_{in}) shows only an on mode without off mode. This means that the tested air-conditioner cooling capacity is insufficient to cover the building load (q_{build}). Notably from 13.5 hours to 19.8 hours, the indoor temperature (T_{in}) is over 26.5°C, even with the full operation of the product. Because the specification of the tested product (Table 2) is for moderate temperature condition (ISO T1 condition), the high temperature condition (ISO T3 condition) of the Middle East cannot be applied to this product. Nevertheless, this study conducted tests in the Middle East temperature condition to identify the limitations of RL machine learning due to harsh environmental conditions. Results show that even though the product capacity is insufficient, the trained deep neural network (DNN) continues to send 22°C of signal to cool the room.

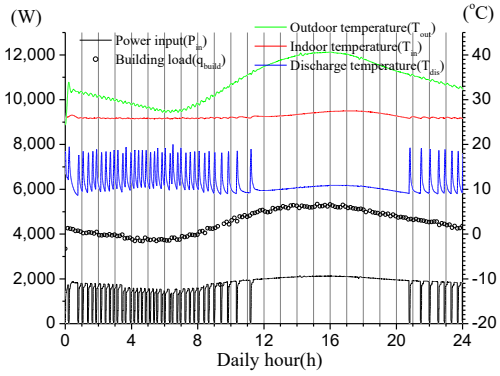

Fig. 15. Day 4 of RL results under the Middle Eastern summer climate

Table 3. Temperature mean, S.D., minimum, maximum values and power consumptions

Case	Mean of T_{in}	S.D. of T_{in}	Min. of T_{in}	Max. of T_{in}	P_{24h} (kWh)
Normal usage of T_{set} =26ºC (Fig. 7)	26.19	0.600	25.00	27.46	17.63
Simple thermostat of T_{set} =26ºC, 27ºC (Fig. 8(a))	26.39	0.431	25.34	27.29	17.52
Simple thermostat of T_{set} =22ºC, 30ºC (Fig. 8(b))	26.09	0.163	25.78	26.37	21.74
Day 1 of RL (Fig. 9), no climate disturbance	26.07	0.362	25.22	27.08	20.39
Day 2 of RL (Fig. 12), no climate disturbance	25.83	0.081	25.65	26.18	19.33
Day 3 of RL, Korean climate (Fig. 13)	25.90	0.088	25.66	26.12	20.23
Day 4 of RL, Middle Eastern climate (Fig. 15)	26.29	0.551	25.69	27.51	38.99

Finally, the temperature control qualities and power consumptions for each day are summarized in Table 3. The mean value and standard deviation of the T_{in} temperature show good results on day 2 and day 3 of RL. Similarly, the minimum and maximum deviations from the target temperature (26°C) also show minimum errors on day 2 and day 3 of RL. It shows that the application of DQN reinforcement learning in this study can surpass the temperature control ability of the product in normal usage or simple thermostat control cases. In terms of power consumption during one day (P_{24h}), this RL study case (about 20 kWh) is not energy efficient than normal usage case (17.63 kWh). This is because the product was machine-learned only using two action control temperatures of 22 and 30°C to avoid the dead band control zone inherent in the original air-conditioner product and to simplify the RL problem.

5. Conclusion

Reinforcement learning (RL) using a DQN (Deep Q-learning Network) method was applied to household inverter air-conditioner temperature precision control. Three state variables of $[(T_{in}(t) -26), dT_{in}/dt, T_{dis}(t)]$ and two actions of 22, 30°C remote control are used in the DQN model. The practical application of DQN RL to home appliances is seldom found in papers. In this study, after 16 hours of training, we obtained a stabilized indoor temperature close to 26°C. Environmental disturbances were applied during the training using Korean and Middle Eastern summer climates. The Korean climate conditions, which can be covered by product capabilities, showed a more stable and accurate temperature control pattern. Comparing with the normal usage result of T_{set}=26°C (T_{mean}=26.19°C, S.D.=0.600°C, T_{min}=25.00°C, T_{max}=27.46°C) or computer simple thermostat control of T_{set}=22 and 30°C (T_{mean}=26.09°C, S.D.=0.163°C, T_{min}=25.78°C, T_{max}=26.37°C), this study's DQN reinforcement learning recorded more accurate temperature control results (T_{mean}=25.90°C, S.D.= 0.088°C, T_{min}=25.66°C, T_{max}=26.12°C).

The role of electric heat pumps in the decarbonisation of the heating sector in Europe

Martin Forsén, Laure Meljac

NIBE Energy Systems, Post box 14, SE-28521 Markaryd, Sweden

Abstract

Mitigation of greenhouse gases, dependency of fossil fuel and security of energy supply are on top of the agenda in all energy discussions. This sets the focus on energy efficiency and the use of renewable energy in all sectors. The European Union has set ambitious targets to improve energy efficiency, increase the use of renewable energy and reduce greenhouse gas emissions by 2030. Up until recent years most of the focus has been on the electricity and transport sector. The building sector has largely been overlooked. However as approximately 40% of the total energy use in Europe is related to buildings, this sector has one of the largest potential for reducing greenhouse gas emissions. The objective of this paper is to present a general methodology on how to determine greenhouse gas emissions related to different sources of heating and to what extent a wide introduction of electric heat pumps will contribute to a decarbonisation of the heating sector. The methodology is additionally used to calculate primary energy savings as well as to give an indication of potential operating cost savings by use of available statistics for different energy sources. The results show that electric heat pumps has a significant potential to improve energy efficiency (53 – 81%) and reduce greenhouse gas emissions (57 – 99%) while replacing old inefficient boilers in Europe.

1. Introduction

This paper explains the development of a methodology to estimate the potential for a reduction of green housegas (GHG) emissions when heat pumps are replacing conventional heating systems. The main objective of this paper is to make an assessment on GHG-emission reduction and primary energy savings that may be accomplished while replacing old fossil boilers by electric heat pumps. Other types of heat pumps such as thermally driven and fuel engine driven heat pumps are commercially available but not included in the study that serves as a basis for this paper. At local and regional level emission reduction of particles, SOx and NOx may be just as important drivers to phase out the use of old boilers. The model used for all calculations allow for the use of different assumptions of efficiency at appliance level as well as the generation of electricity on national level. The GHG-emission savings are calculated and expressed in terms of carbon dioxide equivalents (kg CO_2eq). The calculations are performed by use of emission factors (ef_{xx} [kg CO_2eq/kWh]) for different energy carriers and national emission factors for the generation of electricity. The example calculations of primary energy savings are, where existing, based on official primary energy factors for different energy carriers.

2. On how to compare energy efficiency of different heating systems

When we are to compare the energy efficiency of heating systems, we need to realise that the result will depend on the boundaries for the system in view. Different stake holders would set the boundaries from different perspectives. The end user of a heating system would naturally define the efficiency as the useful heat in

relation to the amount of energy that needs to be purchased. This is however not sufficient when energy systems are studied from a broader perspective, as energy losses and emissions from different types of heating systems appear at different stages in the energy chain. An electric boiler might seem very efficient from the perspective of the end consumer, but if we take into account for distribution losses and losses at point of electricity generation and even further up the energy chain, it is evident that electric heating is not as efficient as the customer might perceive. In order to obtain an impartial comparison of the energy efficiency and total emissions for different types of systems, it is essential to extend the system boundary beyond the external wall of the heated building.

If we start with the actual energy needed to heat a building and add all the losses in the heating appliance, distribution and if applicable power generation as well as energy use for extraction, refinement and transportation of fuels we end up at a final value that gives a better representation of the energy needed to supply one unit of heating. The total amount of energy including the energy content of the energy carrier itself and all the energy required for extraction, refinement, transformation and distribution is often referred to as primary energy. An assessment of primary energy use is often required in order to enable a fair comparison of different heating systems using different energy carriers. In order to simplify a primary energy assessment, it is common to use a set of precalculated primary energy factors (PEF) for different energy carriers. The primary energy use is given by the purchased energy multiplied by the PEF for the energy carrier in use. The European standard EN 15603 defines a methodology, including a few alternatives, on how to calculate PEF.

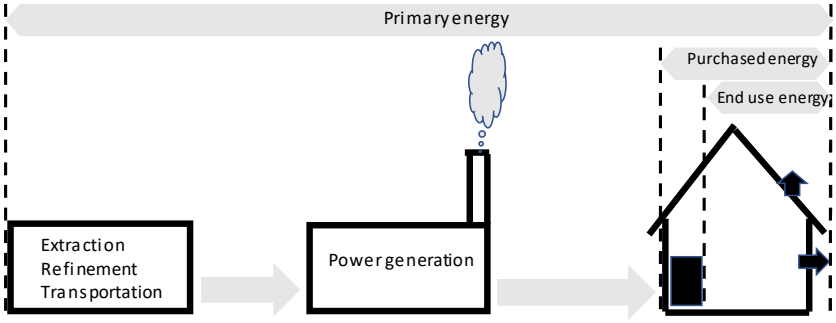

Figure 1 System boundaries for primary energy definition

2.1 The use of primary energy factors, PEF

Within the European Union there are several policy instruments e.g. the Energy Efficiency Directive and the Energy Performance of Buildings Directive [1, 2] that requires the use of PEF for different energy carriers. The default value for the primary energy factor for electricity for all Member States has recently been reviewed and changed from 2,5 to 2,1. The revision was based on a study initiated by the European Commission and finalised 2016 [3]. The study presents 4 principal methods that may be used to calculate the PEF and elaborate pros and cons for each method. It is evident that the applicable system boundaries and time frames chosen for the calculation of the PEF will vary from country to country and thus result in different values. It is however vital that the calculations of the PEFs are made in a transparent manner avoiding arbitrary assumptions chosen to fit a predefined purpose. As this study is focusing on the transformation of the heating in buildings, we have chosen to use the PEFs that have been established for use in the building codes in different countries.

3. Calculation of primary energy savings

While assessing the potential primary energy savings that can be achieved by replacing conventional boilers with electric heat pumps we need to take into account for the efficiency of the appliances we are addressing as well as the primary energy factors for electricity and the energy carrier of the system we are considering to

replace. Even though the model we are describing in this paper is generic and may be used for any type of heating system, the derivation is given for the example of replacement of an existing gas boiler.

The primary energy use of a gas boiler may be expressed as follows;

$$E_{Prim\ Gas} = \frac{Q_H \times PEF_{gas}}{\eta_{gas}} \quad (1)$$

Where;

$E_{Prim\ Gas} = Primary\ \ energy\ \ use\ \ of\ \ a\ gas\ boiler$

$Q_H = Annual\ \ heating\ \ demand$

$PEF_{gas} = Primary\ \ energy\ \ factor\ \ for\ \ gas$

$\eta_{gas} = Annual\ \ efficiency\ \ \ \ of\ \ the\ gas\ boiler$

The primary energy use of an electric heat pump may be expressed as follows;

$$E_{Prim\ HP} = \frac{Q_H \times PEF_{el}}{SPF} \quad (2)$$

Where;

$E_{Prim\ HP} = Primary\ \ energy\ \ use\ \ of\ \ the\ heat\ \ pump$

$Q_H = Annual\ \ heating\ \ \ demand$

$PEF_{el} = Primary\ \ energy\ \ factor\ \ for\ \ electricity$

$SPF = Seasonal\ \ performance\ \ factor\ \ of\ \ the\ heat\ \ pump$

By use of equation 1 and 2 we may now deduce the relative primary energy savings.

$$\frac{\frac{Q_H \times PEF_{gas}}{\eta_{gas}} - \frac{Q_H \times PEF_{el}}{SPF}}{\frac{Q_H \times PEF_{gas}}{\eta_{gas}}} = \frac{\frac{PEF_{gas}}{\eta_{gas}}\left(1 - \frac{PEF_{el}\ \eta_{gas}}{PEF_{gas}\ SPF}\right)}{\frac{PEF_{gas}}{\eta_{gas}}} \quad (3)$$

Thus, the relative primary energy savings are given by the relation between the primary energy factors and the relation between the annual efficiencies of the appliances.

$$Relative\ \ \ primary\ \ energy\ \ savings = \left(1 - \frac{PEF_{el}}{PEF_{gas}}\frac{\eta_{gas}}{SPF}\right) \quad (4)$$

Equation (4) is in its form general and may be used to calculate the relative primary energy savings that may be achieved while replacing any type of heating system with a heat pump. In order to make the calculation for replacement of oil or solid coal the primary energy factor for gas (PEF_{gas}) and the annual boiler efficiency (η_{gas}) shall be replaced by the respective constant for the relevant system.

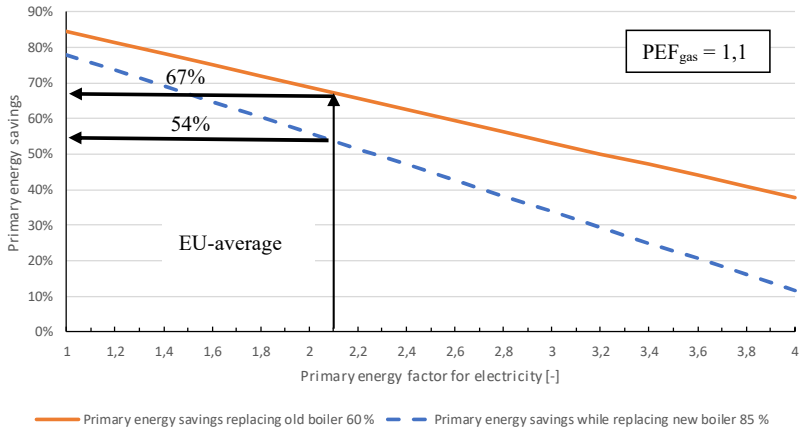

Figure 2 Primary energy savings - heat pump replacing boiler

Figure 2 illustrates the primary energy savings that will be achieved by replacing boilers with an electric heat pump operating at an annual SPF of 3,5. The European Union has established that the average of European electricity generation corresponds to a primary energy factor of 2,1. This value may be used by the Member States to assess national improvements of energy efficiency. However, Member States are free to establish their own primary energy factor based on the national mix of the generation of electricity. The ongoing transition of the electricity sector characterised by an increasing share of renewables is improving the efficiency over time and thus leading to a lower primary energy factor. These improvements enhance the primary energy savings further.

Table 1 below depicts the calculated primary energy savings that will be achieved for 9 different Member States. The calculations are based on the primary energy factors for electricity that has been established in each country to be used in the building codes.

*Table 1 Primary energy savings; old boiler (60%), new boiler (85%), * PEF for Sweden = 1,85 is to be confirmed during 2020*

Country	PEF$_{elec}$	Primary energy savings, old boiler	Primary energy savings, new boiler
France	2,58	60%	43%
Germany	1,8	72%	60%
The Netherlands	2,56	60%	43%
The United Kingdom	1,5	77%	67%
EU-average	2,1	67%	54%
Czech	3,0	53%	34%
Slovakia	2,2	66%	51%
Poland	3,0	53%	34%
Finland	1,2	81%	74%
Sweden*	1,85	71%	59%

The results reveal that significant energy savings may be achieved by replacement of old inefficient boilers (53 – 81%). Furthermore, it can be seen that a replacement of more efficient boilers contributes to an improvement in the heating sector (34 – 74%).

4. Calculation of reduction of greenhouse gas (GHG) emissions

While addressing the greenhouse gas emissions, expressed in the form of CO_2-eqvivalents, we may in an analogous manner derive a general equation as depicted below.

The GHG-emissions generated by a gas boiler may be expressed as follows;

$$GHG_{gas} = \frac{Q_H \times e_{gas}}{\eta_{gas}} \tag{5}$$

Where;

$GHG_{gas} = green\ \ house\ \ gas\ \ emissions\ \ \ \ generated\ \ \ \ by\ a\ gas\ \ boiler$

$Q_H = Annual\ \ heating\ \ \ \ demand$

$e_{gas} = Emission\ \ \ \ factor\ \ \ \ for\ \ gas$

$\eta_{gas} = Annual\ \ efficiency\ \ \ \ \ \ of\ \ the\ gas\ \ boiler$

The GHG-emissions generated by a heat pump may be expressed as follows;

$$GHG_{HP} = \frac{Q_H \times e_{elec}}{SPF} \tag{6}$$

Where;

$GHG_{HP} = green\ \ house\ \ gas\ \ emissio\ \ ns\ \ generated\ \ \ \ by\ a\ heat\ \ pump$

$Q_H = Annual\ \ heating\ \ \ \ demand$

$e_{elec} = Emission\ \ \ \ factor\ \ \ \ for\ \ electricity$

$SPF = Seasonal\ \ \ \ performance\ \ \ \ factor\ \ \ \ of\ \ the\ heat\ \ pump$

By use of equation 5 and 6 we may deduce the relative reduction of greenhouse gases that may be achieved while replacing a gas boiler with a heat pump.

$$\frac{GHG_{gas} - GHG_{HP}}{GHG_{gas}} = \frac{\frac{\cancel{Q_H} \times e_{gas}}{\eta_{gas}} - \frac{\cancel{Q_H} \times e_{elec}}{SPF}}{\frac{\cancel{Q_H} \times e_{gas}}{\eta_{gas}}} = \frac{\frac{\cancel{e_{gas}}}{\cancel{\eta_{gas}}}\left(1 - \frac{e_{elec}}{e_{gas}}\frac{\eta_{gas}}{SPF}\right)}{\frac{\cancel{e_{gas}}}{\cancel{\eta_{gas}}}} \tag{7}$$

Thus, the relative reduction of greenhouse gases is given by the relation between the primary energy factors and the relation between the annual efficiencies of the appliances.

$$Relative\ \ \ \ GHG\ emission\ \ \ \ savings\ \ \ = \left(1 - \frac{e_{elec}}{e_{gas}}\frac{\eta_{gas}}{SPF}\right) \tag{8}$$

Figure 3 below illustrates the reduction of greenhouse gas emissions that will be achieved by a replacement of gas boilers with electric heat pumps (SPF = 3,5) as a function of the emission factor for the generation of electricity. Results show that an electric heat pump that replace a gas boiler will contribute to a reduction of GHG-emission by the order of 65 – 75% if we base the calculation on the European average emission factor for generation of electricity (295,8 gCO_{2eq}/kWh_{elec}) [4].

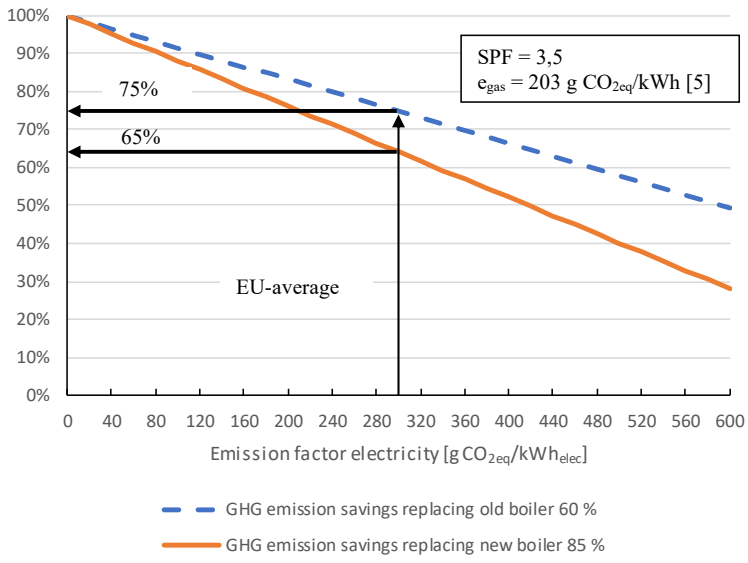

Figure 3 Reduction of greenhouse gases

Figure 3 visualise the impact of the carbon intensity of the electric grid. The reduction of greenhouse gas emissions by retrofitting old boilers with electric heat pumps are significant in all European countries, but varies a great extent depending on the carbon content of electricity. Poland is one of the countries that has one of the highest emission factors for electricity in Europe (773,3 gCO_2/kWh_{elec}) [4] show the lowest potential, but in this case it might be relevant to perform the assessment based on the assumption that the heat pump replace an old coal-fired boiler which is still used to a large extent. In this case a heat pump retrofit will decrease the greenhouse gas emissions by the magnitude of 60% and the benefits will increase over time as the greening of the grid will come into effect. Table 2 below show the potential of reduction of GHG-emissions in 9 European countries, based on the latest available data of the carbon intensity in the national grid. The calculations are based on replacements of gas boilers in the gas dominated countries (France, Germany, The Netherlands, The United Kingdom and EU-average) and a replacement of coal boilers in Czech, Slovakia and Poland. As none of these systems are common in Finland nor Sweden the calculations are based on oil boilers in this case.

Table 2 Reduction of greenhouse gases; old boiler (60%), new boiler (85%), (e_{elec}= emission factor for electricity 2016 [4], e_{gas}= 203 g CO_{2eq}/kWh, e_{gcoal}= 334 g CO_{2eq}/kWh, e_{oil}= 267 g CO_{2eq}/kWh [5])

Country	Energy source being replaced	e_{elec} [g CO_{2eq} /kWh_{elec}]*	GHG-emission reduction, old boiler	GHG-emission reduction, new boil
France	Gas	58,5	95%	93%
Germany	Gas	440,8	63%	47%
The Netherlands	Gas	505,2	57%	40%
The United Kingdom	Gas	281,1	76%	66%
EU-average	Gas	295,8	75%	65%
Czech	Coal	512,7	74%	63%
Slovakia	Coal	132,3	93%	90%
Poland	Coal	773,3	60%	44%
Finland	Oil	112,8	93%	90%
Sweden	Oil	13,3	99%	99%

Table 2 reveal the significant emission reduction that may be achieved by a replacement of boilers with electric heat pumps. Improvements in heat pump technology and the phase out of carbon intensive electricity generation will increase the benefits even further with time. The current trend in the electricity sector is positive and is expected to continue at an even higher pace in several countries. Figure 3 depicts the evolvement of the

national emission factor for the generation of electricity [4]. In 2016 the share of renewable electricity reached 29 % in Europe. The share of renewable electricity is by now higher than coal and lignite. The transition from fossil fuels to renewable electricity in conjunction with increased efficiency has led to a decrease of the emission factor of 43 % between 1990 and 2016.

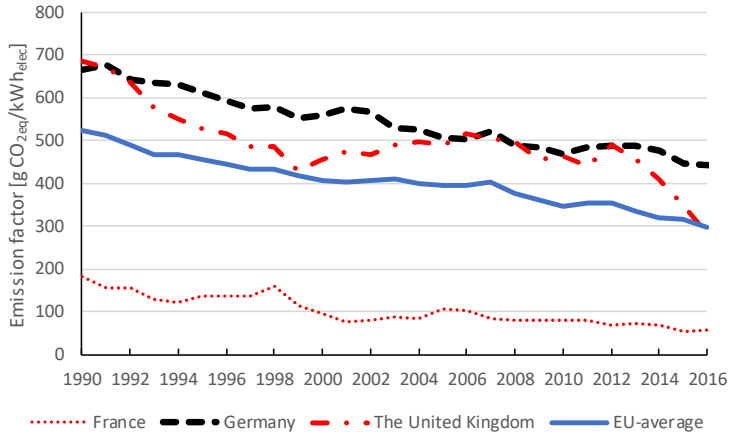

Figure 4 Development of the emission factor for electricity generation 1990 – 2016 [4]

5. Economical aspects

In view of the Paris agreement and binding European targets it is evident that there is an urgent need to transform the heating sector. Up until recently there has been a strong focus on how to decarbonise electricity and transport. The heating and cooling sector has so far not attracted the attention it deserves and requires, but changes are on their way. The European Directive on energy performance of buildings (EPBD) sets a requirement that all new buildings within the European Union need to meet a "nearly zero energy building" definition by 1 January 2021. The member states of the European Union are presently at the point of re-defining their building codes to meet this requirement. The EPBD is expected to serve sufficiently for new construction but as this will only address a minor fraction of the energy use of the whole building stock it is essential to implement comprehensive renovation programs. The European Commission published a "green deal" communication in December 2019 [6] which states that the European Union and its Member States should engage in a "renovation wave". The European Union will enforce the legislation related to the energy performance of buildings that will start with an assessment of the national long-term renovation strategies in 2020. The annual renovation rate of the building stock varies in between the Member States from 0,4 – 1,2 %. This rate will need to at least double in order to reach the energy efficiency and climate targets [6]. Several Member States are aware of the significant benefits that are offered by heat pumps but the economical incentives for end consumers to make a shift differ greatly between the Member States.

The relative savings of the operational costs that may be achieved by a replacement of an existing boiler with an electric heat pump is largely determined by the energy price ratio between electricity and the energy carrier to be replaced. In analogy with the expressions for primary energy savings and reduction of greenhouse gases the potential annual savings of the operational costs may be expressed as;

$$Relative\ \ savings\ \ of\ annual\ \ operation\ \ costs\ \ = \left(1 - \frac{Price_{elec}}{Price_{gas}} \frac{\eta_{gas}}{SPF}\right) \tag{9}$$

Where;

$$Price_{elec} = Price\ of\ electricity \quad \left[\frac{euro}{kWh}\right]$$

$$Price_{elec} = Price\ of\ gas \left[\frac{euro}{kWh}\right]$$

The quota between the energy prices for electricity and the relevant energy carrier we are comparing with constitute the previously mentioned energy price ratio. By use of equation (9) we may draw a chart of the potential savings of the annual operational costs as a function of the energy price ratio.

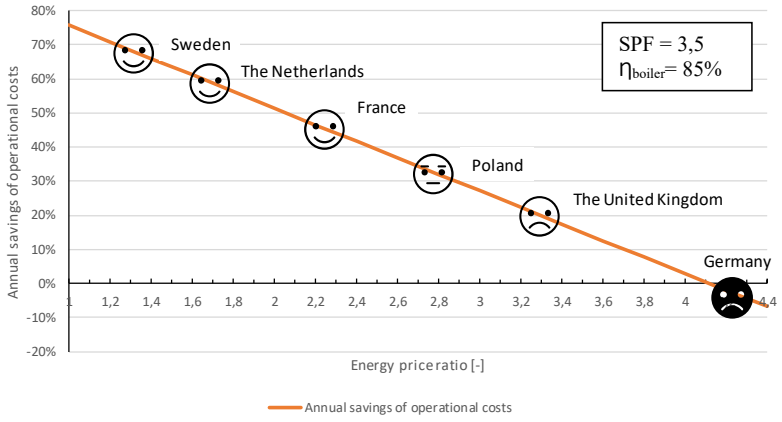

Figure 5 Annual savings of operational costs

Figure 5 depicts the potential annual operational cost savings that may be achieved by a heat pump compared to a modern boiler while taking into account for relevant energy price ratios 2018 [7] on a few selected markets. As these calculations are based on average energy prices and rough estimations on annual efficiencies the results may only be seen as an indication of the level the economic attractiveness of heat pumps. In reality substantial differences may prevail both in terms of energy prices and efficiencies. It is however evident that the low energy price ratio for Sweden has served as the single most important economic driver for the development of the Swedish heat pump market. As of today, heat pumps are used in more 50% of the single-family houses and the use of heating oil that for decades was the dominant source of heating is almost entirely abandoned. The low energy price ratio in Sweden is to a large extent the result of the introduction of a carbon tax 1991. On the other side of the scale the German heat pump market is suffering from high energy price ratios partly because of the energy price policy induced the “energy turnaround” (energiewende) that introduced additional taxes on electricity in order to finance the development of renewable electricity. Given the good example of Sweden it is evident that some sort of progressive energy price policy may play a very important role in order to stimulate the transformation of the heating sector. The energy price policy may as in Sweden be in the form of a carbon tax or as mentioned in EU Green Deal Communication [6] an inclusion of the heating sector into the emission trading system.

Abstract

Combining a heat pump cycle with an Organic Rankine cycle and adding a thermal storage enables an innovative and reversible energy storage concept. As both processes use similar components, it is conceivable to combine these in one single cycle with two operation modes.
Within an ongoing research project at University Erlangen-Nuremberg, a combined HP-ORC pilot plant is designed and constructed. One focus in the research is the combination of the compressor of the heat pump and the expander of the ORC in one single machine (e.g. screw-type). Besides the pressure ratios and temperature levels, the lubrication is an interesting challenge, as it differs in quantity and function.
Several innovative designs of the lubrication system are conceivable. The oil separator is an essential component of the lubrication circuit. With methods of CFD-simulation, a close look at the separation in both operation modes (HP and ORC) is possible. This paper describes preliminary considerations, shows design methods and identifies solutions for the lubrication management of a reversible compressor-expander unit.

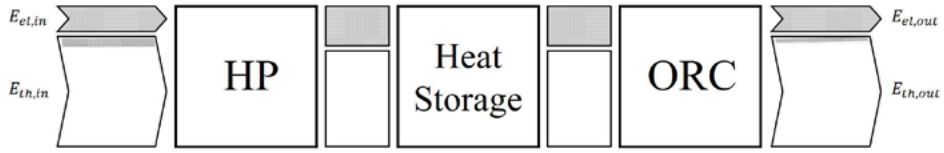

Fig. 1. Diagram of energy flows for the HP-ORC-concept (el.: electric, th.: thermal)

1. The combined HP-ORC-concept

1.1. Fluctuating renewable energies and the need for energy storages

Reaching the goals of the *Paris Agreement*, a significant increase in the electrical power production coming from renewable energy sources takes place. Due to the fluctuating character of renewables (especially PV, wind) improvements of energy distribution and storage are strongly required [1]. Several storage concepts are known, which differ greatly in storage capacity, efficiency and lifecycle-costs, so that there is a different area of application for each. *Pumped Thermal Energy Storage* is a big scale medium-term concept group that includes the *Carnot Battery,* a combination of heat pump and Organic Rankine Cycle.

1.2. The HP-ORC-concept (Carnot Battery)

The heat pump cycle (HP) is a well-known method to lift a medium's temperature by using electrical energy in a very efficient way. The Organic Rankine cycle (ORC) is a system that converts heat or thermal energy to mechanical energy and (via a generator) electrical energy. Using both concepts together and adding a thermal energy storage leads to the combined HP-ORC-concept (see figure 1). The concept also known as *Carnot Battery* can act as medium-term electrical energy storage. Electrical energy to be stored runs a heat pump cycle using waste heat energy to increase the temperature level of a thermal storage medium. In case of need, an Organic Rankine cycle converts the thermal energy of the storage medium (lowering the temperature level again) back into electrical energy. The achievable power-to-power efficiency and storage capacity strongly depends on the temperature levels of the application [2]. As both processes consist of similar components, it is possible to combine the cycles using the components reversibly and save investment costs.

2. Reversible use of a compressor and expander

The combination of a heat pump cycle and an Organic Rankine cycle requires some further considerations. The heat exchangers, being the most expensive parts of the cycles, can already reduce the investment costs significantly when used reversibly [3]. A diverse task is the combination of the compressor (HP) and the expander (ORC) in one single machine. The combination is conceivable for any type of volumetric machine [4]; in the current case, a screw type is investigated. Comparing the two operation modes of the concept, the outstanding differences are the temperature and pressure levels of condensing and evaporating and thus the inlet and outlet conditions of the machines. While the temperature variations are manageable, the different pressure levels are a relevant factor for process design. One fundamental number of the compression or expansion step is the pressure ratio Π, which is defined as the ratio of the higher pressure to the lower pressure:

$$\Pi_{com\ pression} = \frac{p_{out}}{p_{in}} \quad (1)$$

$$\Pi_{expansion} = \frac{p_{in}}{p_{out}} \quad (2)$$

During the heat pump mode, the working fluid's temperature rises from the temperature level of the waste heat (where the evaporation takes place) to the upper storage temperature (where the condensation takes place). Applying the ORC, the working fluid reduces its temperature from the upper storage level (evaporation) nearly

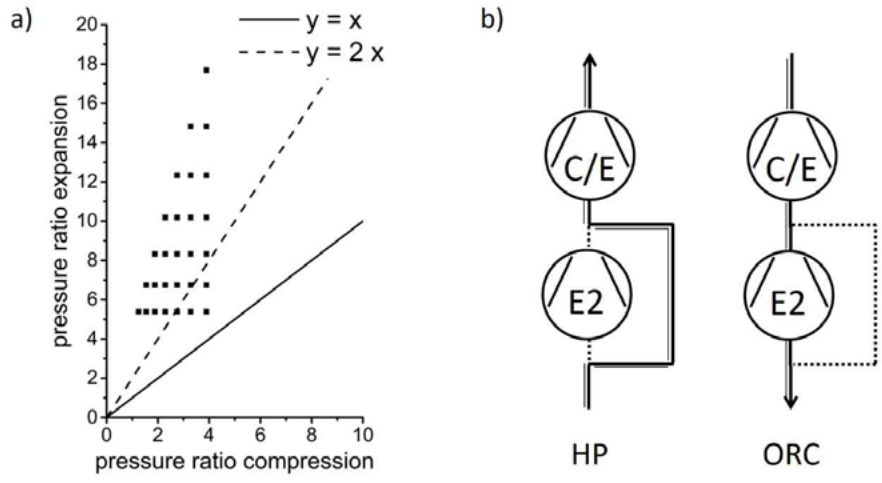

Fig. 2. Comparison of pressure ratio for compression and expansion (a) and concept of combined machine layout (b)

down to ambient temperature (condensation). Since the temperature levels of the phase changes differ in the two modes, the pressure ratios at the machines differ significantly, being much higher in the ORC-case. Figure 2a) shows these numbers for different temperature scenarios (dots) of the storage concept. The full line in the figure indicates the symmetrical case, when the pressure ratio at expansion equals the pressure ratio at compression. Regarding the location of the typical operation scenarios of a combined HP-ORC-application, apparently this case does not occur. The location of the operation field is much more in the range of

$$\Pi_{expansion} = n \cdot \Pi_{compression} \quad ; with\ n = 2;3 \tag{3}$$

Particularly for volumetric machines (e.g. screw compressor, screw expander), there is a fluid sensible relation between the built-in volume ratio θ and the pressure ratio, with κ being the isentropic exponent [5]:

$$\Pi = \theta^{\kappa} \tag{4}$$

Equation (4) shows the challenge to select a single machine, which meets the requirements of both compression and expansion having different pressure ratios. A solution to this is a serial approach as seen in figure 2b). Adding an extra expansion unit (E2) to the reversible machine (C/E) in expansion case (ORC) and bypassing it in compression case (HP) enables two different pressure ratios. These can be adjusted to the main operating point by the selection of proper machinery.

3. Lubrication of a combined machine

The lubrication of screw machines brings several advantages (no need of gears, better sealing, temperature regulation) thus an oil-injected compressor or expander is frequently used. Still the lubrication comes with some challenges especially for a reversible use. It differs for compressors and expanders due to the reversion of the thermodynamic process. In the compressor, the main function of the lubricant is the heat transport: the cooling of the compressed gas is necessary to increase the efficiency and lower the thermal load on the component parts. In contrast, there is no cooling necessary for the expander case, because expansion of the gas already lowers its temperature. That leads to a difference in the mass flow of the lubricant, being smaller in the expander-case.

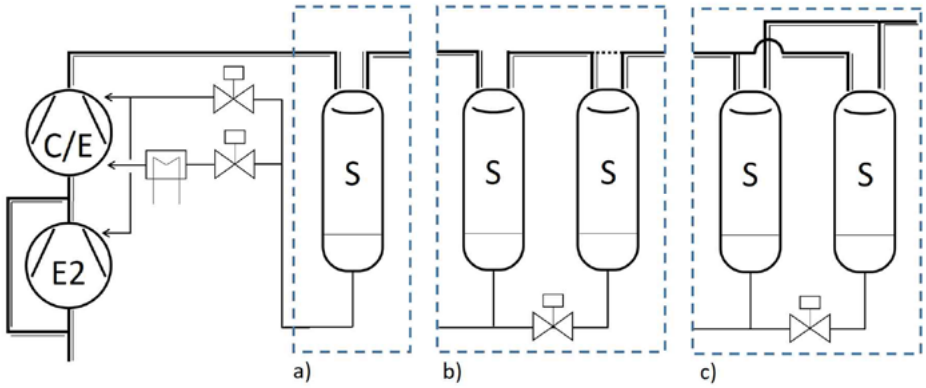

Fig. 3. Lubrication chart of combined compression-expansion-machine with: a) single separator, b) two serial separators, c) two parallel separators

One main part of the lubrication circuit is the oil separator, which divides the refrigerant vapour from the oil. Here again, two different approaches have to be compared: While in the HP-case, it is straightforward to locate the separator downstream of the compressor, cool the separated lubricant and re-inject it at the low-pressure side, the separation process for an expander is often quite different. Locating the separator downstream as well would lead to a huge apparatus because of the bigger volume flows at low pressure. To avoid this, it can be placed upstream. That leads to the fact, that the lubricant follows the refrigerant's way all through the ORC and is separated just before the expander, to be injected into the proper places. Due of the relatively low mass flow, the lubricant does not affect the refrigerant circuit too much. Furthermore, this setup enables the combination of the lubrication for a combined compressor-expander-unit very well (see figure 3a)).

Nevertheless, the different mass flows of lubricant and different volume flows of refrigerant influence the design of the separator particularly. Several layouts are conceivable: to adapt the performance to each case it might be necessary to add a second separator. It can be placed as a serial (figure 3b)) or parallel setup (figure 3c) improving the separation efficiency or halving the volume flow respectively. For further investigations of the fluid dynamics in a vapor-liquid-separator, numerical analysis was carried out.

4. Fluid dynamics in oil separators

4.1. CFD model

The main function of this setup is to enable vapor-liquid separation for the HP-mode and ORC-mode. Therefore, it is necessary to use a symmetrical separator design. In general, the vertical vapor-liquid separator consists of four sections [6]: the inlet diverter, the gravity settling section, the liquid collection section and the mist extractor. In this study, both the vapor-liquid inlet (diameter 0.03 m) and the vapor outlet (diameter 0.03 m) are placed on top of the vessel (diameter 0.12 m, height 0.4 m), which are separated by a divider to prevent short cut flow. Droplets of liquid settle in the liquid collection section, where an outlet for the liquid is placed at the bottom of the vessel.

To predict the fluid flow behavior inside the separator and to calculate the separation efficiency, Computational Fluid Dynamics (CFD) is used. There are two approaches for multiphase flow modeling: Euler-Euler and Euler-Lagrange. For the Euler-Euler method, continuous-continuous phase interactions form a discrete interphase between them. They are immiscible with each other and it focuses on the fluids motion in a specific location. With the Euler-Lagrange method, the fluid is considered as continuous phase, while the disperse phase can be solid particles liquid droplet or gaseous bubbles. Each particle is tracked separately and the motion can be predicted.

Studies of vertical gas-liquid separators [7,8] have shown a combination of the volume of fluid (VOF) model, as a simplified version of the full Eulerian model, with the discrete phase model (DPM) is suitable for simulation of multiphase separation processes. Hereby oil-droplets as a dispersed phase are solved under a

Lagrangian frame until it reaches the final destination where boundary conditions apply and the vapor as continuous phase is solved using an Eulerian frame of reference.

4.2. Boundary conditions

In this study, a steady vapor-liquid simulation is implemented in ANSYS FLUENT 19.1. With the criteria of quality and skewness of the mesh, a computational mesh-grid-independent solution was performed. Prism layers were set at the wall and tetrahedral elements placed inside the separator. To save computational time, a symmetric boundary condition was placed. The Reynold Stress Model (RSM) calculates turbulence. The inlet mass flow was defined accordingly to table 1 for the liquid and vapor phase for the following simulated cases. As it typically appears for the storage concept, the mass flow in the ORC-case is slightly smaller than in the HP-case. The droplet size of the oil in the vapor stream follows a particle size distribution. As there is no physical data for the specific case available, the mean droplet size is assumed to be 250 microns. This will be valuated experimentally in a pilot plant set up. For the serial HP-mode, just the second apparatus was simulated, as the first one is identical to the single HP-mode. The inlet conditions at the second separator are equal to the outlet conditions of the first; the droplet size is reduced to 150 microns, assuming the smaller particles to be less separated in stage one. In the parallel HP-mode, vapor and oil mass flow is halved. Static pressure was set at the outlets as for the bottom outlet hydrostatic pressure was set. Furthermore, phase interaction, Ishii Zuber drag forces and virtual mass are included. The surrounding fluid flow remains unaffected by the droplet motion. Physical transport processes, which take place at the phase boundary surface (warm and cold transport), are not considered in this work.

Table 1: Fluid properties for HP- and ORC-modes

	HP- mode, single	ORC-mode, single	HP- mode, serial (2)	HP- mode, parallel (1/2)
Gas flow rate	0.3 kg s^{-1}	0.2 kg s^{-1}	0.3 kg s^{-1}	0.15 kg s^{-1}
Liquid flow rate	0.04 kg s^{-1}	0.02 kg s^{-1}	0.004 kg s^{-1}	0.02 kg s^{-1}
Operating pressure	163800 Pa	91300 Pa	163800 Pa	163800 Pa
Operating temperature	411 K	368 K	411 K	411 K
Gas density	83.61 kg m^{-3}	48.78 kg m^{-3}	83.61 kg m^{-3}	83.61 kg m^{-3}
Liquid density	1048.48 kg m^{-3}	1048.48 kg m^{-3}	1048.48 kg m^{-3}	1048.48 kg m^{-3}
Droplet size	250 µm	250 µm	150 µm	250 µm

4.3. Simulation results and discussion

Stochastic model of turbulent dispersion is included in the particle trajectory calculations. 10500 particles were injected at the inlet. Through the DPM, escape zones and trapped areas were assigned to count the particles, which reached the liquid collection section. Equation 5 provides the predicted separation efficiency with the number of oil droplets at inlet and outlet:

$$\eta = \left(\frac{n_{oil,in} - n_{oil,out}}{n_{oil,in}}\right) \cdot 100\ \% \tag{5}$$

Table 2 shows the calculated separation efficiencies for the considered cases.

Table 2: Separation efficiency

Case	HP-mode, single	ORC-mode, single	HP-mode, serial (2)	HP-mode, parallel (1,2)
Separation Efficiency	89.4 %	98.6 %	86.9 %	84.3 %

Figure 4 shows the particle velocity magnitude for the four different cases. The inlet is on the left for HP and on the right for ORC. According to the simulation results, separation in HP-case could reach an efficiency of about 89 %. An improvement because of parallel use of two similar separators cannot be seen, even though the volume flow halves (84 %). Conversely, a second serial apparatus can increase the separation efficiency furthermore (89 % at first stage, 86 % at second stage) reaching in total a number of 98.6 %. Having a symmetrical geometry, the reversible use of the separator in the ORC-case is not an issue per se. Yet the inlet conditions change (lower pressure and therefor lower density), resulting in different flow conditions. Here a separation efficiency of about 98 % results. Further simulation results show a strong dependence of the particle size.

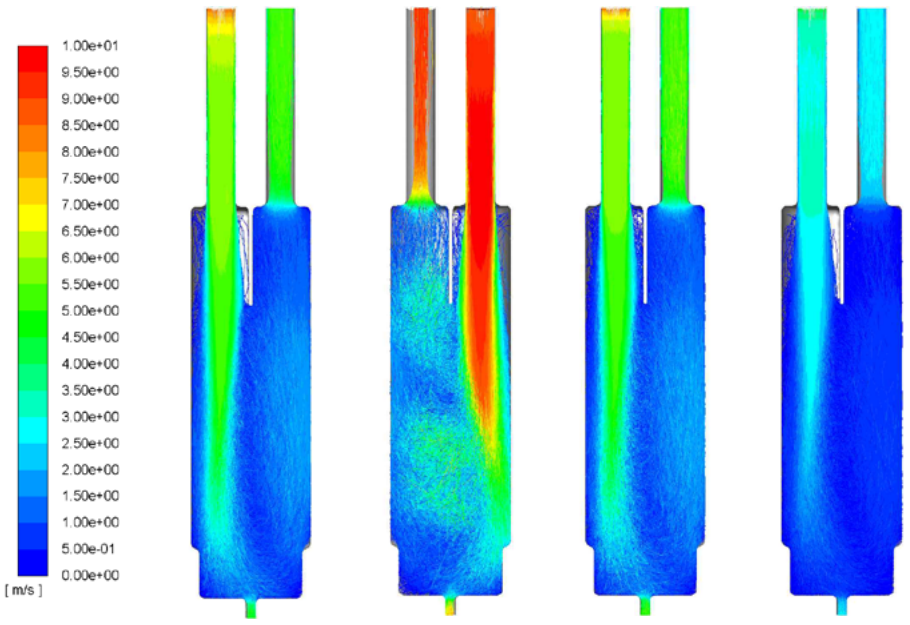

Fig. 4. Particle velocity magnitude of oil droplets in different separation setups

To sum up, the separation efficiency is mainly a function of particle size, volume flow and lubricant mass flow. Combining a heat pump compressor and an Organic Rankine cycle expander two different lubrication situations meet. Of course, it is feasible to find an optimal separator for each task, but combining the function in just one separator comes with smaller declines. The study shows that separation in ORC-mode is slightly more efficient; hence, the separation apparatus should be bigger in HP-mode. This challenge can be resolved by adding a second apparatus. Here the study shows an advantage of the serial setup compared to the parallel one. Even though the results are valid in general, the droplet size assumption has to be confirmed experimentally and updated to the simulation. Therefore, a pilot plant setup of the combined HP-ORC concept will be launched in 2020.

Development and Implementation of Industrial High Temperature Heat Pumps for Waste Scrubbing Process

Gilbong Lee*, Beomjoon Lee, Junhyun Cho, Ho-Sang Ra, Young-Jin Baik, Eun Seok Wang, Hyung-Ki Shin, Young-Soo Lee, Chulwoo Roh

Thermal Energy Systems Laboratory, Korea Institute of Energy Research, 152, Gajeon-ro, Yuseong-gu, Daejeon, 34129, Korea

Abstract

In this study, industrial heat pump which can generate low pressure steam was developed. The heat pump uses process waste heat of 50-60℃ to generate 120℃, 2kgf/cm2 steam. By implementing this, the overall thermal energy efficiency of a factory can increase. In case of R134a, the discharge temperature and pressure of compressor was expected to be in supercritical state around 200℃/10 MPa. To locate operation points in lower temperature and pressure zone, R245fa was selected as a working fluid. Cycle and system design was performed based on R245fa properties. With the experiment results of small-scale, reciprocating-compressor system, large scale system design of screw-compressor was carried out. Since this system was to be applied to actual operation, control logic with high reliability was also developed. After in-lab tests, the heat pump was installed to supply steam for waste scrubbing process in a chemical factory.

1. Introduction

Emission of greenhouse gases is largely related to energy consumption and energy efficiency is expected to play as an important role as renewable energy to deal with global warming issues.[1] Among residential, commercial, industrial and transport sectors, the industrial sector generally contributes the largest portion in energy consumption. For South Korea industrial sector consumed about 61.7% of final energy in 2012.[2] Energy consumption by functions in manufacturing showed that feedstock accounted for the largest portion of 57.2% followed by heat energy of 29.1%.[3] (Table 1) Therefore it is an important research target to find methods of reducing heat energy in industrial sector. Conventional heating methods like combustion and electric heating is considered to reach limit in efficiency. Alternative heating methods are being sought to improve thermal efficiency. Among them heat pump is considered as one of the most prominent candidates. Heat pump system satisfies heat demand by transferring energy from low temperature source to high temperature sink. Energy is used in changing pressure and temperature of working fluid – refrigerant in heat pump. The total transferred heat is sum of energy input and extracted energy from low temperature source. Therefore heat pump can deliver more heat than input energy.
Heat pump can be applied to use low temperature heat source to generate hot temperature energy such as space heating and hot water. As a low temperature heat source, heat pumps can use air, river, lake/sea water or even ground (underground) energies.[4] This versatility of energy source has made heat pump to be considered as a renewable energy system. In EU, heat pump satisfying minimum SPF (Seasonal Performance Factor) is regarded as renewable energy system.[5] Some countries have implemented subsidy programs to expand installation of heat pump since it can emit less greenhouse gases than conventional boilers using fossil fuels.

Table 1. Energy consumption in manufacturing industry by functions in 2010, South Korea

Function	PJ (10^{15} J)	Portion (%)
Heat	1,312	29.1
Power	398	8.8
Feedstock	2,574	57.2
Miscellaneous	216	4.8
Total	4,501	100

Currently main market of heat pump is residential, commercial and district heating/cooling market. The penetration status of heat pump in the industrial sector is very low. In one milk powder factory in Denmark, a compression/absorption heat pump was installed to preheat process air up to 80ºC by extracting heat from coolant of 40ºC.[6] In England one chocolate factor installed heat pump system to simultaneously heat the process water and cool glycol mixture.[7] Most of heat pump application in industrial sector are in production of hot water for processes. For a higher temperature application, Andrea et al. proposed the application of absorption heat pump type 2 to reduce middle pressure steam in pulp factory and showed high potential in energy saving.[8]

Table 2 is the temperature distribution of heat demand in German in C. Lauterbach's report.[9] According to the report, heat demand of 100ºC or less occupies 9% and that of 100-200ºC was 8% of similar contribution. Temperature distribution of heat demand however showed different pattern among industrial sectors. For example, paper and rubber product sector need almost twice amount of heat in 100-200ºC as that in below 100ºC zone. Fig. 1 is thermal energy demand distribution in French industry by D. Bobelin et al.[10] The analysis focused on heat demand below 140ºC. The heat demand below 100ºC was reported to be small compared to heat demand of above temperature.

Most of the thermal energy in industrial processes is supplied in the form of steam in order to maintain a stable temperature. Typically, steam below 140ºC is termed as low pressure steam. Since there is high demand of heat above hot water temperature, many researches have been conducted to increase the temperature of heat pump cycle. In this paper, high temperature heat pump cycle to generate low pressure steam was developed. The design temperature of heat sources are 60-70ºC waste heat and the product target was120ºC low pressure steam. In addition to basic cycle design, application of internal heat exchanger was considered. Test rig of 40 kW scale steam heat pump was constructed and performance evaluations were conducted.

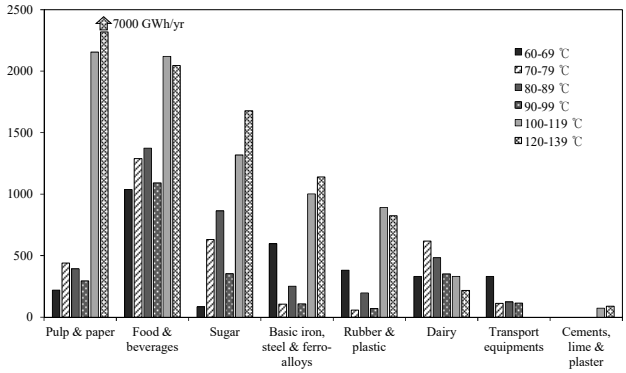

Figure 1 Distribution of the heat demand per industrial branch[10]

2. Design of high temperature heat pump cycle for steam generation

2.1. Basic Cycle Design

As a base cycle for high temperature heat pump, vapor-compression cycle was applied. In this cycle, compressor increases the pressure and temperature of refrigerant by transforming mechanical energy. The discharged refrigerant releases heat energy to high temperature heat sink in condenser. The temperature difference between heat sink and refrigerant in condenser is generally in order of 10ºC. The lower the temperature difference is, the lower the input energy compressor requires. This eventually increases the efficiency of system. The optimization of heat pump system is directed to the minimization of temperature difference in condenser.
Fig. 2 is heat and mass transfer diagram of steam generation heat pump cycle. In closed loop, the generated steam will be circulated to boiler again, while in open loop additional water should be supplied as the steam is exhausted to low temperature process or in the air. Fig. 2 is open loop configuration. Steam can be produced by either direct heating or by pressure reduction in circulating water (flashing method). Since the density difference between saturated liquid and saturated vapor of water is so large, the condenser of heat pump may become too bulky under direct heating method. Therefore in this study, pressure reduction method was used for steam production. In this method, only small portion of circulating water is transformed to low pressure saturated vapor. (less than 10%) Large amount of saturated liquid is recirculated to condenser and make-up water is mixed along the circulation. After circulation pump the pressure of process water is increased. Since the portion of saturated liquid is very high, the circulating water undergoes single phase heat transfer in condenser.

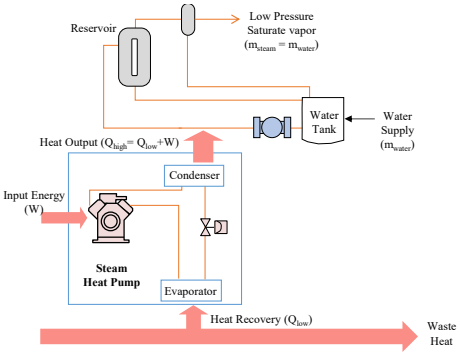

Figure 2 Cycle diagram of steam generation heat pump

To produce low pressure steam with heat pump, the condensation temperature should rise up to 130ºC. Table 3 gives characteristics of refrigerant candidates for high temperature application.[11] R134a is one of the most commonly used refrigerant in current market. It has critical temperature around 100ºC. This means that heat pump cycle of R134a would undergo supercritical process to generate steam. If refrigerants have critical temperature above 130ºC, they would have advantage in efficiency. R1234ze(Z), R245fa and R365mc satisfy

this requirement for critical temperature. Among them R245fa was chosen since it has no flammability and is easily purchased.

Table 3 Basic characteristics of refrigerants for high temperature heat pump applications

Refrigerant	GWP	Flammability	T_c [℃]	P_c [MPa]
R134a	1430	-	101.1	4.06
R755	1	-	31.0	7.38

Heat pump system of R134a makes hot water with low temperature heat source (such as geothermal energy, sea water, ambient air). The target heat pump of R245fa makes low pressure steam with waste heat source of 60-70ºC. Considering the difference in the operation temperature range R245fa and R134a have similar operation pressure. Thermo-physical properties related to heat transfer are listed in Table 4 with different saturation pressures. Chen suggested boiling heat transfer as combination of convective heat transfer and nucleate heat transfer.[12] Column 10 and 11 of table 4 are the relative convective heat transfer coefficient when values of R134a are assumed as 1. The velocity was assumed to be the same. Dittus-Boelter correlation was used to calculate heat transfer coefficient. From the relative values, R245fa may show similar heat transfer performance in vapor phase but have poor performance in liquid phase. This is because R245fa has disadvantage in thermal conductivity and viscosity in liquid phase. For the enhancement factor of convection heat transfer many researchers suggested Martinelli parameter as key parameter.[12] Since R245fa has higher density in saturated vapor phase than R134a, enhancement factor of R245fa will decreases in evaporation heat transfer compared to R134a. In condensation, R245fa may show similar heat transfer performance as R134a.
Although the final product of steam heat pump cycle is vapor, the heat transfer in condenser is single phase if pressure reduction method is applied. Considering the working temperature difference, the condensation heat transfer will not change much compared to R134a. All of these will imply that conventional cycle design approach of R134a could be applied to the design of R245fa based heat pump design with only minor modification. Therefore refrigerant change approach from R134a to R245fa was applied in the construction of test apparatus for the preliminary research.

ρ: density, h: enthalpy, liq: liquid, vap: vapor, gf: fluid to gas
"relative" means values of R245fa compared to R134a under same pressure

Dittus-Boelter correlation: $\alpha_{liq} = 0.023\,\mathrm{Re}_{liq}^{0.8}\,\mathrm{Pr}_{liq}^{0.4}\left(\frac{k_{liq}}{d_i}\right)$

Martinelli parameter: $X_{tt} = \left(\frac{1-x}{x}\right)^{0.9}\left(\frac{\rho_{vap}}{\rho_{liq}}\right)^{0.5}\left(\frac{\mu_{liq}}{\mu_{vap}}\right)^{0.1}$

2.2. System Reliability and Efficiency

The most common causes of compressor failure are refrigerant flood back, flooded starts, liquid slugging, overheating, lack of lubrication, etc.[13] Refrigerant flood back occurs when refrigerant is not heated up to superheated phase in the evaporator. This is caused by low evaporation load or failure of evaporator. Under compression with refrigerant flood back, foaming phenomenon in lubricant of compressor is generally occurred. Flooded start is when compressor starts its initial operation with a large amount of liquid refrigerant within the compressor shell. This happens when the system is over-charged with refrigerant or the system is stayed for a long period. Under flooded start, massive and instant exit of lubricant occurs. This causes temporal lack of lubrication of compressor. Overheating operation is caused by high compression ratio, low suction pressure, high superheat, etc. High compressor temperature causes negative effect to lubrication.
Adequate superheat is needed for the protection of refrigerant flood back. It is also important to secure lubrication performance in compressor. Compressor lubricant performs roles such as sealing, anti-friction, cooling, etc. Under normal operation lubricant mixes with refrigerant in compressor. Daniel chart shows trends of lubricant/refrigerant mixture with isobaric curves.[14] It shows refrigerant concentration, viscosity with different temperature and pressure of lubricant and Fig. 3 is an example for R32.[15] Since the pressure of lubricant is same as that of refrigerant the difference between lubricant temperature and refrigerant saturation temperature can be used as the index of reliability. This definition is similar to the definition of superheat. In practical application, superheat would be used as an alternative index to lubricant superheat. Under constant pressure, concentration ratio of refrigerant stiffly increases as temperature approaches saturation temperature of refrigerant. Since the viscosity of HFC refrigerants is much lower than pure lubricant, lubrication performance was impaired as superheat becomes small.[16] Whether using suction superheat or discharge superheat as the criteria of reliability depends on the position of oil reservoir in compressor. In low pressure shell, oil reservoir is placed in suction part. Low suction superheat may tremendously increase the concentration of refrigerant damaging the lubrication performance. However in high pressure shell compressor, the oil reservoir is placed in discharge part. Therefore the negative effect of low suction superheat can be compensated in high pressure shell type compressor.[17] In summary, adequate superheat where the oil reservoir is placed should be maintained to secure lubrication performance.

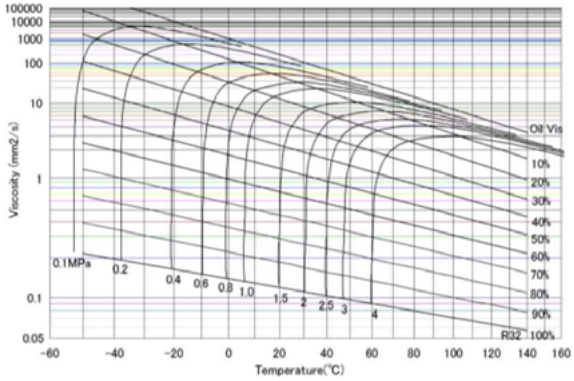

Figure 3 Daniel chart of New-PVE68 with R32 [15]

For commonly used R134a the isentropic line moves away from saturated vapor line (bubble line) as the pressure increases. However R245fa shows different trend, moving toward the bubble line (Fig. 4) Discharge superheat affects lubrication of high pressure part in compressor. Therefore certain amount of discharge superheat should be maintained for reliability.
Fig. 5 shows discharge superheat trends with different suction superheat and operation pressures. The suction pressure was fixed as 400 kPa and the isentropic efficiency of compressor was assumed as 0.8. If compressor has to have adequate superheat for the entire operation range, more suction superheating is required for R245fa. This means that the design point of suction superheat of R24fa should be higher than R134a. High suction superheat requires large temperature difference between refrigerant and secondary fluid in evaporator. This causes low evaporation pressure and low efficiency.

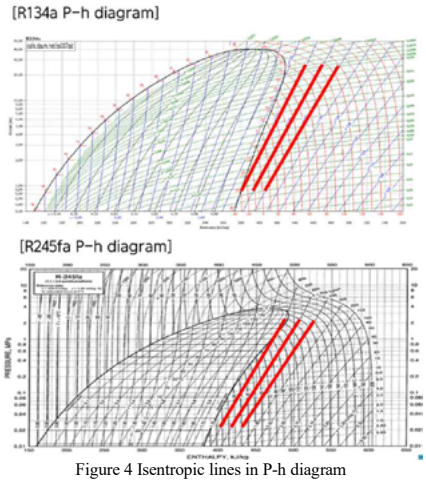

Figure 4 Isentropic lines in P-h diagram

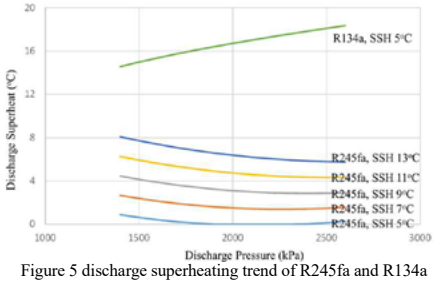

Figure 5 discharge superheating trend of R245fa and R134a

2.3. Application of Internal Heat Exchanger

In the previous chapter it was shown that the requirement of superheat of R245fa may cause performance decrease in heat pump cycle. With evaporator only, the temperature gradient of refrigerant will increase to meet the requirement. The temperature difference between heat source and evaporator will also increase. To meet this, evaporation pressure of heat pump system will drop resulting in high compression work and low capacity. High temperature heat pump system of 40 kW for steam generation was designed to examine this trend. Fig. 7 shows system performance changes under different suction superheat. If the minimum value of discharge superheat is set as 10ºC, about 7% of COP was decreased due to high suction superheat.
Internal heat exchanger (IHEX) transfers heat between condenser outlet fluid and evaporator outlet fluid. With this, system has additional suction superheat and heating capacity. As IHEX provides superheat for compressor, unnecessarily low pressure in evaporator can be eliminated. The cycle diagram of IHEX integrated heat pump is fig. 8. Table 5 shows performance comparisons with and without IHEX. IHEX increased evaporation pressure by 0.4 bar.

Figure 6 Experimental apparatus of steam generation heat pump development (40kW scale)

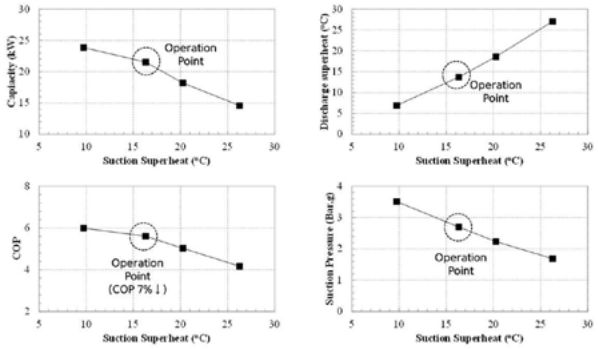

Figure 7 Performance characteristics of R245fa heat pump cycle with various suction superheat

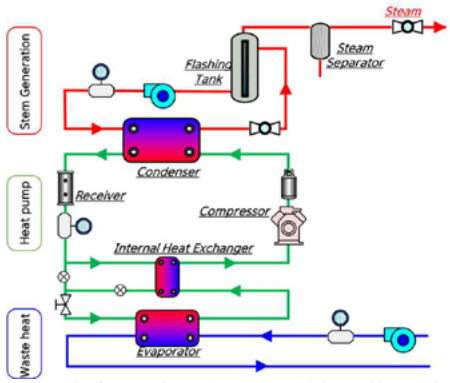

Figure 8 Cycle diagram of steam heat pump with internal heat exchanger

To further analyze the effect of IHEX simple parametric analysis was performed for R134a and R245fa to see effect of suction superheat. Condensation pressure and evaporation pressure were set as 2200 kPa and 400 kPa. Isentropic compression, constant volumetric efficiency, and no subcooling were assumed. Under these conditions, performance with 5ºC suction superheat was selected as reference point. The relative performances with different suction superheat were listed in Table 6. According to the table, increasing superheating also increase the compression work. However it also increase the heating capacity of the system. Therefore the heating COP is to have a tendency to increase as well. More improvement is seen in R245fa cases. This is due to higher specific heat at vapor phase and relatively low latent heat. R245fa has lower sensitivity in discharge superheat and higher sensitivity in efficiency than R134a. Therefore R245fa has more advantage in applying IHEX than R134a.

Table 5. Performance comparisons between with and without internal heat exchange

Parameters		W/O IHEX	W IHEX	Difference
Evaporation Pressure	bar, g	2.88	3.64	0.76

3. Field Test and Evaluation of High Temperature Heat Pumps for Waste Scrubbing Process

In the industry field, steam is widely used in the processes such as refining, extraction, and food processing. Many researchers have been working on developing energy saving method of steam generation using low temperature waste heat. High temperature heat pump which can generate low pressure steam is one of the technical candidates for this. In this study, a heat pump system that produces steam of over 100ºC with capacity of 0.5 ton/h was developed based on cycle design methods in chapter 2. The steam heat pump utilizes waste heat of 50-70ºC, producing 110-120°C steam using a flash tank. Then, the developed steam heat pump system was tested at a Chemical Polycarbonate (PC) production line in Yeosu Industrial Complex.

Fig. 9 shows a conceptual diagram of the steam heat pump apparatus, which receives heat from the heat source water on the left side and produces steam through a flash tank on the right side. The evaporator superheat of the heat pump unit was controlled by the EKC315 superheat controller. The target value was 5°C based and the measuring point was the evaporator outlet. An ICM valve was used as an expansion valve to since the outlet temperature of condenser is normally about 100ºC. The control of the flash tank is the most important factor for the stable operation of the steam heat pump. The main factors of flash tank control are the pressure of the steam generated and the flash tank level. The pressure of the flash tank determines the temperature of the steam generated.

The manufactured steam heat pump system is shown in Fig. 10. Performance improvement and stability evaluation were conducted in the laboratory prior to the installation in the demonstration site. To maintain the stability of the system, control of flash tank pressure and liquid level in the tank are important. The level control of the flash tank is conducted with the differential pressure gauge, the pressure reducing valve, the two-way valve and the GH1000 controller. Stable make-up water supply is required to reduce the pressure fluctuations of the generated steam. To do this, it is necessary to properly set the pressure reducing valve, select the suitable inner diameter of the two-way valve, and set the PID gain of the GH1000 controller. In the performance improvement process, the several modifications were conducted such as refrigerant amount optimization, unit insulation, EKC operation optimization, steam pressure optimization and flashing pressure reducing valve optimization operation. The final performance in the laboratory was Steam 118.3ºC, capacity 362.6 kW, and COP 3.73.

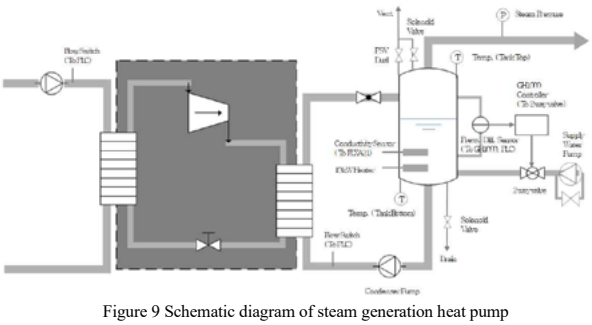

Figure 9 Schematic diagram of steam generation heat pump

Figure 10 Steam generation heat pump unit

The pressure of the steam line of the target process was about 0.16 MPa, which corresponds to steam temperature of 115ºC. The pressure control of the steam outlet of the flash tank became unnecessary because the main steam supply line maintained stable pressure. Fig. 11 shows the high temperature heat pump package installed in the demonstration site of a chemical factory. It consists of a heat pump unit and a flash tank unit. The installation in the chemical plant took about two months, and the operation of the steam pump system started in February 2018. The performance of the steam heat pump during the test run period is as follows; Steam output: approx. 0.53 ton/h, steam heat pump performance: calorie 348 kW, COP 3.03. Fig. 12 shows steam production and heat source water temperature during the period.

4. Conclusions

In this study cycle characteristics of high temperature heat pump cycle were analyzed. As the demand for energy saving has increased in the industrial sector, interest for heat pump which recycles waste heat to produce low pressure steam has increased. R245fa was considered as suitable refrigerant of heat pump cycle for steam generation condition since the critical temperature of R245fa is above the operation temperature of steam

generation condition. Similar design concepts of R134a hot water heat pump could be applied to design steam heat pump cycle when steam is produced through flashing process.
Superheat is an important index for reliability and efficiency. In compressor, lubricant mixes with refrigerant. Small temperature difference to saturation temperature implies stiff concentration increase of refrigerant - high solubility of refrigerant to lubricant. Therefore certain amount of superheat should be maintained in oil reservoir part of compressor. R245fa tends to decrease superheat under compression process which is contrary to R134a. In designing R245fa cycle, design point of suction superheat must be higher because of this characteristic.
With internal heat exchanger, discharge superheat can be secured without increasing temperature difference in the evaporator. Simple parametric analysis was performed for R134a and R245fa to see effect of suction superheat. The results showed that R245fa has more favorable thermo-physical characteristics in applying internal heat exchanger compared to R134a. Therefore internal heat exchanger can be suggested as an essential component in R245fa heat pump cycle. The steam heat pump manufactured through this study was installed at a chemical plant and verified the performance. The heating capacity of the system was 350 kW and COP was 3.03 from the operation in the demonstration site.

Abstract

Renewable energy systems play a major role in the reduction of CO_2 emissions in industrial processes. However, selecting a suitable renewable energy system is difficult since the development of standardized concepts for assessing the ecological and techno-economic performance of such a system is lagging behind the advances made in the technologies themselves.
This article introduces a diagram-based approach for the quick evaluation and comparison of energy systems by using the vapor compression heat pump cycle as an example. On the basis of known technical key parameters of the heat pump cycle, transparent and highly flexible performance indicators are deduced like the relative energy cost and CO_2 savings during heating operation. The proposed evaluation concept demonstrates efficient practical use for economic and ecological technology comparison in several example scenarios. A parameter study shows the influence of key parameters in the heat pump cycle with regards to the system savings.

Keywords: heat pump, techno-economic analysis, cost savings, ecological assessment, graphical assessment;

1. Introduction

The consumer driven demand for sustainable products is steadily increasing, forcing companies to overthink their ecological impact. Therefore, companies are faced with the task to develop business models with sustainable replacements for technologies that are affecting the environment [1-2]. However, there are currently no standardized tools to give comprehensive and reliable statements about the impact of switching between technologies. This slows down the implementation process and market penetration of renewable energy systems. Comprehensible performance indicators are needed to develop a common understanding of the economic potential of switches between technologies. Furthermore, time and money constraints rarely justify in-depth system studies like a pinch analysis during pre-projects and business case development. Industrial stakeholders and consultants therefore need easily accessible tools for the quick assessment of the economic and ecological potential of new technologies for their evaluation and decision making process.

This article formulates an effective approach to compare different heating technologies. The premise is to give a clear indication for the more beneficial system by calculating its potential relative savings. The proposed method expands on considerations made by Lange [3]. It is based on observations for energy technologies in general and is then refined for vapor compression heat pump systems. Key parameters are used to customize the method for heat pump cycles and a comprehensive graph is presented that further emphasizes the practicability of the approach. The approach can be used for either economic or ecological purposes by using suitable specific costs in the calculation which is demonstrated with several example scenarios. These scenarios

E-mail address: dominik.seliger@tuwien.ac.at.

are examples for the effectiveness and comprehensibility of the relative savings as a key figure as well as the approach itself. Furthermore certain parameters are discussed to understand how these should be adapted to have positive impact on the overall relative savings.

2. Derivation of economic performance indicators

In order to evaluate and compare two different technologies the same framework must be applied: Every considered technology has the function to fulfill a certain heat demand, Q_D, in a certain time period Δt. During the defined time period Δt all considered technologies are working in a steady state, meaning that every process variable is assumed to be constant.

2.1. Comparison of two energy technologies

Any technology for heat supply causes costs mainly due to the consumption of other energy sources, Q_i. Each of these energy sources has a specific cost c_i. Therefore, the operating costs C to provide a certain heat demand Q_D are:

$$C(Q_D) = \sum_i Q_i(Q_D)\, c_i \tag{1}$$

However, most technologies only consume one type of energy to meet a certain heat demand. These technologies shall be named direct conversion technologies from this point onward. Operating costs as defined in equation 1 can be expressed for these direct conversion technologies as follows:

$$C = Q\, c \tag{2}$$

Equation 2 is also valid for technologies which use only one energy source with significant specific costs, making the costs for other energy sources negligible. Furthermore, for direct conversion technologies the efficiency η is defined as:

$$\eta = \frac{Q_D}{Q} \qquad \text{or} \qquad Q = \frac{Q_D}{\eta} \tag{3}$$

One indicator for a beneficial technology are lower operating costs in comparison to reference technologies. An easy criterion, that identifies technology A as superior to B is:

$$\frac{C^A(Q_D)}{C^B(Q_D)} < 1 \tag{4}$$

If this criterion is used to compare two direct conversion technologies, equation 2 and 3 can be used to transform equation 4 to a cost-efficiency-ratio:

$$\frac{\eta^B\, c^A}{\eta^A\, c^B} < 1 \tag{5}$$

Finally, the relative savings $\hat{S}$ by using technology A instead of B can be calculated as:

$$\hat{S} = \frac{C^B - C^A}{C^B} = 1 - \frac{C^A}{C^B} \tag{6}$$

If only direct conversion technologies are considered, equation 6 can be modified by using the cost-efficiency-ratio:

$$\hat{S} = 1 - \frac{\eta^B\, c^A}{\eta^A\, c^B} \tag{7}$$

Equation 7 shows that the relative savings for switching between any two given technologies may be calculated using only the specific costs for input energies and efficiencies, regardless of the heat demand Q_D.

2.2. Relative savings with a vapor compression heat pump system

One of the main technical parameters for a vapor compression heat pump system is the coefficient of performance, COP. In a steady state the supplied heat, Q_D, and the required work, W^{HP}, are proportional to their process variables, $\dot{Q}_D$ and $\dot{W}^{HP}$. Therefore the COP can be calculated as follows:

$$COP = \frac{Q_D}{W^{HP}} \tag{8}$$

For every vapor compression heat pump system exists an ideal reverse Carnot cycle for comparison [4] The ideal cycle is based upon isentropic changes of state in the compressor and throttle as well as upon isotherm changes of state in the condenser and evaporator. For this ideal system the coefficient of performance reaches its maximum, COP_{max}. Due to the first and second law of thermodynamics, COP_{max} can be calculated by using only the temperatures in the evaporator, T_{eva}, and the condenser, T_{con}:

$$COP_{max} = \frac{T_{con}}{T_{con} - T_{eva}} \tag{9}$$

Like most other efficiencies, the COP relates benefit to cost. However, typical values for the COP are above 1 and the range varies due to the temperature levels of the system, making a direct comparison difficult. As a universal performance indicator the second law efficiency η^{HP} is introduced. This factor compares the ideal performance, COP_{max}, to the actual performance of a heat pump system, COP:

$$\eta^{HP} = \frac{COP}{COP_{max}} \tag{10}$$

If equations 8 and 10 are combined, W^{HP} is calculated as follows:

$$W^{HP} = \frac{Q_D}{\eta^{HP}\, COP_{max}} \tag{11}$$

The relative savings $\hat{S}$ can be derivated by combining considerations analogue to chapter 2.1 with the established technical parameters of a heat pump system and. The operating costs for a heat pump system are:

$$C^{HP} = W^{HP}\, c_W^{HP} + Q^{HP}\, c_Q^{HP} \tag{12}$$

Additionally to electrical work W^{HP}, each heat pump system is supplied with a low grade heat Q^{HP} that is either waste heat or taken from the environment. Therefore Q^{HP} causes no costs in most cases, reducing the specific costs c_Q^{HP} to 0. Equation 12 is then reduced to:

$$C^{HP} = W^{HP}\, c_W^{HP} \tag{13}$$

Inserting equation 11 into 13 leads to the operating costs for heat pumps with regards to heat demand Q_D:

$$C^{HP} = \frac{Q_D}{\eta^{HP}\, COP_{max}}\; c_W^{HP} \tag{14}$$

Equation 14 calculates the operating costs based upon general key technical parameters of a heat pump system. These costs may also be compared to other systems using equations 4 and 6. For a reference system based on a direct conversion technology, equation 4 yields:

$$\frac{1}{COP_{max}} \frac{\eta^{ref}\, c_W^{HP}}{\eta^{HP}\, c^{ref}} < 1 \qquad \text{or} \qquad \frac{\eta^{ref}\, c_W^{HP}}{\eta^{HP}\, c^{ref}} < COP_{max} \tag{15}$$

Finally, the relative savings $\hat{S}$ for operating a heat pump system instead of a reference system are:

$$\hat{S} = 1 - \frac{1}{COP_{max}} \frac{\eta^{ref}\, c_W^{HP}}{\eta^{HP}\, c^{ref}} \tag{16}$$

Which can also be transformed to:

$$\hat{S} = 1 - \frac{1}{COP} \frac{\eta^{\mathrm{ref}} c_W^{\mathrm{HP}}}{c^{\mathrm{ref}}} \tag{17}$$

Figure 1 shows a graph illustrating $\hat{S}$ for higher practicability. The graph is based on the two main components of equation 16 and 17 which are a coefficient of performance, either COP or $COP_{\max}$, as well as the according cost-efficiency-ratio. Note that the term for the cost-efficiency-ratio changes with the according coefficient of performance. Therefore the use of Figure 1 is more flexible depending on which technical key parameters for the heat pump system are known.

The linear nature of equations 16 and 17 makes Figure 1 easily to use. Straight lines for a constant COP or $COP_{\max}$ can be added at will due to the following rules:

- $\hat{S} = 1$: Relative savings of 100% are only possible if the relative cost savings are 0 regardless of the coefficient of performance. Therefore any straight line has to cross the y-axis exactly at 1.0.
- $\hat{S} = 0$: For relative savings of exactly 0%, the cost-efficiency-ratio is equivalent to the coefficient of performance. Consequently, a line for a constant value of COP or $COP_{\max}$ crosses the x-axis at that value.

These characteristics strongly increase the overall applicability of the diagram since it is also possible to make rough sketches and estimations on the go. Furthermore, several approaches to use the equations 16 and 17 or Figure 1 exist, depending on the required result. Aside from calculating relative savings it is possible to show necessary technological or economic thresholds to guarantee an economic benefit.

2.3. Ecological assessments and inclusion of a pollutant tax

The operational ecological costs of technologies are mainly represented by their production rate of environmental pollutants such as CO_2. For an ecological assessment the equation system above may be used by simply inserting the specific production rate p of a pollutant instead of the specific economic costs c of an energy source Q in equation 2. This amount for the ecological costs C_{ecol}

$$C_{\mathrm{ecol}} = Q\, p \tag{18}$$

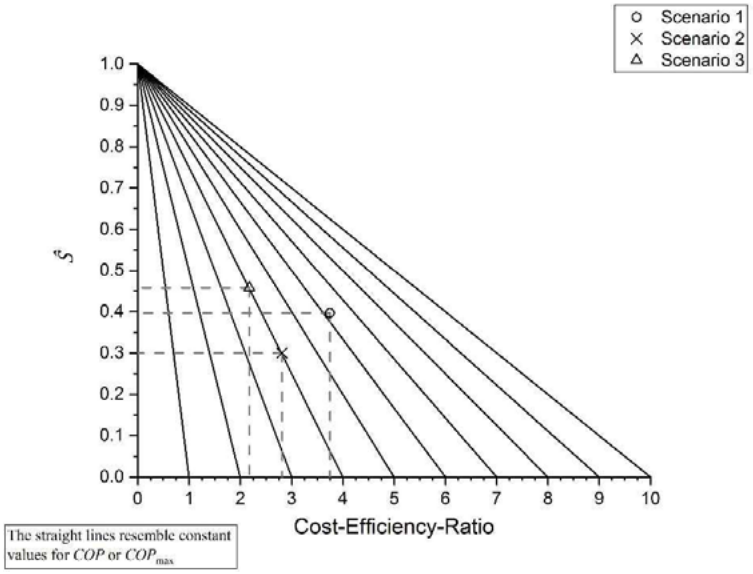

Fig. 1: The relative cost savings as a function the cost-efficiency-ratio for an array of constant $COP_{\max}$ or COP values as calculated with equation 16 or 17 respectively. The marked points show results for example scenarios given in section 3. By using the corresponding cost-efficiency-ratio, Figure 1 can be applied for equation 20 and 23 as well.

This allows the use of the same approach as shown in chapter 2.1 and 2.2 for the calculation of the relative savings in pollutant production, $\hat{S}_{\mathrm{ecol}}$, resulting from a technology switch:

$$\hat{S}_{\mathrm{ecol}} = 1 - \frac{\eta^{\mathrm{B}}\, p^{\mathrm{A}}}{\eta^{\mathrm{A}}\, p^{\mathrm{B}}} \tag{19}$$

$$\hat{S}_{\mathrm{ecol}} = 1 - \frac{1}{COP}\,\frac{\eta^{\mathrm{ref}}\, p_W^{\mathrm{HP}}}{p^{\mathrm{ref}}} \tag{20}$$

For future considerations the inclusion of a pollutant tax t might also be of relevance. By using the pollutant production rate p and the specific costs c of the energy source Q, the overall economic costs result in:

$$C_{\mathrm{econ}} = Q\,(c + p\,t) \tag{21}$$

By using equation 21 instead of equation 2, the relative economic costs savings change to:

$$\hat{S}_{\mathrm{econ}} = 1 - \frac{\eta^{\mathrm{B}}\,(c^{\mathrm{A}} + p^{\mathrm{A}}\,t)}{\eta^{\mathrm{A}}\,(c^{\mathrm{B}} + p^{\mathrm{B}}\,t)} \tag{22}$$

$$\hat{S}_{\mathrm{econ}} = 1 - \frac{1}{COP}\,\frac{\eta^{\mathrm{ref}}\,(c_W^{\mathrm{HP}} + p_W^{\mathrm{HP}}\,t)}{(c^{\mathrm{ref}} + p^{\mathrm{ref}}\,t)} \tag{23}$$

Equation 20 and 23 are of similar structure as equation 17 and therefore Figure 1 may also be used if the correct cost-efficiency-ratio is applied. However, note that equations 20 and 23 can be only applied if the used waste heat source for the heat pump, Q^{HP}, does not result in additional pollutant production.

To use this method it is necessary to know the specific production or emission rate of the considered pollutant for the used energy sources. Energy suppliers usually reference their used energy mix but not necessarily their specific impact on environmental resources. Aside from rough key figures about certain energy types it is possible to perform a system analysis for further information. Nevertheless, one of the more efficient approaches is to use tools like GEMIS. GEMIS is an open source database plus an analysis model to determine energy and resource flows. It considers the life-cycle for processes and scenarios and therefore includes secondary contributions like raw material and transportation. However, for quick calculations the GEMIS database delivers key figures for the main energy sources as well [5].

3. Evaluation of example scenarios

The set of equations derived in chapter 2 as well as Figure 1 can be used to examine possible applications for heat pumps. Depending on the requirements they may be used either to calculate the relative cost savings coinciding with a technology switch, or to determine the necessary technical boundaries for predefined minimum savings. Several predefined scenarios are analyzed in the following section to demonstrate the approach for practical applications.

3.1. Scenario 1 – comparison of a heat pump system and purchased saturated steam

The first scenario considers an industrial process that is currently supplied with saturated steam at $100\ °C$. The steam, which is bought from an external supplier at $10\ \mathrm{cent/kWh}$, provides thermal energy for an industrial dryer at constant temperature. An unused waste heat source allows a theoretical evaporator temperature of $40\ °C$ and enables the implementation of a heat pump system. The company pays $15\ \mathrm{cent/kWh}$ for electrical energy including secondary costs. Experimental data shows second law efficiencies for high temperature heat pumps between 0.40 and 0.60 [6], therefore it is safe to assume a minimum second law efficiency of 0.40. The relative cost savings are required to justify a technology switch.

To use Figure 1, the cost-efficiency-ratio and the according COP_{max} have to be calculated. Due to the fact that steam is bought and used directly for heating the dryer at a constant temperature, the corresponding efficiency is 1.

$$\frac{\eta^{\text{steam}}\, c_W^{\text{HP}}}{\eta^{\text{HP}}\, c^{\text{steam}}} = \frac{1.00 \cdot 15\ \text{cent/kWh}}{0.40 \cdot 10\ \text{cent/kWh}} = 3.75$$

$$COP_{\max} = \frac{T_{\text{con}}}{T_{\text{con}} - T_{\text{eva}}} = \frac{(100 + 273)\ \text{K}}{(100 - 40)\ \text{K}} = 6.22$$

To evaluate the relative economic cost savings, either equation 16 or the graph for $\hat{S}$ can be used. Inserting the calculated $COP_{\max}$ and cost-efficiency-ratio in Figure 1 shows that the implementation of a heat pump system instead of purchasing steam leads to relative cost savings of about 40% for the given boundaries. As shown in equation 15 the economic threshold for the implementation of a heat pump system is the equilibrium of $COP_{\max}$ and the cost-efficiency-ratio. In this particular case the specific costs for the electrical energy have to increase by approximately 66 % in order to reach this equilibrium. Furthermore, Figure 1 allows to identify the required cost-efficiency-ratio in order to meet a given relative economic saving. This procedure is shown in scenario 2.

3.2. Scenario 2 – comparison of a heat pump system and a natural gas heater

This scenario examines a heat pump system that may be used as an alternative to a natural gas heating system for a household. The gas furnace uses condensing technology and has an average fuel utilization efficiency of 0.90 [7] at a cost of $8\ \text{cent/kWh}$. Electrical power is supplied at a cost of $25\ \text{cent/kWh}$. The heat pump system must lead to relative cost savings of at least 30% to ensure a reasonable return of investment. Point of investigation is the COP.

Again the cost-efficiency-ratio is calculated first, but in regards to COP, not $COP_{\max}$:

$$\frac{\eta^{\text{gas}}\, c_W^{\text{HP}}}{c^{\text{gas}}} = \frac{0.90 \cdot 25\ \text{cent/kWh}}{8\ \text{cent/kWh}} = 2.81$$

Using the graph for $\hat{S}$, and a calculated cost-efficiency-ratio of 2.81 leads to a minimum of 4.0 as COP for any profitable heat pump system as shown in Figure 1. At this point the versatility of the diagram based approach can be demonstrated. Assuming that the heat pumps available on the market only reach a COP of 3, the relative cost savings decrease to approximately 5%, making their implementation less feasible.

3.3. Scenario 3 –ecological evaluation of scenario 2

Aside from the relative energy cost savings it is also possible to evaluate the ecological impact of a technology switch as defined in scenario 2 by using the specific CO_2 production of the energy sources. Key figures taken from the GEMIS-database show that burning natural gas emits about $250\ \text{g}_{\text{CO2}}/\text{kWh}$ whereas using electric power produces $605\ \text{g}_{\text{CO2}}/\text{kWh}$ [8].

This can be translated into a cost-efficiency-ratio as well:

$$\frac{\eta^{\text{gas}}\, p_W^{\text{HP}}}{p^{\text{gas}}} = \frac{0.90 \cdot 605\ \text{g}_{\text{CO2}}/\text{kWh}}{250\ \text{g}_{\text{CO2}}/\text{kWh}} = 2.18$$

Using the minimum COP of 4.0 as estimated in scenario 2 and the new cost-efficiency-ratio of 2.18 leads to minimum CO_2 savings of about 45% during operation as seen in Figure 1. Due to the fact that the idea to give emissions a certain economic value is gaining popularity, it is important to make these upcoming changes quantifiable. Scenario 4 demonstrates the economic impact of a tax on emissions for a change of technology.

3.4. Scenario 4 –considering a pollutant tax for scenario 2 and 3

A CO_2 emission tax of $0.01\ \text{cent/g}_{\text{CO2}}$ is introduced to study the impacts of a pollutant tax on the future profitability of the technology switch as demonstrated in scenario 2.

Considering equation 23, the cost efficiency ratio including a pollutant tax is as follows:

$$\frac{\eta^{\text{ref}}\,(c_W^{\text{HP}} + p_W^{\text{HP}}\, t)}{(c^{\text{ref}} + p^{\text{ref}}\, t)} = \frac{0.90 \cdot (25\ \text{cent/kWh} + 605\ \text{g}_{\text{CO2}}/\text{kWh} \cdot 0.01\ \text{cent/g}_{\text{CO2}})}{8\ \text{cent/kWh} + 250\ \text{g}_{\text{CO2}}/\text{kWh} \cdot 0.01\ \text{cent/g}_{\text{CO2}}} = 2.66$$

The new cost-efficiency-ratio is lower than without a CO_2 tax when compared with scenario 2. This leads to several main conclusion:

- Using the same COP as calculated in scenario 2, 4.0, leads to relative cost savings of about 33%, which is higher than without a CO_2 tax.
- With minimum savings of 30%, as suggested in scenario 2, and the new cost-efficiency-ratio, the new minimum COP is 3.8. A pollutant tax would therefore lower the technical requirements for the heat pump system.

These considerations clearly indicate, that the heat pump system is economically better when a CO_2 tax is introduced. However, this relates mainly to the higher CO_2 savings calculated in scenario 3. If the CO2 tax would be raised indefinitely, the threshold for the relative cost savings would be the same as the relative CO_2 savings.

4. Parameter study

The presented example scenarios highlight the ease of the approach. However, the key parameters are further examined to develop an understanding how the system would behave if certain inputs are changed. These considerations can also be facilitated when analyzing potentials or optimizing systems in general.

4.1. Influence of condenser and evaporator temperature on relative cost savings

In regard to vapor compression heat pumps the main technical parameters are the temperatures in the condenser and evaporator, T_{con} and T_{eva}. These temperatures determine the ideal Carnot process that is used for comparison and therefore determine the $COP_{\max}$ as seen with equation 9. To understand the influence of the temperatures, equation 9 is combined with equation 16:

$$\hat{S} = 1 - \frac{T_{\mathrm{con}} - T_{\mathrm{eva}}}{T_{\mathrm{con}}} \frac{\eta^{\mathrm{ref}}\, c_W^{\mathrm{HP}}}{\eta^{\mathrm{HP}}\, c^{\mathrm{ref}}} = 1 - \left(1 - \frac{T_{\mathrm{eva}}}{T_{\mathrm{con}}}\right) \frac{\eta^{\mathrm{ref}}\, c_W^{\mathrm{HP}}}{\eta^{\mathrm{HP}}\, c^{\mathrm{ref}}} \tag{24}$$

Equation 24 shows a linear dependence between the temperature ratio $T_{\mathrm{eva}}/T_{\mathrm{con}}$ and the relative cost savings $\hat{S}$. This is also presented with various cost-efficiency-ratios in Figure 2. Several statements can be made by analyzing equation 24 and Figure 2:

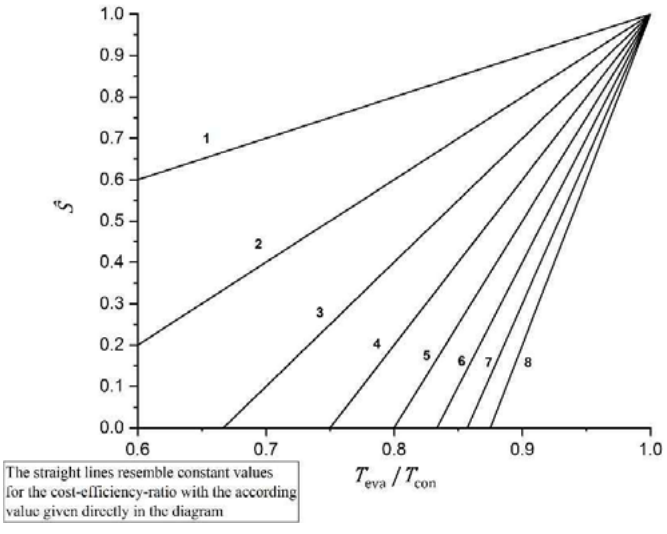

Fig. 2: Relative cost savings as a function of the temperature ratio of the vapor compression heat pump cycle for an array of constant cost-efficiency-ratios. $T_{\mathrm{eva}}/T_{\mathrm{con}} \leq 0.6$ is equivalent to $COP_{\max} \leq 2.5$ which is currently outside of feasible heat pump applications.

Several statements can be made by analyzing equation 24 and Figure 2:

- Increasing T_{eva} or decreasing T_{con} improves the relative cost savings whereas decreasing T_{eva} or increasing T_{con} reduces the relative cost savings. More specifically, smaller differences between T_{eva} and T_{con} lead to higher cost savings.
- For $T_{eva} = T_{con}$ the relative cost savings are always 100% because the utilized waste heat can theoretically be used directly and without a heat pump.
- Each cost-efficiency-ratio has temperature combinations that allow positive relative cost savings. However, the maximum profitable temperature difference between T_{con} and T_{eva} may be very small, depending on the temperature level. More specifically, higher cost-efficiency-ratios reduce the economically beneficial temperature difference.
- The same temperature difference at higher temperature increases the temperature ratio and therefore results in better relative savings as long as the cost-efficiency-ratio remains constant.
- The theoretically lowest temperature ratio is 0 which coincides with a COP_{max} of 1. A COP_{max} below 1 is therefore impossible.

4.2. Considerations about the cost-efficiency-ratio

The cost-efficiency-ratio has a significant influence on relative savings aside from the temperatures of the heat pump cycle. Any change in the specific costs or technology efficiencies leads to a change in the overall ratio. Statements about changes in the cost-efficiency-ratio can therefore be translated to each of its parameters if their position in the numerator or denominator is considered.

Relevant for considerations about the cost-efficiency-ratio are equations 15 and 16. Moreover, equation 16 can be developed into a graph aside from Figure 1 as shown in Figure 3. This allows the following statements:

- Relative savings are guaranteed when equation 16 is used and the cost-efficiency-ratio is below 1 due to COP_{max} always being greater or equal to 1. However, the regular COP theoretically may still be below 1.
- In order to have positive relative cost savings, the coefficient of performance has to be higher than the respective cost-efficiency-ratio.
- Both, an increase of the coefficient of performance or a decrease of the cost-efficiency-ratio, lead to improved relative savings. However, it is more beneficial to lower the cost-efficiency-ratio by a certain percentage, e.g. 5%, than to improve the respective coefficient of performance by the same percentage.

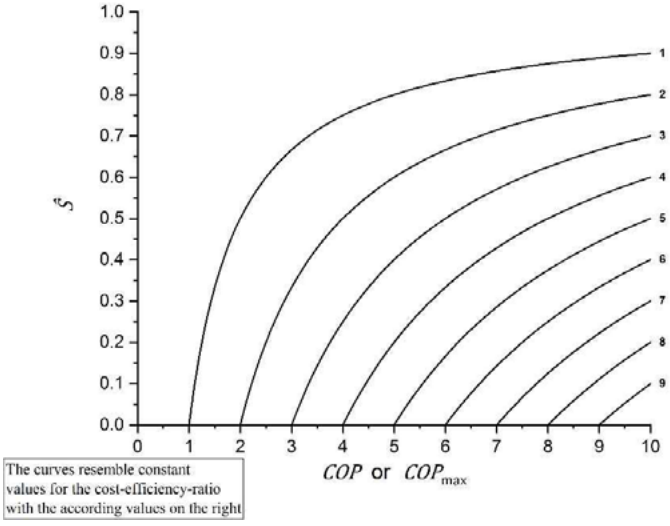

Fig. 3: Relative cost savings as a function of the COP or COP_{max} with an array of curves for constant cost-efficiency-ratios.

5. Conclusion

The derived equations are an accessible and fast tool for assessing and comparing vapor compression heat pump systems with other heating technologies. Based on general known key parameters the relative savings are a clear indicator for the more viable system. Companies may use either the established equation system itself or the graph shown in Figure 1 for estimations about economic potential and therefore for their decision making.

Aside from economic use, the here shown system may also be used for an ecological comparison. The structure of the cost-efficiency-ratio allows the comparison of any number of aspects, as long as the specific costs are of the same type. Comprehensive and reliable statements about ecological effects may be given in combination with databases like GEMIS. If taxes for CO_2-production are introduced in the future, the shown method for a fast economic and ecological evaluation will become even more useful.

Future research in the course of the project CORES (COmbind Renewable Energy Systems) will link the heat pump with other renewable energy technologies like solar thermal energy, photovoltaics and thermal energy storages for optimization in industrial applications. For further improvements the approach may be extended to include a comprehensible assessment about investment costs and amortization periods.

Abstract

Long-term studies of GSHP heating and cooling systems for six different buildings (commercial, institutional and multi-family buildings) have been conducted in Germany by SIZ energy+. Three of them are equipped with borehole heat exchangers and the others use energy piles as a heat exchanger. The paper deals with a demonstration of the investigated buildings, the measured values and performance and the obtained results that include important findings and experiences, problems encountered and possible preventive measures to avoid mistakes.
After ten years of operation it can be stated that the systems work and achieve their planned efficiency but require constant control and regulation to avoid faulty operation. An analysis of the implemented control strategies shows that, for all these heating and cooling systems, holistically coordinated control strategies that are verified during commissioning are required.

1. Introduction

The integration of heat pumps in the energy supply of buildings is an increasingly applied technology for heating but also for cooling applications. As the number of available and installed heat pump systems increases, the number of possible usable low-temperature heat sources is also increasing.

In practice, heat pumps still often function unsatisfactorily or at least sub-optimally today. The reasons for this are often insufficient connection to the low-temperature heat source and/or incorrect dimensioning of the corresponding heat exchanger. In some cases, heat pumps are not operated in accordance with the design conditions, which is often due to overoptimistic assumptions during planning, but also partly to user-dependent operating errors. In many cases, the primary energy, ecological and economic potential of a heat pump system is greater than achieved in practice. [1-3]

In Germany, the geothermal systems for heating and cooling of office and non-residential buildings have been implemented since 1990. While the first buildings were still pilot projects, most of the systems used nowadays are state-of-the-art. When the monitoring started in 2004 [1-3], there were no examinations or comparative studies from real operation dealing with the functionality and efficiency of the installed heat pumps and their system components. The advantages of a monitoring during operation have been recognized over time in practice, so that nowadays a pronounced increase in knowledge can be stated.

Within the framework of the IEA HPT Annex 52, the Steinbeis-Innovationszentrum (SIZ) energie+ is investigating the interaction between heat pumps and geothermal borehole heat exchangers as well as energy piles using six different buildings (commercial, institutional and multi-family buildings) in a long-term monitoring period of up to > 10 years. The aim is to obtain and document reliable knowledge about the actual

E-mail address: franziska.bockelmann@stw.de.

performance of the buildings with regard to energy consumption, user comfort and operation. Such measurements can also be used to gain insight in how the various system components and control strategies affect overall performance, to identify best practices, design and installation issues that lead to poor performance and to give guidance on how unanticipated consequences of the design can be partially or totally avoided.

For the majority of the examined systems, errors have been analyzed and rectified so that operation-as-planned could be implemented. Subsequently, optimization measures were carried out with regard to a more efficient operation of the geothermal heat storage system in heating and cooling mode, where it was feasible.

2. Monitoring buildings and systems

Within the framework of a "low-level monitoring", four office buildings as well as a school and a multi-family house are measured and analyzed more precisely (Table 1). The six buildings are newly constructed buildings in different locations in Germany. Three building are equipped with borehole heat exchanger and the other three with energy piles, which serve as heat sources for the heat pump system.

The year of construction and commissioning of the buildings took place in the years 2002 to 2016. However, most of the measurement data is not available from the beginning of the building's use. The buildings will be evaluated in the period from 2006 to 2018. For some buildings, however, the data is only available since 2011 or 2017 (commissioning of the building or data transmission). The geothermal systems are integrated in the buildings for heating via a heat pump and for cooling in free cooling mode and via a reversible heat pump [1,3].

The energy concepts for all buildings contain the combination of floor heating or another low-temperature system to heat the building with a heat pump. In the building, heat and cold are distributed resp. transferred via concrete core activation and ventilation systems. In some buildings, high-temperature distribution systems with convectors or radiators are implemented to cover the peak loads of the heating. These building are either connected to the district heating network or use a gas condensing boiler [1,3].

Concerning the school, it is necessary to add, that in addition to the energy piles, a so-called "Agrothermiefield" was installed beneath the sports field. Agrothermie is basically an area collector, that is installed in a new and innovative process using a special plowing technology. The pipe system is plowed with a newly developed sword plow up to 2 m depth under the sports field of the school.

As part of the monitoring of the six buildings, all relevant data will be collected in order to be able to describe the buildings and their plant technology with sufficient accuracy. The measurement concept provides the recording of all essential heat flows and electricity consumption, so that a balanced assessment including the individual producers and consumers is possible.

For older or already commissioned buildings, additional measuring equipment had to be installed. For the other buildings, the monitoring and measuring concept was already defined during the construction phase so that the data can be obtained directly from the system control. For reasons of cost and time, the additional equipment was installed on top of the existing system technology in such a way that data access was given without intervening the building services or structural changes. Depending on the requirements, this could be achieved through the use of mobile digital measurement technology (additional heat meters with temperature and volume flow sensor at relevant points). The measured datasets mainly were recorded on-site either by a computer or by the building management system. Via remote access, the recorded data could be retrieved.

The measured values are recorded every 15 minutes so that parameters of the system components can also be mapped. The measurements and analysis include among other things operating modes, control strategies, the ground source heat extraction and injection, fluid temperatures as well as seasonal performance factors.

Depending on the building, the monitoring extends over two to more than 10 years, so that at least two heating and/or cooling periods are available for evaluating the performance of individual system components and for determining characteristic values.

Table 1. Buildings, heat exchanger systems and supplied systems of the buildings investigated in the monitoring

	Building (anonymized building code)			Ground heat exchanger		Heat supply system
Borehole heat exchanger	AOV Office building	Year: Net floor area: Heating load: Cooling load: Add. heat source:	2010 6750 m² 262 MWh per year 62 MWh per year Gas boiler	Quantity: Length of borehole: Overall length: Extraction / Injection:	25 100 m 2500 m 174 / 206 MWh per year	radiator concrete core activation ventilation

3. Monitoring

In addition to technical practicability, energy as well as ecological and economic aspects play a central role in the decision for or against a particular heating or cooling system. When comparing geothermal systems with

conventional systems, the question arises as to whether they can guarantee a similarly high level of thermal comfort in buildings and what usable advantages they offer with regard to the above-mentioned aspects.

In the following sections, the monitoring results of the six buildings and systems are used to discuss energy yields and system efficiency as well as system performance.

Some of the systems had already been in operation for several years before they were analyzed in more detail as part of this project. Therefore, in some of the buildings and plants faults were hidden for a long time and were only discovered during monitoring and corrected as far as possible. The measurement results reflect the fault detection and correction as well as the subsequent operational optimization and therefor vary considerably from year to year in some cases.

The results documented in the following are therefore not target or guideline values for other projects, but rather are intended to show optimization successes and potentials as well as possibilities and limits of the geothermal systems.

3.1. Seasonal performance factor

In order to ensure a uniform basis in the evaluation of the heat pump performance, the boundaries for the calculation of the Seasonal Performance Factor (SPF) are set in advance in according to the boundaries defined by SEPEMO [4]. The boundaries can be found in Figure 1.

In the evaluation and comparison of the monitored plants, only SPF2 is described more detailed in this paper. In addition, depending on the available measurement data, the heating and cooling cases are considered separately, so that a seasonal performance factor is determined for both heating and cooling cases.

$$SPF\,2 = \frac{\text{thermal energy of heat or cold supply of the heat pump and free cooling}}{\text{electrical energy of the compressor of the heat pump and circulating pump on earth side}} \quad (1)$$

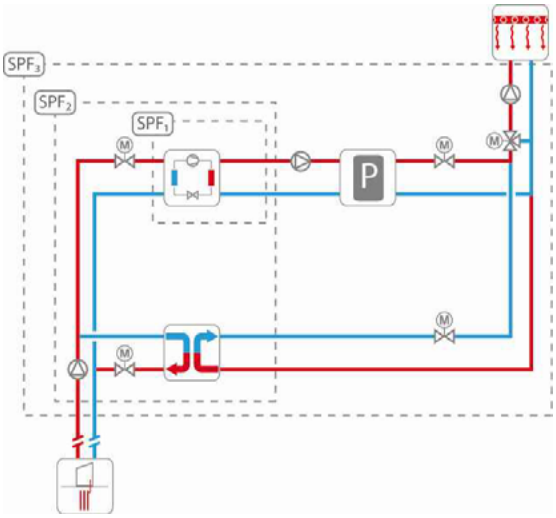

Fig. 1. Boundaries for the calculation of the seasonal performance factor

The seasonal performance factor of heat pumps, free cooling and cooling machines vary widely in their magnitude. From a primary-energy perspective, heat pump operation with a SPF greater than 3 is considered efficient. In active cooling mode, the SPF should reach a value greater than 2.5. Free cooling operation is particularly efficient. Here, electrical energy consumption on the generator side is only required for driving the circulating pumps of the geothermal system. With correct dimensioning and mode of operation, SPFs of 20 to 50 – or higher - can be achieved [1].

With seasonal performance factors of less than 3, the operation of some of the monitored plants was not as efficient as planned when the monitoring started. Within the scope of the monitoring, the systems and the operation could be optimized to such an extent that all plants achieve seasonal performance factors between 3

and 6 (Figure 2 and 3). Larger leaps in the seasonal performance factor, e.g. in the energy pile system of the VGH or the GEW system, are usually due to system optimizations or hydraulic changes. Causes for slight fluctuations, such as in the energy pile system of the EFB building, are, for example, due to varying requirements depending on the weather as well as varying underground temperatures. A decisive influence on the seasonal performance factor of the cooling system is the proportion of the very efficient free cooling operation in relation to the active cooling mode.

The comparatively low seasonal performance factors of the borehole heat exchanger system of the GEW building with almost optimized operation are related to the deviating objective. The building is heated and mainly cooled by the geothermal system. Only the supply air is cooled to room temperature in summer by an independent system. In order to cover the cooling loads from the building even on extreme summer days, the heat pump is reversible and can therefore also provide active cooling during the summer. Since the GEW borehole heat exchanger system, unlike the other systems, is not designed primarily for basic but also for peak load coverage, the reversible heat pump run a large part of the operating time in less efficient partial load operation. Furthermore, this heat pump is not a standard product and was individually designed at the time. According to the age and the construction method, seasonal performance factors > 3 are not to be expected.

The results of the EFB, AOV, KON and WGG buildings show that targeted quality assurance and operational monitoring pay off right from operational start-up. Up to now, seasonal performance factors of up to 5 have been achieved here. (Figure 2 and Figure 3) It should also be noted that operational monitoring is also helpful after a calibration phase. Thus, it can be stated that after the end of the actual research project and the optimization phase (2010/2011), the seasonal performance factor at the VGH fell below 3.0 again. The faults here relate to the plant technology.

On the basis of the evaluations of the buildings and heat pump systems, it can be summarized that (Figure 2 to 5)

- the majority of the buildings meet the consumption calculated in the planning and there are no major user-dependent changes,
- the heat pump systems are generally reliable and efficient,
- for the heating mode, seasonal performance factors larger than 3 are achieved for most systems. SPF over 5.0 were determined for two systems. For one building, the seasonal performance factor is below 3.0 according to the measured data, which is due to the design and the plant itself.
- for cooling operation, seasonal performance factors of around 4 can be achieved for most systems if there is a priority active cooling process (reversible heat pump). The free cooling operation of the EFB system alone leads to seasonal performance factors of around 40 in cooling mode.

The reasons for the low seasonal performance factors include, among others

- the continuous operation of the system (running times),
- non-coordinated operating strategies as well as heating and cooling curves between the operating states of heating, active cooling and free cooling, and
- changed setpoints, e.g. outdoor air temperature as the starting value of the cooling mode, were not reset to standard mode after changes in the settings due to defective equipment, and
- faulty measurement.

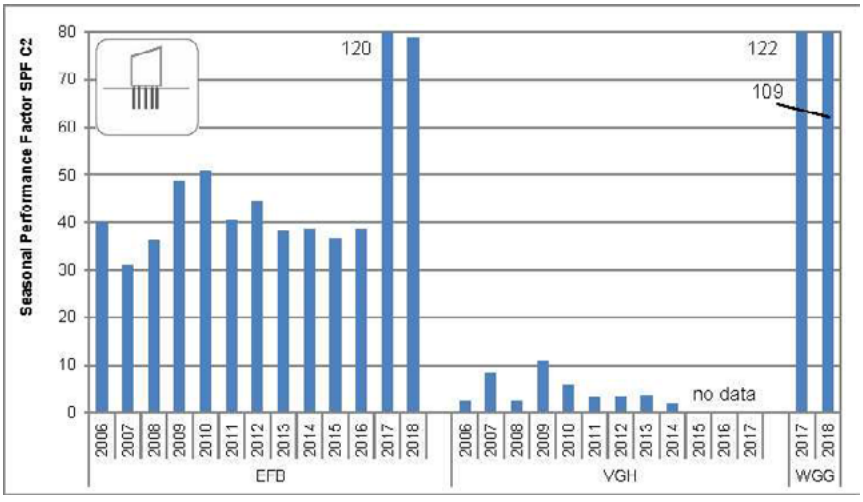

Fig. 5. Seasonal performance factors cooling for the monitored buildings with energy piles

3.2. Heat extraction and injection

The specific annual energy yields for the various heat sources and heat exchanger systems are shown in Figure 6 per meter of borehole heat exchanger or energy pile.

The largest specific energy extraction occurs in the KON and WGG. In one year up to 170 kWh/(m a) and 107 kWh/(m a) are extracted from the ground. The AOV and GEW have the highest specific heat injection. A maximum of 120 kWh/(m a) and 96 kWh/(m a) are injected into the ground. The average specific heat extraction for borehole heat exchangers is 80 kWh/(m a) and for energy pile systems 50 kWh/(m a). The values for heat injection are 75 kWh/(m a) for the borehole heat exchangers and around 34 kWh/(m a) for the energy piles.

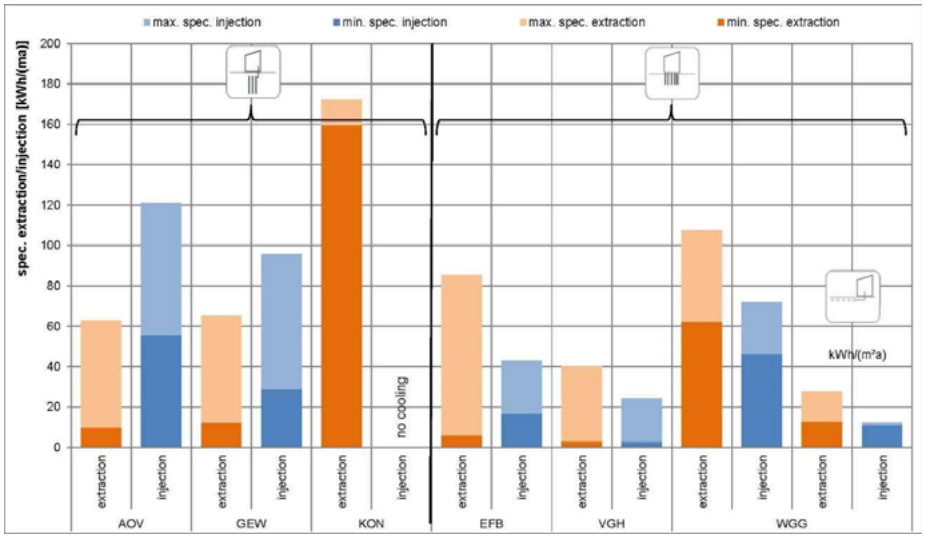

Fig. 6. Specific heat extraction and injection of the monitored heat exchangers

Ground storage systems are planned with the aim of achieving a constant temperature level in the ground over the years and a permanently stable operation for approximately equal yields of heat extraction and injection. The energy yields recorded as part of the monitoring vary from year to year, mainly because of the system optimizations, but also as a result of the influence of the weather and the resulting varying consumption. Overall, the extracted heat corresponds approximately to the planned values. The heat injection, on the other hand, deviates considerably from the planned values for some plants. The reasons for this are faults in current operation or an excessively high temperature level in the ground for free cooling operation as a result of operating faults immediately after start-up. In order to achieve a constant temperature level over the years, some systems require a higher heat extraction than heat injection due to higher than expected temperatures of the underground.

For inner-city areas, monitoring has shown that less deep systems, such as energy piles, which are used as seasonal storage systems, usually require a higher heat extraction rate than the heat injection. Due to the high density of buildings and the high degree of surface sealing, the near-surface layers in inner-city areas are relatively warm. With a well-adjusted balance between heat extraction and heat injection, the temperature level of the heat sink is usually too high for free cooling operation in summer.

For the AOV, it can be noted that the heat injection is noticeably higher than the heat extraction (in 2015: 3.5 times). A well-adjusted heat balance is therefore not available, despite an almost 100% heat supply via the heat pumps. It is therefore essential to ensure that more heat is extracted from the ground or that significantly less heat is injected into the ground due to server cooling. On the basis of the total energy quantities, it can be seen from the annual balance sheets that since 2011 significantly less heat has been extracted than assumed in the planning / design. It can also be seen, however, that the optimizations and modifications to the heat pump have increased heat pump operation and have thus also enabled significantly more heat to be extracted from the ground since 2013. The heat injection could be significantly reduced by outsourcing the servers and the associated server cooling (2017). In 2018, a good balance between heat injection and heat extraction can now be established. (Figure 7)

In the case of the GEW building, heat extraction was significantly increased from 2009 onwards. For the years 2009 to 2018, heat extraction is between 230 and 330 MWh/a. During the years 2011 to 2017, reduced active cooling mode and an increased proportion of free cooling will lead to a reduction in heat injection into the ground. During this period, the heat injections were between 220 and 270 MWh/a. In 2018, 405 MWh/a were injected into the ground as a result of the further increase in cooling machine operation. (Figure 7)

For the EFB, it can be noted that around two times more heat is being extracted from the ground than being injected during the summer. The aim is to cool down the underground and enable a higher proportion of free cooling in summer. In 2009, the heat extraction of 142 MWh/a was almost three times higher than the heat injection which was 53 MWh/a. Both heat extraction and heat injection were significantly reduced in the years

2013 to 2018 due to errors in the heat pump and control problems and amount to 10 MWh/a to 33 MWh/a for extraction and 28 MWh/a to 55 MWh/a for injection. (Figure 8)

At VGH, the planned heating and cooling operation was implemented during the monitoring process until 2009. From 2014, heat extraction from the ground was reduced to between 5 MWh/a and 43 MWh/a due to a new control system and new software for the heat pump. No scheduled operation has been restored since the software changeover. (Figure 8)

The alternating heating and cooling operation of the WGG requires a coordination between the Agrothermie and energy piles. For the years 2017 and 2018 the energy piles have a heat extraction of 63 MWh/a and 107 MWh/a as well as a heat injection of 46 MWh/a and 72 MWh/a. The extraction and injection values of the Agrothermie in the same period are 56 MWh/a and 121 MWh/a for the extraction and 48 MWh/a and 53 MWh/a for the injection. Since beginning of the building's use, adjustments have been made to the control strategies of the two sources on the basis of the brine entry and exit temperatures of the geothermal low-temperature heat sources and their heat exchangers. The inefficient year-round continuous operation of both sources (parallel operation), which was implemented at the beginning, was replaced by a prioritization (addition / removal of one source). To increase the efficiency, the two sources have been controlled separately in the winter months since the changeover. The changeover is based on the higher brine outlet temperatures per source system. During the heating period, the heat pumps primarily use the energy piles (higher brine temperature level). To ensure that the piles are kept frost-free, they are only operated up to a brine entry temperature of > 3 °C. Afterwards the heat is removed from the Agrothermie. A reverse priority is planned for the cooling period. The Agrothermie will act as a priority and then the bored piles will be controlled to ensure, among other things, regeneration of the energy piles.

For an assessment of the efficiency of the Agrothermie, the energy piles were deactivated during the heating period 2018/2019. The control adaptation serves to determine the heat injection and extraction in a heat pump system with the sole heat source of an Agrothermie. It has been shown that the field can serve as the sole source for the heat pumps up to and including December (and beyond). For the future operation of both heat sources, however, it must be ensured that there is a balance in both sources and that the soil is overcooled neither in the Agrothermie nor in the energy piles. Regeneration is necessary in both cases. (Figure 8)

The KON system is running according to plan and without any incidents. The heat extraction amounts to about 150 MWh/a in the years 2017 and 2018. (Figure 7)

The success of the optimization measures and error corrections carried out can be clearly seen in the buildings. Nevertheless, a well-adjusted balance was not fully achieved.

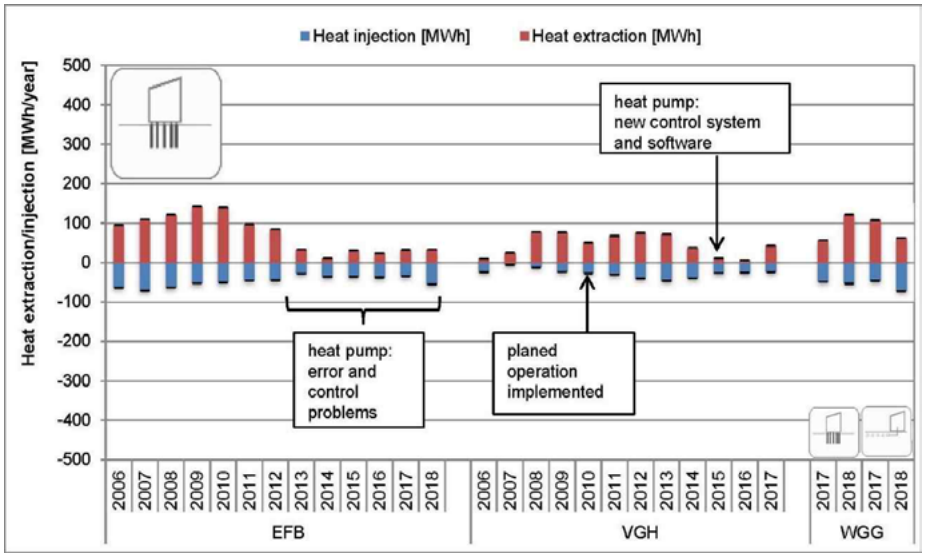

Fig. 8. Annual heat injection and extraction of the energy pile systems

4. Operating experiences

The experience gained from the project monitoring shows that it is possible and sensible to integrate geothermal systems into innovative energy concepts for office buildings as well as schools and multi-family houses. However, a regulation phase is required during which the direct interaction between the geothermal system, the building, other thermal conditioning systems and not least the users is optimized. A lack of experience of contractors and plant operators often significantly prolongs this regulation phase. Compared to conventional heating and cooling systems, geothermal low-temperature sources are subject to a special feature with regard to the detection of system and operating faults due to their inertia and the interaction of base and peak load components. Without targeted operational monitoring, errors due to system inertia remain unnoticed until defined operating parameters can no longer be achieved. As this usually only happens after years, the ground is -in the worst case- already significantly undercooled or overheated. Once the fault has been rectified, the ground may no longer be usable for the intended operating mode - heating or cooling - for a longer period of time. The ground must first be thermally regenerated.

Many of the results presented in this paper have been generalized, as they have not only been found in individual buildings. In one building, the points listed may have been more serious/amplified than in another. We would like to consider the following statements generally valid, although they should also be checked/monitored for all buildings in the future.

Essential points of the performed defect and error removal at the buildings and plants examined by measuring technology and the resulting problems were among others:

- Hydraulic investigation: like incorrect installation of valves and check valves or opening valves without heating or cooling medium.
- Defects in dimensioning and design: system components dimensioned / designed too small, e.g. plate heat exchanger, circulating pumps.
- Control of the geothermal system: poorly coordinated control strategies or circulation pumps running 24/7.
- Coordination of the individual exchange systems and components.
- Faulty operation is usually not due to the geothermal system, but to the technical and operational integration of the single system modules in the complex overall system.
- Errors in design and implementation but particularly faults in control and operation.

Important findings and experience:

- Heat is drawn from other sources instead of using the ground (district heating, internal loads, etc.). In some buildings, an unequal energy balance in the ground was recorded. In addition, other installations did not function reliably, so that no continuous and controlled heat extraction and injection into the ground could be recorded. This led to overheating or cooling of the ground. The supply of district heating or similar must be limited exclusively to covering peak loads.
- Faulty operation: under- or overheated soil, free cooling not possible and temperature level between heat sink and building often not tuned. Adaptation of heating and cooling curves as well as control and release limits of heat pumps, rev. heat pump and free cooling during operation is mandatory.
- Adaptation of room set points and general set points to the actual boundary conditions.
- Control and recording of the function of a building combined with installation of geothermal system is important, it is not a system that works for itself.
- Constant control required: Changes in the operation modes will be forgotten to reset.
- Slow system →late fault detection, long-term consequences.

Fault prevention:

- "Keep it as simple as possible" – simple energy concepts with simple systems and modules are needed.
- Quality assurance during the construction phase as well as comprehensive final inspection and commissioning after completion.
- Improved and early integration of geothermal systems into building concept and control strategies.
- We have to talk! Consultation between architect, building services planner and geothermal planning.
- Monitoring:
  By monitoring the operating condition of most buildings, it is possible to prove that they are not in accordance with the design. For this reason, error analyses and error corrections are necessary at the beginning of monitoring in order to transfer the buildings to regular operation. Only then can the operating data be used for the objective of the project and the actual measurements and evaluation can begin.
  - Minimum measurement equipment for monitoring of operation.
  - Monitoring of operation to detect and eliminate performance faults >> adjust operation to real boundary conditions.
  - Monitoring of annual energy amount (heat injection and extraction) as well as brine temperatures.

5. Conclusion

In addition to reducing the energy requirements of buildings, the sustainable (e.g. CO_2-neutral) coverage of energy requirements is a focus of research and development. From the perspective of the use of regenerative energies and energy-efficient construction, in recent years, the ground has increasingly been integrated into energy concepts as a supplier of heat and cooling in conjunction with a heat pump for the heating and cooling of modern office and administration buildings as well as multi-family houses. Heat pump technology will therefore continue to play an important role in the future supply of heat and cooling. In order to exploit the potential of this energy supply variant as efficiently as possible, the choice of a low-temperature heat source and the most suitable heat exchanger for the respective application is of decisive importance.

The results from the research work and the scientific monitoring of the projects, as well as their implementation in practice—presented in the paper—show that it is generally possible and sensible to integrate ground-coupled heat pumps into innovative energy concepts. By monitoring six buildings and their geothermal systems for more than 10 years, it has been shown that, for a successful and permanent operation of energy pile and borehole heat exchanger systems, a high-quality standard has to be maintained during planning, implementation and operation.

It also becomes clear that it is not only a harmonious energy concept and innovative plant technology that lead to an energy-efficient building. Even with detailed, careful planning, malfunctions often occur during operation, which can cause rising energy consumption or cause discomfort. For this reason, quality assurance (operational analysis and optimization) is of crucial importance for ground-coupled supply concepts, especially in the first years of operation and beyond the project phases. This is the only way to ensure that buildings and systems achieve their planning objectives and long-term functionality, as well as progress in system energy efficiency and user comfort. For all heating and cooling systems in this study, it was found that holistically coordinated control strategies are required, and these must be double-checked and monitored during operation

until regular operation is achieved. In cooperation with the building management, possible errors and optimization potentials could be identified step by step, the operation of the systems optimized and the balancing phase shortened. Most of the considered buildings and their ground-coupled heat pumps could be brought into operation as planned and now operate efficiently with an SPF H2 between 2.5 and 6 and in cooling mode between 4 and greater than 100 (depending on the proportion of free and active cooling). The results also show that there is generally no significant difference in operation and performance between a borehole heat exchanger and an energy pile.

In general, it should be stated for all buildings that a balancing phase and continuous monitoring of the injection and extraction quantities should not be neglected. As found in earlier monitoring projects and also in the buildings currently under investigation, it is only possible to detect errors and inconsistencies which have a decisive influence on the operation of the plant through long-term monitoring. Continuous monitoring, adjustment and maintenance is therefore necessary to ensure the intended operation of the plant.

Acknowledgements

The research projects (032736A, O3ET1024A and 03ET1605) were funded by the German Federal Ministry for Economic Affairs and Energy. We would like to thank all building owner and operator for their help and support as well as providing measurement data and information about the monitored buildings.

Abstract

Recently, the development of hybrid and electric vehicles has been promoted. Along with this, since the impact reduction for cruising distance and the securing of the heat source are problems, changes are also required for the air conditioner. Therefore, high efficiency of the air conditioning system by improving efficiency of the heat exchanger has become more necessary. However, due to frost formation of the outside heat exchanger in a cold climate region, increase of pressure drop and decrease of heat transfer rate are supposed to be an application difficulty of HP systems.

The objective of this study is to analyze the mechanism of frosting phenomenon in a fin-less heat exchanger. This is intended to clarify the advantage in terms of frost strength and defrosting performance of a fin-less heat exchanger.

In this research, the frost and defrost multi cycle experiment are established and the qualitative characteristics are investigated. Through observation of frost layer growth in the continuous experiment, ice column growth such as initial ice column diameter and ice column distance is grasped and influence of wettability on ice column growth is also confirmed.

1. Introduction

Currently, as a power train alternative to gasoline and diesel vehicles in the automotive industry, the development of hybrid and electric vehicles has been promoted. Along with this, since the impact reduction for cruising distance and the securing of the heat source are problems, changes are also required for the air conditioner. Therefore, high efficiency of the air conditioning system by improving efficiency of the heat exchanger and changing to hat pump system has become more and more necessary. However, due to frost formation of the outside heat exchanger by using in the cold climate region, increase of pressure drop and decrease of heat transfer rate are expected to be a problem on HP systems.

Multi-flow type heat exchanger having a corrugated-louvered fin is the mainstream of the heat exchanger for a vehicle, and the fin and tube miniaturization is progressing in order to improve the performance. Thereby, since the retention amount of the condensed water or melting water between the fins increases, frost strength and defrosting performance is feared to be reduced. As improved method for these problems, fin-less type heat exchanger has been proposed to prevent the retention of condensate. This study is to analyse the mechanism of frosting phenomenon in fin-less heat exchanger, it is intended to clarify the advantage in terms of frost strength and defrosting performance fin-less heat exchanger for the current heat exchanger.[1)-3)]

2, Methodology

2.1. Experimental Apparatus

Fig.1 is a schematic diagram of experimental apparatus. Experimental apparatus is composed of constant temperature and humidity air chamber, blower, orifice flow meter, test section and the duct. The air controlled by temperature and humidity from the chamber, is flowing into the test section by the blower and then returned to the chamber. Air temperature and humidity before and after the test section is measured by the temperature and humidity sensors. In addition to the area of frost layer, diameter and interval distance of crystal columns were measured by using an image processing. Experimental system is almost same as previous paper.(paper number) To establish the defrosting condition, the hot water heating is adopted and its system is shown in Fig.2.

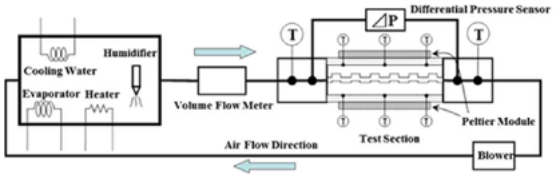

Fig. 1. Schematic of Experimental Apparatus

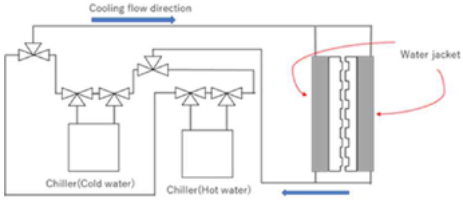

Fig. 2. Circuit diagram including Water Jacket (Defrost)

2.2. Test Section

Fin-less heat exchanger has a shape like Fig.3. In this study, we focus on the air side passage, and a test section focusing on only one flow path is prepared as shown in Fig.4. Test section has a periodic convex-concave shape as shown in Fig.5, and the size of each part is defined as shown in Fig.6.

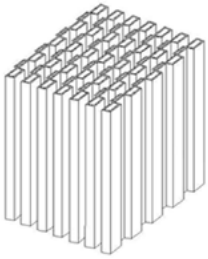

Fig.3. General View of Heat Exchanger

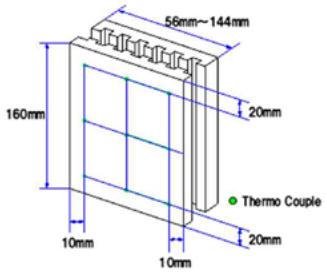

Fig.4. Test Section Plate

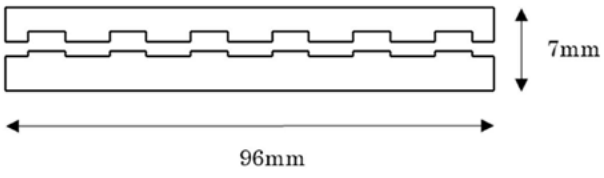

Fig.5. Flow Channel of Test Section

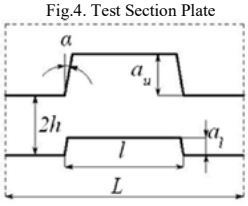

Fig.6. Detail of Flow Channel

2.3 Experimental methodology and condition

First, air conditions in the air chamber are adjusted to the experimental aimed value as shown in table 1. Turn off the blower after confirmation of the steady state, and the test section was cooled down to a set temperature. The experiment started after reaching the set temperature, and to measure the temperature, humidity and pressure drop across the test section until channel blockage, and the state of frost growth was taken by camera. Then, the test section was removed, and frost weight was measured. Air flow rate decreases in accordance with frost growth, however the blower output was fixed. Design parameters of test section are shown in Table 2.

After the end of each experiment, the height of the frost layer was taken by camera from the top of test section, and the height of the frost layer was measured. The captured image can be incorporated into image processing and analysis software, and then the height of frost layer is measured.

Table 1. Experimental Conditions

Number of convex-concave	N	—				6	
Contact Angle (Wettability)	-	deg		60~90		~10	150~

3. Result and Discussion

3.1. The heat transfer rate and pressure drop

The channel blockage time is the time until the air flow rate becomes zero or the increase rate of the approximate curve of the air flow rate becomes zero.

The purpose of the experiment was to clarify the effects of the height of the convex part and the surface treatment, focusing on the pressure loss and the amount of heat absorption, in the air flowing through the test section simulating a row of concave and convex plate. Obtained experimental result is substituted for the following equation and the heat transfer rate is calculated.

$$\dot{Q} = \dot{Q}_s + \dot{Q}_l = \dot{m}_a C_p \Delta T + \dot{m}_a \Delta W (\hbar_{fg} + \hbar_{fg}') \quad (1)$$

h_{fg}: Latent heat of condensation h_{fg}': Latent heat of solidification

However, since the amount of water whose state changed from water to ice is unknown from the experimental results, Equation (1) is calculated on the assumption that all the water amounts obtained from the absolute humidity difference are frozen instantly.

3.2. The heat transfer rate of each flat plate

This experiment consists of 2 cycle frost and defrost experiment. The result of the convex-concave flat plate with different heights and the wettability is shown from Fig.7. to Fig.11. Fig.12. and Fig.13. show total heat flow rate.

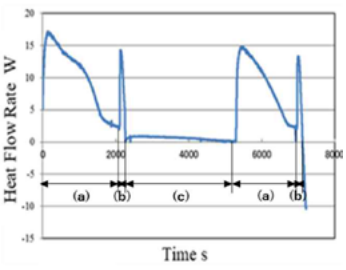

Fig. 7 Heat Flow Rate of No.1 Plate

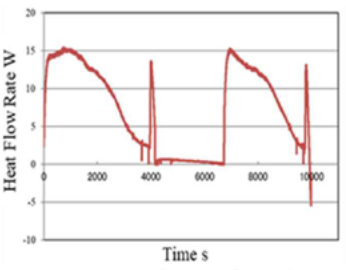

Fig. 8 Heat Flow Rate of No.2 Plate

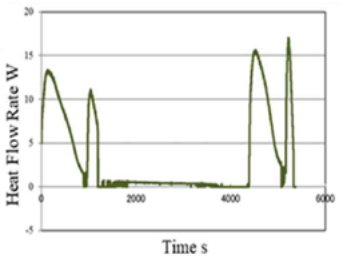

Fig. 9 Heat Flow Rate of No.3 Plate

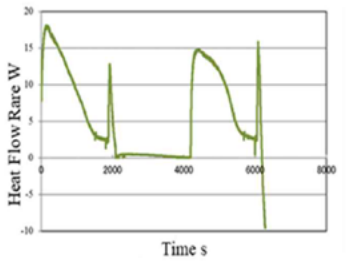

Fig. 10 Heat Flow Rate of Hydrophilic Surface

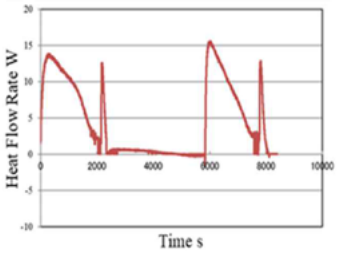

Fig. 11 Heat Flow Rate of Hydrophobic Surface

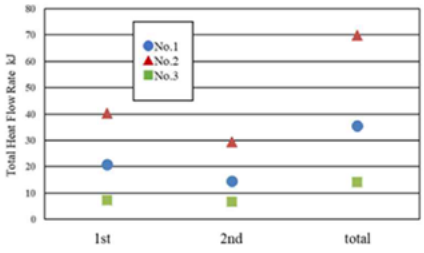

Fig. 12 Total Heat Flow Rate (Comparison with Convex Height)

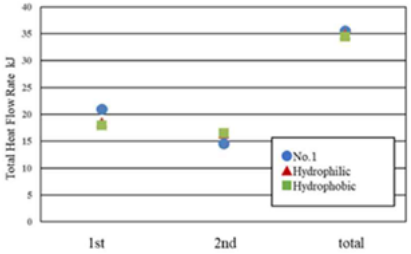

Fig. 13 Total Heat Flow Rate (Comparison with Surface Condition)

From Fig. 12, No.2 experimental convex-concave plate having the lowest height achieves the highest heat flow rate. Also, from Fig.13, the surface treatment (difference wettability) does not have the clear effect on heat flow rate.

3.3. Blockage arise time of each experimental convex-concave plate

The channel blockage time is the time until the air flow rate becomes zero or the increase rate of the approximate curve of the air flow rate becomes zero. Fig.14. to Fig.22. show that the pressure drop of second cycle compared with height and wettability as the parameter.

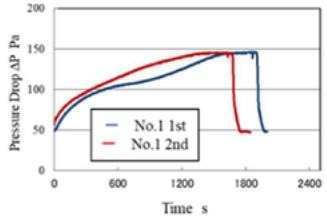

Fig. 14 Pressure Drop of No.1 Plate

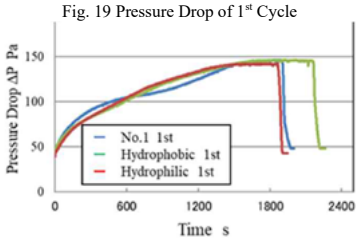

Fig. 21 Pressure Drop of 1st Cycle

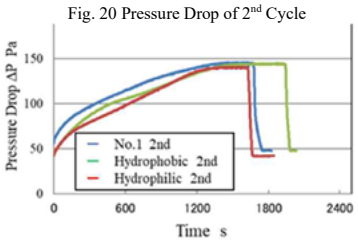

Fig. 22 Pressure Drop of 2nd Cycle

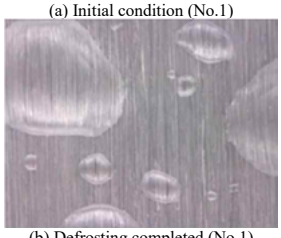
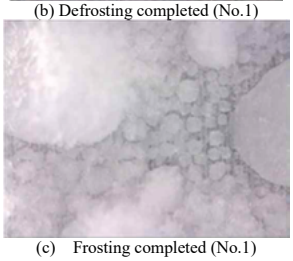


Each test piece plates, second cycle experiment is earlier to close as shown from Fig.14. to Fig.20. Comparison is made by wettability; the hydrophilic plate is earlier to close than other test pieces (Fig.21 and Fig.22).

3.4. Observation of Frost Crystals Growth



By changing the one side of the aluminium plate to acrylic plate, the test section was visualized. After frost crystals appear, the interval distance and diameter distance were measured. Fig.23. is shown No.1 plate, Fig.24. is shown hydrophobic plate and Fig, 25. is shown hydrophilic plate.

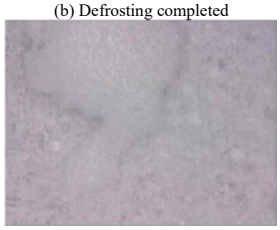

Fig.24. Observation of Frost Crystals Growth (Hydrophobic)

(a) Initial condition

(b) Defrosting completed

(c) Frosting completed (Hydrophilic plate)

Fig.25 Observation of Frost Crystals Growth (Hydrophilic)

The air flows from right to left on test piece. The hydrophilic test section has different trend to compare with other test pieces. In the first cycle, it is confirmed that droplets are generated like the other test pieces and ice crystals grow from there. However, in the second cycle, it is confirmed that the frost crystals are growing as they were without small droplets coalescence each other. Moreover, after the defrosting is completed, the generation of droplets is observed in other test pieces, but this hydrophilic test piece is not so clear as compared with the other test pieces. Much more in detailed observation movies will present in conference.

Next, the initial crystal column diameter and ice column interval are measured using image processing in the same manner as the frost layer area measurement for the frost column in each channel taken by frost layer growth observation. The initial crystal column diameter is measured when the formation of frost columns is confirmed growing with ice droplets as the nucleus. The number of ice droplets is counted for the crystal interval, and the interval is defined as the distance between crystals assuming that it is uniformly distributed in an image area. However, since it is difficult to count the number of ice droplets in the second cycle of hydrophilic test piece, the distance between the ice drops that could be confirmed is taken as the ice column interval. The future task is to improve the accuracy of the measurement method of ice column diameter and ice column interval. The measured ice column diameter and ice column interval are summarized in Table 3.

Table 3. Various amounts of initial frost crystals forming

Hydrophilic	0.013	0.054	0.007	0.036

3.5 Analysis of frost layer growth

The growth process of the frost layer is classified into “Crystal growth stage”, “Frost layer growth period”, and “Frost layer full growth stage”. Crystal growth stage: Needle-like crystals are generated with ice droplets as nuclei, forming crystals, forming a frost layer with a large porosity and rough surface. Frost layer growth stage: Side branches occur on the side of the frost column, filling the voids, forming a frost layer with a small surface roughness and a flat surface The calculation is based on Yamashita's model[7], which is obtained by multiplying a constant to Tao et al [6]. Water vapor transport through the frost layer considered to be a porous layer and is divided into a frost layer density increasing component and a frost layer height increasing component that diffuse inside the frost layer according to the concentration gradient. As mentioned, using analysis method is almost same as previous paper[4]. Here important key equations[5)-8)] are summarized as below .

$$(\delta L_f/\delta t) = C_2 \times (h_D / \rho_I) \times (X_a - X_{fs}) \quad (2)$$

$$(\delta d/\delta t) = C_3 \times 2 \times (h_D / \rho_I) \times (X_{\ddot{y}} - X_I) \quad (3)$$

$$T_Y = k_\alpha \times T_\alpha + (1 - k_\alpha) \times T_w \quad (4)$$

$$\rho_f = \frac{\int_0^{Lf} [\frac{\pi}{4} d^2 \rho_I + (l^2 - \frac{\pi}{4} d^2) \times \rho_a] \times dz}{l^2 \times Lf} \quad (5)$$

h_D = Mass transfer coefficient [kg / m^{2}sΔX] , X_{fs} = Absolute humidity of Frost Layer Surface [kg / kg´] X_f = Absolute humidity of frost layer [kg / kg´], k_a ・ C_2 ・ C_3: Constant , X_a = Absolute humidity of air [kg /kg´] d = Crystal column [m] , X_l = Absolute humidity crystal column [kg / kg´]

$$\dot{m} = \dot{m}_d + \dot{m}_h = h_D \times (X_a - X_{fs}) \quad (6)$$

$$\varepsilon = \frac{\rho_i - \rho_f}{\rho_i - \rho_a} \quad (7)$$

$$\dot{m}_d = D_{eff} \times \frac{d\rho_v}{dz} = D_{eff} \times \frac{M_v}{RT_f} \times \frac{dP_v}{dz} \quad (8)$$

$$D_{eff} = \mu \times D_v = \frac{\varepsilon}{\tau} \times D_v \quad (9)$$

$$\partial \rho_f / \partial t \times (t_f \times A_w) = \dot{m}_d \times A_w \quad (10)$$

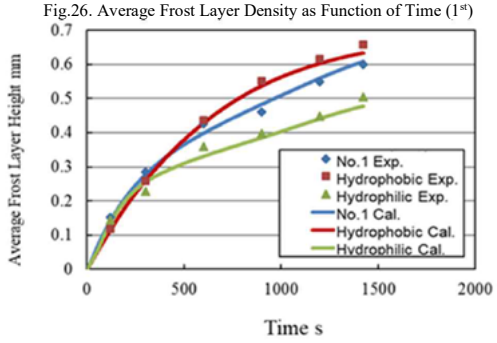

Fig.28. Average Frost Layer Height as Function of Time (1st)

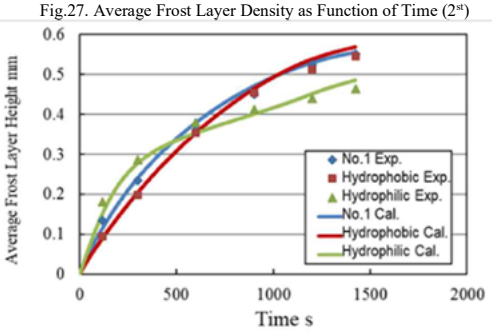

Fig.29. Average Frost Layer Height as Function of Time (2nd)

From Fig. 26. to Fig. 29, it is confirmed the difference between experimental value and calculated value in crystal growth stage are large. Therefore, it is necessary to improve accuracy of the analysis model of this stage.

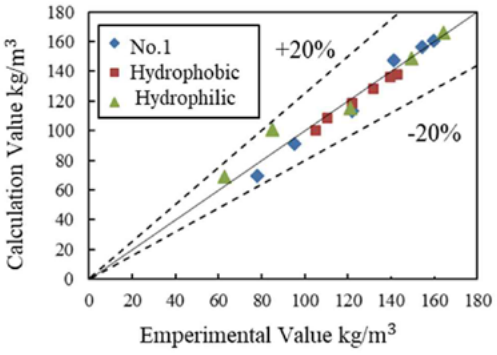

Fig. 30. Error Band of Frost Layer Density (1st)

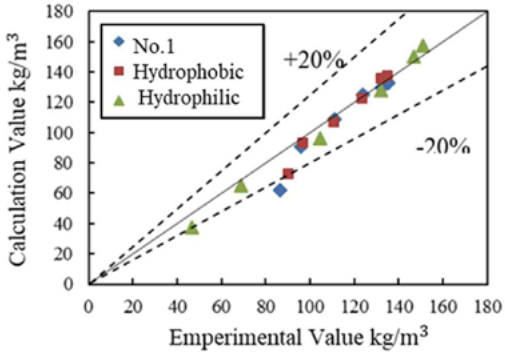

Fig. 31. Error Band of Frost Layer Density (2nd)

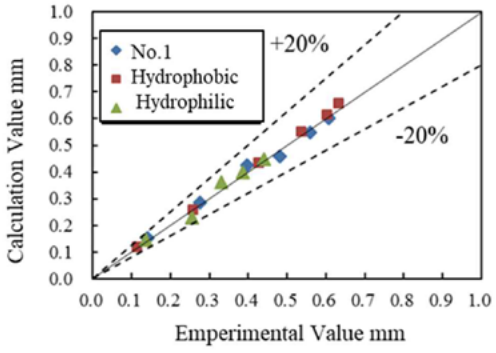

Fig.32. Error Band of Frost Layer Height (1st)

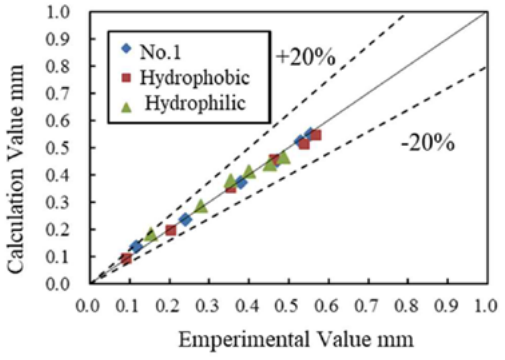

Fig. 33. Error Band of Frost Layer Height (2nd)

From Fig. 30. to Fig.33. show the error band of frost layer density and frost layer height, respectively. Table 6 shows the average error rate.

Table 6 Average Error Band

	No.1		Hydrophobic		Hydrophilic	
	1st	2nd	1st	2nd	1st	2nd
Ave. Frost Density	5.91%	8.79%	3.15%	2.23%	7.48%	5.92%
Ave. Frost Height	4.27%	4.04%	6.09%	3.01%	10.1%	5.95%

From Fig. 30. to Fig. 33., the error band of calculated value is about 10%. Particularly, the average error band is about 2% in No.1.

4. Conclusion

(1) A multi-cycle frost and defrost experiment using a water-cooled jacket is established, and the qualitative frost and defrost characteristics are grasped.
(2) By frost layer growth observation in multi-cycle experiments, the growth of crystal such as initial crystal diameter and spacing is determined, and the effects of convex height and wettability on crystal growth are confirmed.
(3) The calculation results of the analytical model of the frost layer growth on the convex-concave plate are summarized with an error of less than 10% on average, using experimental values as the setting values in the calculation.

(4) Within the scope of this study, the combination of No. 1 plate and the hydrophobic surface treatment had the most frost resistance.

Abstract

In EV market, two key factors are driving range and cost. The conventional heat pump system can extend driving range in cold season, but it has lots of components and has complicated structures. The cost of heat pump is also more expensive than normal air-condition system with air PTC heater.
To solve these challenges, secondary loop system has been considered for EV thermal management system based on coolant system. However, it has weak point in regard to fast cool down, warm up and maximum performance due to heat loss. To solve those problems, some refrigerant is in study, and we did drop in test with efficient & flammable refrigerants (R1234yf, R152a, R290). Test result shows the possibility of secondary loop system & challenges.

Keywords: Secondary loop; Heat Pump; Flammble refrigerant; R152a; R290

1. Introduction

In the EV market, which is growing in size over time, EVs are valued as mileage and price. Among them, many electric vehicles use heat pump system to increase the mileage, but the heat pump system has a large number of parts and a complicated system configuration, which makes it less competitive in terms of price. On the other hand, electric heaters are often used in general A / C systems to solve electric car cooling / heating at low prices. In winter, the use of electric heaters is the biggest factor in reducing the mileage of electric cars.

After all, in order to increase the competitiveness of electric vehicles, a simple configuration and a low-cost heat pump system are required. As a solution, a secondary loop heat pump system is attracting attention these days. However, the secondary loop heat pump system has a heat transfer process of refrigerant-cooling water-air, and in this process, heat exchange efficiency is reduced, and performance is lower than that of a direct system for refrigerant-air heat exchange.

In this study, the refrigerant was studied as a method to improve the performance of the secondary loop heat pump system. Drop-in evaluation was performed on three refrigerants R1234yf, R152a, and R290 with different characteristics, and the cooling / heating performance of each refrigerant was compared.

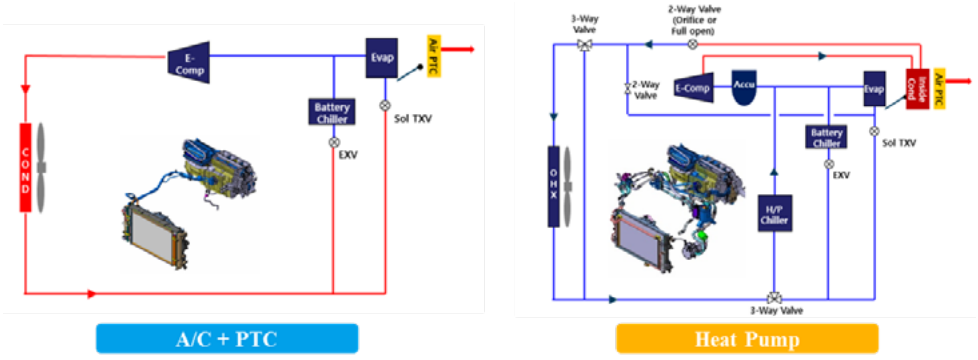

Fig. 1. A/C+PTC System / Heat Pump System

2. Body

2.1. *Secondary Loop System Definition*

Comparing current direct heat pump systems with secondary loop systems shows a number of differences in component count and pipe connections. The current heat pump system has a large number of heat exchangers for cooling and heating, and includes a plurality of refrigerant valves for changing the direction of the refrigerant, and the increase in the number of components increases the price of the heat pump system. Secondary loop systems can reduce the number of components because there is no need to switch the refrigerant direction, which leads to a lower price.

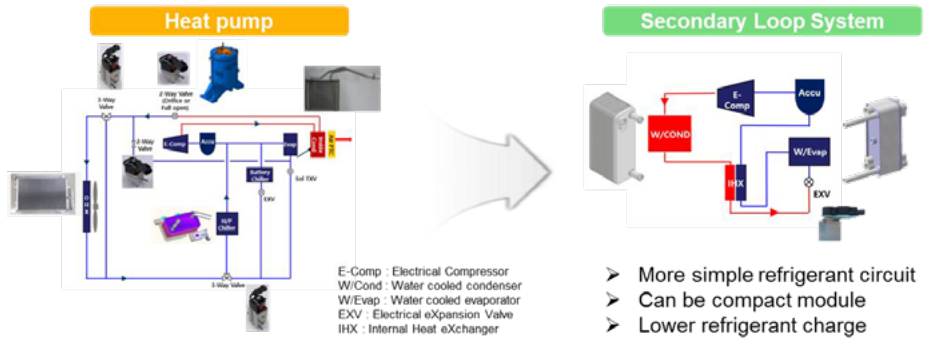

Fig. 2. Direct heat pump system / Secondary loop system

In a secondary loop system, cooling and heating are operated by circulation of the coolant. When cooling, the coolant heat exchanged from the evaporator is drawn to the heat exchanger in the HVAC, and when heating, the coolant heat exchanged from the condenser is drawn. Figure 3 shows the coolant circuit at A/C mode and H/P mode.

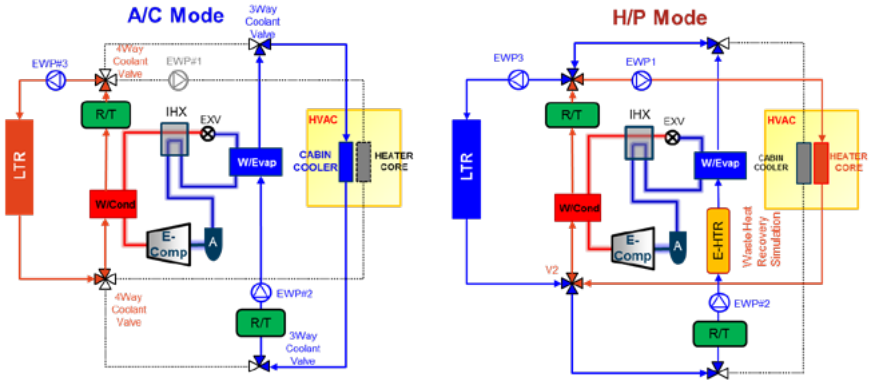

Fig. 3. Cooling mode and heating mode in secondary loop system

The advantage of the secondary loop is that the system is simpler in construction, and the disadvantage of the secondary loop is that the performance is degraded due to the heat exchange process. In fact, when R1234yf refrigerant used in the current heat pump is used in the secondary loop, cooling performance is reduced by about 22% and heating performance is reduced by about 15%.

2.2. Refrigerant Characteristics Comparison

With R1234yf refrigerant, it is difficult to satisfy the performance in the secondary loop system. There are limitations in refrigerant characteristics. In this study, we applied the refrigerant of R152a and R290 to check whether the performance can be satisfied in the secondary loop. R152 and R290 are low-GWP eco-friendly refrigerants and low cost. In addition, the heat of vaporization is large relatively, which can lead to higher performance.

Table 1 Refrigerant characteristic comparison

	Market Application	Environmental Regulation (GWP)	Safety Regulation	Estimated Cost ($/kg)	Heat of vaporization (kJ/kg) at 0°C	Heat of vaporization (kJ/kg) at 60°C	System Matching
R134a	Current (will Phase down)	1430	A1	3.4	198.6	139.1	Direct
R1234yf	Launched (Global)	3	A2L	66.8	163.3	110.4	Direct
R152a	TBD	124	A2	-	307.1	229.3	Indirect
R290	TBD	3	A3	3.1	374.9	259.2	Indirect

The p-h diagram (Fig. 4) shows that the heat of vaporization of these two refrigerants is large, and in particular, R290 has a relatively lower saturation temperature at the same pressure, which improves the cooling performance and heating performance.

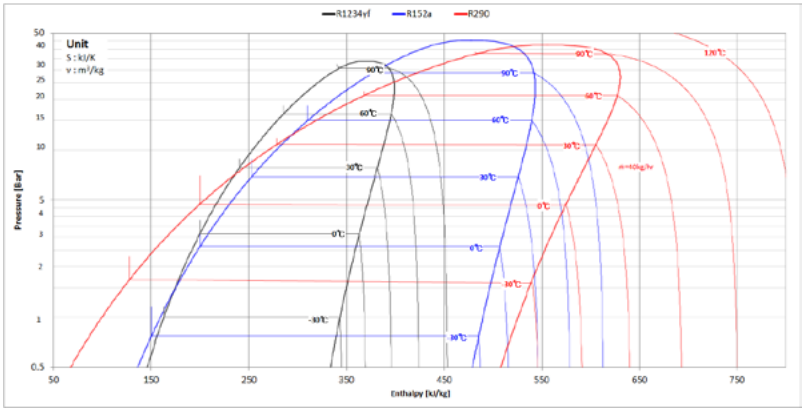

Fig. 4. p-h Diagram of Refrigerants

2.3. Bench Rig Test Result

Figure 5 shows the results of the refrigerant charge amount determination test. The test was on A/C high load condition, 35°C ambient temperature and 50% relative humidity. The refrigerant charge amount is reduced by 45% in the secondary loop system compared to the direct heat pump system. Where R152a and R290 are further reduced by 27% and 58%, respectively. If 1000g of refrigerant is charged in the R1234yf direct heat pump system, the refrigerant charge amount of the R290 secondary loop system is about 230g. This is half of the IEC standard 500g (self-contained).

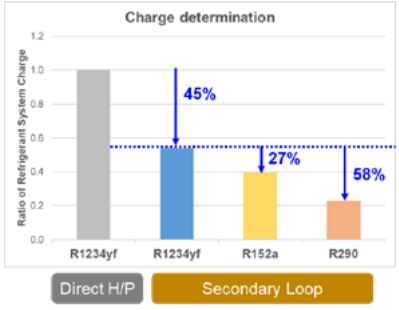

Fig. 5. Results of refrigerant charge determination test

Cooling performance test was performed under an ambient temperature of 35°C, humidity 40% RH conditions. The air flow rate on the HVAC side was 450cmh, and the air flow rate on the air cooled condenser and radiator side was 2.5 m/s. The compressor is a 33cc electric scroll type compressor and was operating 7000rpm.

Figure 6 and 7 show the results of the A/C test. The secondary loop system based on the R1234yf reduces 22% performance over the direct system. The air discharge temperature at the evaporator shows that the direct system is 8.5°C, while the secondary loop system is 11.8°C, because coolant is in between the refrigerant and the air. In more detail, the refrigerant temperature of the evaporator under the above conditions is about 5°C, and in heat exchanger refrigerant cools the air to 8.5°C. On the other hand, in the second loop, when the refrigerant temperature of the evaporator reaches 5°C, and it makes the coolant temperature about 8.5°C, and the 8.5°C coolant makes the air 11.8°C.

In this case, when R152a refrigerant is used, the heat of vaporization is large, and a cycle is formed at a lower pressure and a temperature in the evaporator, thereby improving cooling performance by about 4%. At

the same pressure, the saturation temperature is slightly higher than R1234yf, but the heat of vaporization is relatively large, so performance can be secured at a small flow rate.

When using R290 refrigerant, the effect of the refrigerant characteristics is very huge. Cooling performance is improved by 30%, which is equivalent to a direct system using R1234yf. R290 has a high heat of vaporization and a low saturation temperature at the same pressure. So it is possible to make refrigerant at lower temperature, coolant at lower temperature, and discharge air at lower temperature. However, Pd is formed relatively high, so the compressor power is consumed more, and the COP is lowered, but this COP is similar to the secondary loop system of the R1234yf, which is not a disadvantage of the R290.

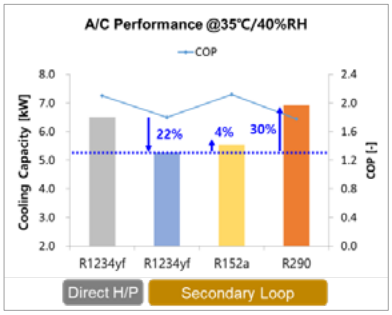

Fig. 6. Results of A/C performance test

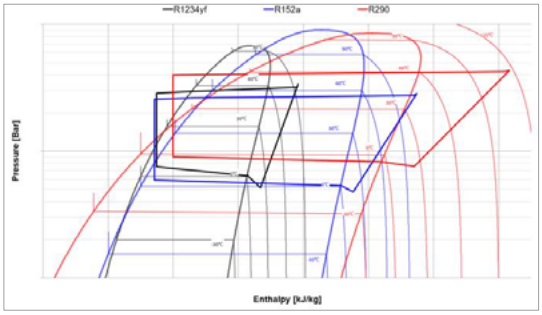

Fig. 7. p-h diagram comparison in A/C mode

Figure 8 and 9 show the results of the H/P test. Heating performance test was performed under an ambient temperature of -20°C. The air flow rate on the HVAC side was 300cmh, and the compressor was operating 5000rpm. The waste heat of the electrical equipment was simulated, and 2 kW of energy was supplied to the evaporator. Since the same heat absorption amount of waste heat was applied, the performance difference was not large. However, the low pressure side refrigerant state at this time can confirm the performance impact of the refrigerant characteristics. R1234yf and R152a have a refrigerant temperature of -20°C or -19°C based on compressor suction side, whereas R290 has refrigerant temperature of -30°C.

What the refrigerant temperature is lower than outside air means that additional heat absorption from outside air is possible. Because the refrigerant temperature on low pressure side of R1234yf and R152a is similar to outside air, heat absorption from outside air is not possible, it makes limited heating performance. However, R290 is lower than outside air by 10°C, so additional heat absorption from outside air is possible, which can improve heating performance.

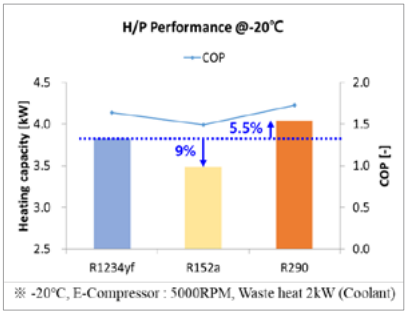

Fig. 8. Results of H/P performance test

Fig. 9. p-h diagram comparison in H/P mode

Figure 10 shows the comparison of heating performance with only outside air heat absorption of R1234yf direct system and R290 secondary loop system. In -20°C condition, the air flow rate on the HVAC side was 300cmh, and the air flow rate on the air cooled condenser and radiator was 2.5m/s. The compressor was operating 5000rpm. Even though R290 is a secondary loop system, the heating performance is about 17%

higher than the R1234yf of the direct system. Because of the temperature and pressure characteristics of R290 described above, it is possible to absorb more outside heat sources than when operating a heat pump with R1234yf.

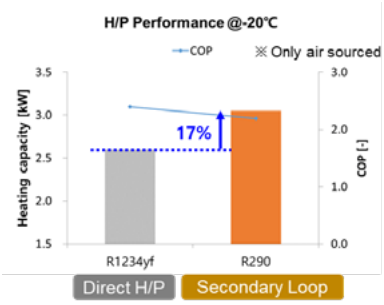

Fig. 10. Results of H/P performance test with only outside heat source

3. Summary/Conclusions

In order to improve the performance of the secondary loop heat pump system, the study was done about the refrigerants. Drop-in test was performed on three refrigerants R1234yf, R152a, and R290 with different characteristics, and the cooling / heating performance for each refrigerant was compared. Changing from direct heat pump system to secondary loop heat pump system based on R1234yf reduces cooling performance by about 22% and heating performance by about 15%. However, using R290 refrigerant improves cooling performance by 30%, equivalent to the direct system of R1234yf. The heating performance is above the direct system of R1234yf due to the increase of outside air heat absorption. The R290 refrigerant can overcome the performance shortcomings of the secondary loop system, which can help reduce the cost of electric vehicles through the application of the secondary loop system.

Abstract

Propane, namely R290, is a perfect candidate to replace hydrofluorocarbon that can help the European Union reaching the 2050 target in terms of CO_2 emissions. However, wide introduction of R290 in products are effectively hindered by international safety standards that limit the allowable charge size of flammable refrigerants.
LIFE, the European Union financing instrument for the environment and climate action is financing a project aiming at establishing technical evidence demonstrating that safety is not compromised while increasing the refrigerant charge size of R290 in heat pumps provided that adapted mitigation measures are in place.
Within the LIFE FRONT project, a test procedure aiming at assessing the risk that may be induced by a heat pump using R290 in case a leak is occurring has been defined. Two water based heat pump prototypes designed to operate with R290 were then tested according to the defined procedure. The tests demonstrate that an appropriate design can ensure a safe operation of a heat pump while increasing the refrigerant charge size well above the 150g limit recommended in the safety standard.

Keywords: LIFE FRONT; heat pump; R290; standards; safety

1. LIFE FRONT project

1.1. LIFE programme

"The LIFE programme is the EU's funding instrument for the environment and climate action created in 1992. The current funding period 2014-2020 has a budget of €3.4 billion.

The LIFE programme is divided in two sub-programmes, one for environment (representing 75% of the overall financial envelope) and one for climate change (representing 25% of the envelope).

The climate action sub-programme supports projects in the areas of renewable energies, energy efficiency, farming, land use, and peatland management.

It provides action grants for best practice, pilot and demonstration projects that contribute to the reduction of greenhouse gas emissions, the implementation and development of European Union (EU) policy and law, best practices and solutions. The European Commission is particularly looking for technologies and solutions that are ready to be implemented in close-to-market conditions, at industrial or commercial scale, during the project duration."[1]

1.2. EU legislative framework

In the context of the world fight against climate change the EU ratified the Kigali agreement and committed to take appropriate measures to reduce the CO2 emissions gradually until achieving net zero emission by 2050.

Actual targets in terms of CO2 emissions are set for 2030 and are associated with several overarching pieces of legislation such as the Energy Efficiency Directive, Renewable Energy Directive and the Energy Performance of Buildings Directive…. Among the pieces of legislation published by EU, the commission regulation 517/2014 (F-GAS regulation) regulating the use of hydrofluorocarbon (HFC) fluids has a major

* Corresponding author. Tel.: +33 6 07 98 45 28

impact on the refrigeration, air conditioning and heat pump industry. Indeed, the F-GAS regulation sets the plan for the usage limitation and phase out of the HFCs having a high global warming potential.

The refrigerants commonly used in refrigeration, air conditioning and heat pump applications are HFCs having a high warming power impact (>2000 kgCO2equivalent). Thus, while restricting the use of HFC, the EU works at ensuring that technical options will be available on due time. These options should replace HFC by low global warming potential (GWP) refrigerants providing high energy efficiency and a high level of safety.

1.3. LIFE FRONT project

LIFE FRONT project constitutes one of the EU initiative to facilitate the switch to low GWP refrigerant in refrigeration, air conditioning and heat pump. Indeed, most of the suitable refrigerants for replacing the commonly used HFC are flammable. However, the EU and international standards, which main concern is safety, set strong restrictions on the use of flammable refrigerants, making it very difficult to introduce appliances using flammable refrigerants on the EU market.

"The LIFE FRONT project aims to remove "barriers posed by standards" for flammable refrigerants in refrigeration, air conditioning and heat pump applications. It strives to improve system design to address flammability risk and encourage thereby wider uptake of climate-friendly alternatives to fluorinated gases."[2]

The LIFE FRONT project gathers several partners: Shecco, HEAT, ECOS, AHT, AIT-Deutschland and NIBE.

AHT, AIT and NIBE are industrial companies, manufacturing RACHP appliances, some of which has been using R290 for years. These companies have a long experience in using R290 and will to share their experience to help overcome the existing limitation for flammable refrigerant usage.

AHT mainly produces commercial refrigerating cabinets. AIT and NIBE are manufacturers of water based heat pumps: air to water, ground source heat pump and exhaust air heat pumps.

1.4. Project objectives

The LIFE FRONT work programme is divided in several steps including;

- Review of existing flammable refrigerant standards and literature review on refrigeration, air conditioning and heat pump safety in relation with flammable refrigerant
- Field survey addressing type and cause of refrigerant leakages including leak hole size and leak flowrate
- Equipment design with improved safety

The outcomes from these steps will serve as a basis for drafting proposed requirements for the standards on flammable refrigerants (such as IEC 60335-2-40:2018). The standard and literature review reports are publicly available on the LIFE FRONT project website http://lifefront.eu.

This paper is more focusing on the third step of the project consisting in building and testing prototypes of heat pumps, specifically designed to operate with R290.

2. Barriers to usage of flammable refrigerants

Barriers to the usage of flammable refrigerants are present in standards and sometimes in national regulation within the EU. Barriers coming from standards can be easily identified whereas it is difficult to get a clear picture of the barriers posed by national regulation. This work only focusses on standard barriers.

Refrigeration, air conditioning and heat pump equipment are covered by safety standards of two kinds: product standards and group standards. The product standards are specific for a type of product whereas group standards cover a broad spectrum of systems and equipment in a generic manner.

Compliancy to safety standards does not necessarily constitute a legal requirement, however, compliancy to product or group safety standards often ensure conformity to the applicable EU legislation and CE marking in particular. Thus, in practice, requirements of safety standards are strictly followed by the industry and shape the products being placed in the EU market.

The existing safety standards related to refrigeration, air conditioning and heat pump equipment are listed in the table below:

Table 1. refrigeration, air conditioning and heat pump safety standards

Standard type	Group		Product		
Standard	ISO 5149	EN 378	EN/IEC 60335-2-24	EN/IEC 60335-2-40	EN/IEC 60335-2-89
Domestic refrigeration			x		
Commercial refrigeration	x	x			x
Industrial systems	x	x			
Transport refrigeration	x	x			
Heat pumps, air conditioners and chillers	x	x		x	

IEC 60335-2-89 has recently been revised and maximum A3 flammable refrigerant charge increased from 150g to approximatively 500g of R290 (13xLFL, Lower Flammability Limit) without adding specific requirements on the product design. As a result the practical cooling capacity of refrigerating circuit using A3 flammable refrigerant has been increased significantly.

In IEC 60335-2-40, the maximum A3 flammable refrigerant charge size depends on the location of the equipment. Maximum refrigerant charge for equipment located outdoors (approximatively 5kg of A3 flammable refrigerant) is enough to provide heating capacity suitable for the EU heating demand in single household dwellings. Maximum refrigerant charge size for refrigeration circuits located in an occupied space indoor depends on the surface area of the room where the equipment is installed and the height at which the part of the equipment containing the refrigerant circuit is positioned.

For heat pumps, in particular ground source and air to water heat pumps, having floor installation, the charge size cannot exceed 150g of R290 unless the room size exceed 35m². As a consequence, ground source or air to water heat pumps designed to be installed indoor cannot use a flammable refrigerant as the provided heating capacity will not fit the usual heat demand of a single dwelling apartment or house in the EU. There is an option defined in the standard to use a so-called “ventilated enclosure” where the charge limit is about 5 kg of A3 refrigerant (irrespective of floor area) but this option is not applicable to air to water or ground source heat pumps.

The requirement on the room size set in the safety standard has been theoretically established to prevent an explosive atmosphere under the assumption of a leak flowrate corresponding to the complete refrigerant charge being released in 4 minutes.

This assumption does not leave any scope for innovation nor option for protective measures that could effectively prevent formation of a flammable mixture using other means and thus ensure that the equipment can operate without compromising safety.

3. Experimental work

3.1. General approach

As of today, according to EN/IEC 60335-2-40, whatever is the heat pump design, with the exception of ventilated enclosure, the maximum charge size of flammable refrigerant cannot exceed 150g if the room where the product is installed does not exceed the minimum floor area. Thus, the safety standard is widely considered a barrier to innovation as it does not allow the manufacturer to develop systems using flammable refrigerant. Similarly, it is not possible to implement appropriate design or mitigation measures that can ensure that flammable atmosphere can be avoided irrespective of the refrigerant charge size.

Within the LIFE FRONT project it is intended to develop a robust test methodology that permits to evaluate whether a product using flammable refrigerant can operate without compromising safety whatever the charge size and the room surface area.

It is the intention to demonstrate that an obligation of providing evidence that a refrigerant leakage under a certain flowrate will not increase the concentration of flammable substances above a certain level could well replace the charge limits.

One part of the LIFE FRONT project work is based on experiments simulating R290 leakages occurring from indoor heat pumps whereby measuring R290 concentrations at the product surrounding. Before performing such tests, two questions demand an answer: what is a valuable criteria while assessing that an equipment does not compromise safety in regards to refrigerant charge size and which leak flowrates can be representative of leakages occurring in refrigeration, air conditioning and heat pump systems?

3.2. Definition of a "tolerable risk level"

Within the LIFE FRONT project, it was needed to define a "tolerable risk level" that needs to be achieved by a heat pump in regards to the use of flammable refrigerant. It was decided that a heat pump reaches this "tolerable risk level" if, in the event of a complete loss of the refrigerant charge, the R290 concentration surrounding the heat pump does not exceed 50% of the lower flammability limit (LFL). In addition, would one or several heat pump parts contain a potential ignition source, and if the components are under Ex-type standards, R290 concentration in the concerned areas shall not exceed 50% of LFL.

Note that, these criteria permit to assess whether a product reaches a "tolerable risk level" at its design phase. The assessment of the heat pump risk level presented in this report does not encompass a risk analysis of the heat pump that covers its complete life cycle including manufacturing, installation, maintenance and dismantling.

Note that the risk associated with the heat pump should be considered in light of the background fire risk arising with electric heat pumps, irrespective of the refrigerants used. Whilst such data is not readily available, that for other refrigerating systems (such as domestic refrigerators and air conditioners) is public. This data infers the additional risk from flammable refrigerant should be less than 1 per 100,000 units per year [4].

3.3. Leak cause analysis and associated leak flowrate

Before starting the experimental test, it was needed to assess what could be a reasonable basic assumption for the refrigerant leak flowrate.

To answer that question, a thorough analysis of the leak causes has been performed. The analysis is based on decades of experience of the project partners in manufacturing heat pumps and are based on the feedback and records from the field and after sales and quality departments. As industrial project partners manufacture hermetically sealed equipment that do not need any refrigerant piping work at installation, the leak causes that may affect the piping work done on site are not shown in table 2.

In parallel of the leak causes analysis, hundreds of leaking parts coming from refrigeration, air conditioning and heat pump equipment installed in the field were collected and analyzed by the project partner HEAT. The data has been stored in a database (http://lifefront.eu/databases). For each leak, the leak cause, leak hole size and leak flowrate are detailed so that it is possible:

- To highlight what is the typical leak flowrate occurring in the field
- To correlate leak flowrate and leak cause

The inputs that came out from both the analysis and the data collection are depicted in the table below. Every leak hole and leak flowrate shown in the table come from field measurements; some of them come from the LIFE FRONT project database and some other from the industrial partners own data bank.

Table 2. leak causes and associated leak flowrate

Component	**Cause of leakage**	**Leak features**		**Associated risk**	**Existing mitigation measures in IEC 60335-2-89 and IEC 60335-2-40 Note that the latest version of the IEC standards have not yet be approved by the EU**
		Hole size	**Flowrate**		
Fins and tubs heat exchanger	Any type of corrosion: galvanic, microbiological…	Small hole: 1 to 100 µm	Small : 1-2 g/day	None	No need for mitigation measures
Air to water heat exchanger (plate, co-axial…)	Crack du to frost of the heat exchanger	Large: more than 1mm²	Catastrophic: 88g/min	Refrigerant is flowing on the hydraulic system and can be ignited when hydraulic system will be vented	Disconnexion of hydraulic system from refrigerant circuit or refrigerant vented outside in case the leak occur: IEC/EN 60335-2-40/A1 section GG.6

	Electrical short circuit with copper pipes	Large: more than 1mm²	Catastrophic: 88g/min	Hole is created on the pipe and refrigerant is ignited by the electrical arc: Fire or explosion	No electrical cable shall be installed close to a refrigerant pipes. For cables installed on site, cable passway shall be clearly marked. Revision IEC 60335-2-40:20xx (not published yet)
Brazing and pipes located in the heat pump enclosure	Defective bending	0,17mm²	22g/min	Risk of fire in case of ignition source	•
	Fatigue rupture due to vibration	0,17mm²	22g/min	Risk of fire in case of ignition source	Mitigation measures given in IEC60335-2-89: 2019: vibration test, section 22.108
	Defective brazing	0,7mm²	Catastrophic 65g/min	Risk of fire in case of ignition source	•
	Fritting, repetitive rubbing of surface	<0,1mm²	<3g/min	Risk of fire in case of accumulation and ignition source	•
	Icing of pipes	0,17mm²	22g/min	Risk of fire in case of ignition source	•
Other components	Schrader valve; expansion valve, 4 way valves, pressure sensor….	Small hole	Low flowrate <3g/year	None	•

One can observe that some of the causes for leakages may be eliminated already at design phase by appropriate mitigation measures, already defined in the existing or upcoming standards. However, adapted design requirements cannot prevent any leak from occurring as equipment material can be altered over time in an unpredictable manner.

Based on these analysis, two heat pump prototypes were tested: one packaged air to water heat pump and one ground source heat pump, both heat pump prototypes designed to be installed indoor. The above table highlights that 88g/min is the maximum flowrate that has been identified. However, this leak flowrate has only been observed in the case of a hole created by an electric short circuit. Considering that this leak cause can be avoided by design, the first test done was based on the maximum flowrate of 65g/min which corresponds to a defective bending. For the second test, it was decided to assess the efficiency of the proposed testing method with a flowrate equal to the maximum: 88g/min (rounded to 100g/min for the sake of simplification).

The objectives of the tests are:

- to define a proper test protocol that is appropriate to evaluate whether an equipment design permits a usage of a flammable refrigerant at a tolerable risk.
- to demonstrate that adapted mitigation measures can be implemented to prevent the refrigerant concentration surrounding the heat pump from exceeding 50% of the LFL in case a leak is occurring.

It is essential to adopt a reasonable leak hole size and associated flowrate. If a too small hole is used then it is likely that the implemented protective measures will be insufficient to mitigate the hazard arising from all leaks. If a too large hole is used then the protective measures would be unnecessarily over-designed.

3.4. Test method

3.4.1. General features

The test method described in this section has been finalised after the tests were performed as experience was gained throughout the tests. Thus, the tests performed over the LIFE FRONT project do not strictly follow the described test method.

3.4.1.1. Test space and arrangement

The appliance to be tested shall be positioned within a test room. The room height shall be no less than 2.2m. The room shall be “tight”. The appliance shall be installed at a height and location as prescribed by the instructions manual, selected to yield the least favourable result.

3.4.1.2. Gas sensors number and positioning

Sampling points to measure gas concentration shall be positioned around the heat pump, no more than 30mm above floor level. There shall be one sampling point at a distance of no more than 0.5m from each exposed side of the heat pump. **오류! 참조 원본을 찾을 수 없습니다.** 1 shows a possible arrangement of the sampling points. The gas sensors shall be suitable for the gas to be detected and under calibration control.

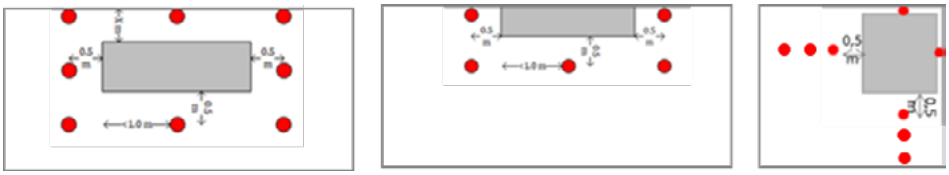

Fig 1. Possible test room set up and positioning of the sampling points; plan view showing the RACHP equipment (grey block) and floor level sensors (red dots)

Note that the gas sensor positioning is only valid where refrigerant density is higher than air density.

3.4.1.3. Leak generation and location

A simulated leak shall be made at the most unfavourable positions on refrigerant containing parts. Several locations might be chosen to be representative or to determine the least favourable one. The jet direction which leads to the highest concentration shall be chosen.

The refrigerant is released through an orifice in vapour phase at a pressure of at least 2bar (gauge), or whatever is necessary for choked flow.

3.4.1.4. Leak flowrates and released mass

Two mass flowrates shall be used: 10g/min and 100g/min. It might be interesting to test an additional intermediate flowrate, 45g/min, to get the concentration developing trend around the product.

The mass released is the refrigerant charge.

3.4.1.5. Test procedure

The tightness of the test room shall be assessed prior any test on the heat pump is performed. Sufficient tightness is demonstrated by a mass of refrigerant equating to about 50% of LFL being released into the room and mixed using a circulating fan. The average concentration at six sampling points throughout the room shall be within ±5% of the arithmetic mean and the mean value shall not decline by more than 5% within a five-minute duration.

For each flowrate and leak location, the refrigerant charge shall be released. The test shall be repeated no fewer than three times at each flowrate and leak location. The heat pump shall be switched off during the test, only the devices that are in operation at all time (fan….) might be operating

3.4.1.6. Recorded data

Measurements of gas concentration shall be recorded at time increments of no more than 5 seconds apart from the time at which the release begins and until the concentration at all sampling points declines for at least three minutes.

3.4.1.7. Criteria

None of the refrigerant concentration detected by the gas sensors surrounding heat pump shall be greater than 50% of LFL. In case gas sensors are installed within the heat pump enclosure, none of them shall detect a gas concentration higher than 50% of LFL.

3.4.1.8. Specific arrangements used for the LIFE FRONT tests

For the tests performed over the project, an enclosure of a size, 3m x 2m x 2.5m height, intended to mimic a typical utility room is built and serves as test room.

R290 is supplied to the leak positions from a cylinder fed into the enclosure via refrigerant hoses **오류! 참조 원본을 찾을 수 없습니다.**. The hose terminates with a 1mm (0.8mm2) diameter orifice fitting in order to ensure choked flow. The mass flowrate and total released mass is modulated with a mass flow controller, calibrated for R290.

To assess the tightness of the enclosure mimicking the utility room, 400g of R290 were released in the enclosure. The air in the enclosure was mixed using a circulating fan. The R290 concentration was then recorded during 30 minutes. Over these 30 minutes, the R290 concentration remained stable, it was concluded that the enclosure that sufficiently tight for the purpose of the tests to be performed.

R290 sensors are used to measure R290 concentration. Some of them are aspired sensors and others are positioned on a gas stand and are diffusion operated.

While tests are on-going it may happen that R290 concentration gets so high that the R290 sensors get saturated; in that event, the gas sensors are disconnected to avoid poisoning them. This is the reason why in the charts shown in the following clauses some curves are interrupted. In order to highlight the impact of the specific heat pump design on the tolerable risk level, the first test was performed on a heat pump designed to operate with a non-flammable refrigerant such as R410A or R407C.

Each performed test starts with a clean room: no R290 neither in the mock utility room nor in the heat pump enclosure. R290 is then released and the test stops after the defined R290 mass has been released. After each test, the R290 is evacuated from the testing enclosure and from the heat pump. The following test starts when the R290 sensors do not detect any R290.

3.4.2. Ground source heat pump prototype

A ground source to water heat pump prototype has been specifically designed to be used with R290. Ground source heat pumps are generally designed to be installed indoor, in a garage or a utility room. The prototype has been tested at NIBE AB facilities at Markaryd, Sweden with the support of HEAT. During the tests, the heat pump has not been in operation.

3.4.2.1. Installation

Three zones, represented on figure 2, are defined as:

- zone A: upper part of the heat pump contains the hydronic components, immersion heater, power supply and all electrical components,
- zone B contains the refrigerating circuit,
- zone C represents the heat pump surrounding. Zone A and zone C represent the zones were R290 concentration shall not exceed 50% of LFL (components in zone A do not comply with ATEX legislation). The red dots represent the gas sensors.

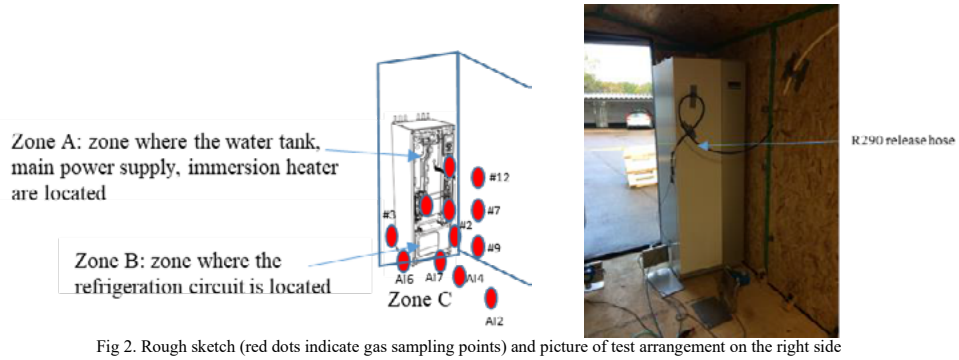

Fig 2. Rough sketch (red dots indicate gas sampling points) and picture of test arrangement on the right side

3.4.2.2. Selection of release locations

The refrigerant is contained in zone B. The leak hose is placed at the centre of zone B. For assessing whether R290 could get into zone A, the leak orifice was oriented first toward the top of zone B. Then, the leak orifice was oriented towards the side panel of zone B against the wall of the room.

3.4.2.3. Selection of flowrates and mass of R290 to be released

Two mass flowrates were selected. The two mass flow considered are: 20g/min and 100g/min. 88g/min is the highest leak flowrate observed according leak the cause analysis, for this test, it was decided to evaluate what will happen in case this catastrophic leak occur (88g/min was rounded to 100g/min).
800g of R290 was released at each test. After the 800g were released, the R290 concentration continued logging for several more minutes.

3.4.2.4. Test conditions

Table 3. test condition for ground source heat pump

Test no.	Release mass flow rate [g/min]	Release location	Orifice height [m]	Released quantity [g]
Tests performed on a ground source heat pump designed for R407C				
1	100	Oriented towards zone A	0.3	400
Tests performed on a ground source heat pump designed for R290				
2	100	Oriented towards zone A	0.3	800
3	100	Centre	0.3	800
4	20	Centre	0.3	800

3.4.2.5. Test results

In the following charts, the doted blue line represents 50% of LFL.

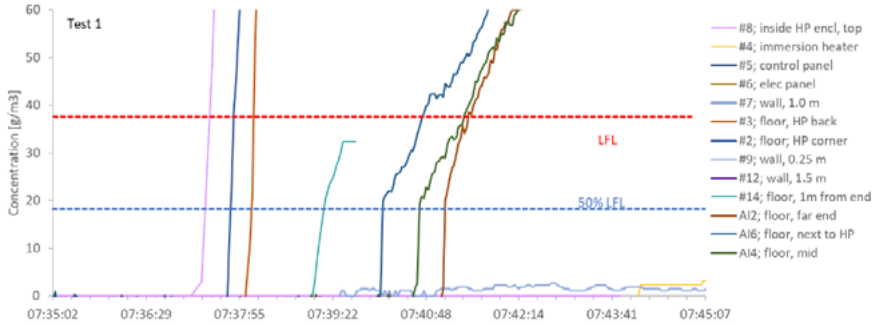

Fig 3. results of test 1 performed on ground source heat pump designed for R407C - 100g/min

For this first test, one sensor was positioned within part B, in the refrigeration enclosure. R290 release starts at 7:36 and ends at 7:40. Only 400g were released. 50% of the LFL is reached everywhere in the room at floor level. One can notice that as there is no ventilation in the room, R290 stagnates at floor level and the concentration remains lower than 50% of LFL at 0.25m height whereas no R290 is detected by the sensors positioned at 1m and 1.5m.

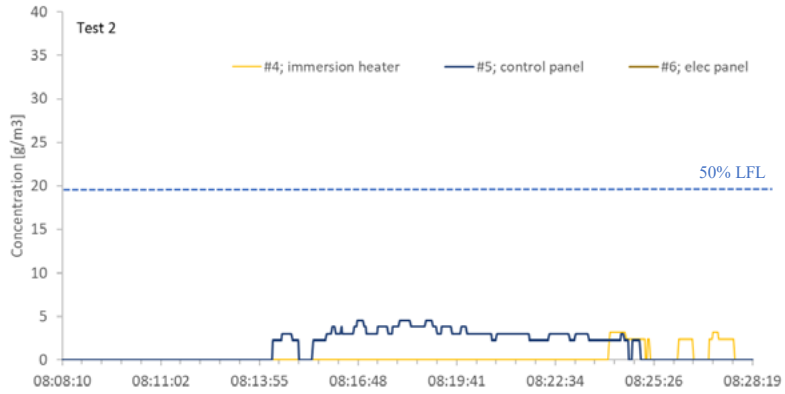

Fig 4. results of test 2 performed on the ground source heat pump prototype designed for R290 – 100g/min

R290 release starts at 8:10 and stops at 8:18. R290 concentration remains far below 50% LFL on zone A. No R290 is detected in the electrical panel where the relays are located.

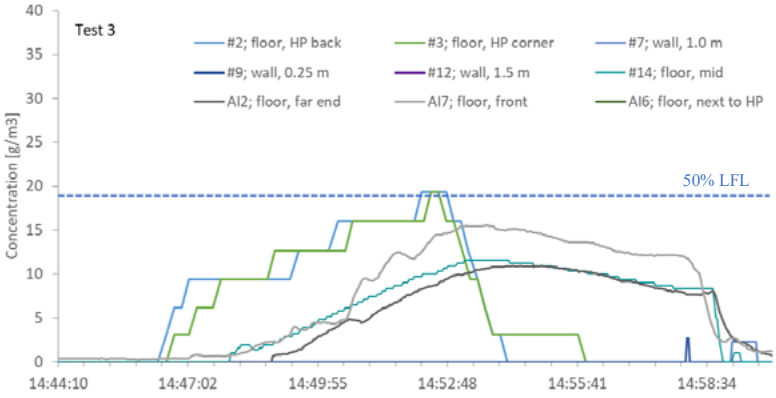

Fig 5. results of test 2 performed on the ground source heat pump prototype designed for R290 – 100g/min

R290 is released at 14:44. The 800g are released after 8 minutes. R290 concentration increases first at the side of the heat pump which is by the wall as well as at the back. Then, the R290 is propagating into the room.

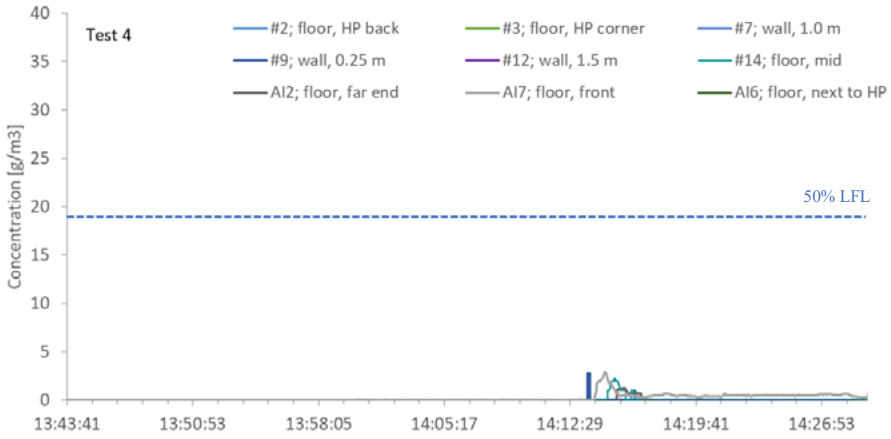

Fig 6. Results of test 3 performed on the ground source heat pump prototype designed for R290 – 20g/min

R290 release starts at 13:43 and ends at 14:23. R290 concentration remains far below 50% of LFL.

From the three tests performed, one can conclude that R290 is not penetrating zone A, where potential ignition sources could be found. The tests also demonstrate that in case there is no air movement in the room, R290 stagnate at floor level. Finally, the test demonstrates that the ground source heat pump design is efficient in preventing the creation of an explosive atmosphere around the heat pump either in the event of a catastrophic leak is occurring in the refrigerating circuit or in the event of a small leak is occurring.

3.4.6. Indoor packaged air to water heat pump prototype

An indoor packaged air to water heat pump prototype has been specifically designed for operating with R290. This prototype has been tested at the AIT technology centre in Kasendorf, Germany with the support of HEAT.

During all tests, the heat pump is not in operation, the compressor and the fan are always off. Generally the heat from the compressor will create convection currents which helps to disperse any releases, the test conditions are thus conservative.

3.4.6.1. Installation

The heat pump consists of three zones: the hydronic unit, which contains the hydraulic and electrical components, the condensing enclosure that contains the refrigerating circuit except evaporator, and the evaporating enclosure that contains the evaporator, the fan and the ducts. Heat pump surrounding, namely zone C, represents the zone where the R290 concentration shall not exceed 50% of the LFL. The red dots on **오류! 참조 원본을 찾을 수 없습니다.**7 represent the R290 sensors, the orange arrows represent the location where R290 is released.

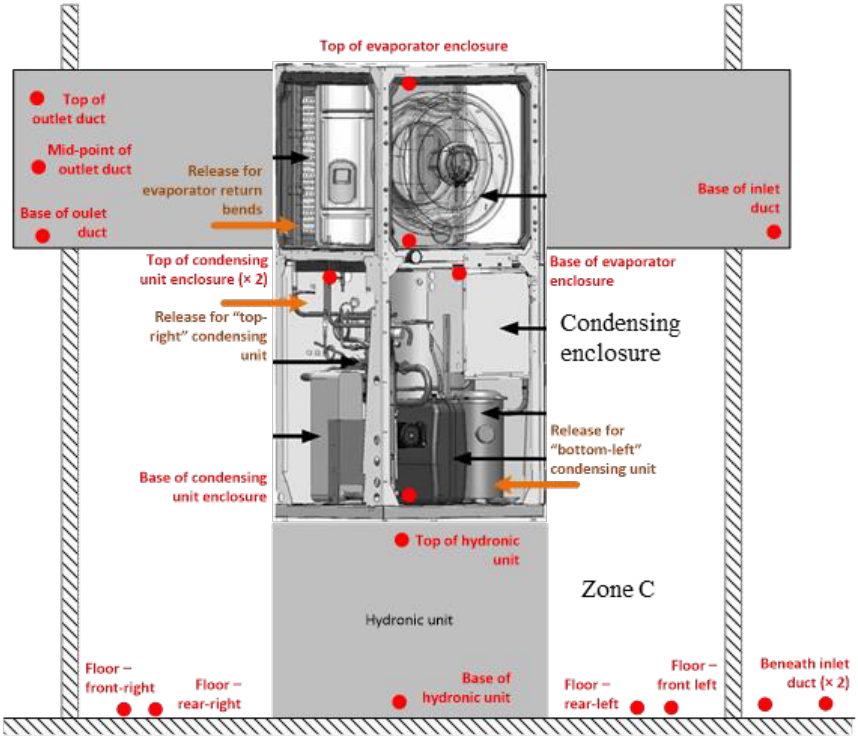

Fig 7. Rough sketch of test arrangement: red dots indicate sampling points and orange arrows are release positions

3.4.6.2. Selection of release locations

Three R290 release locations were defined as being the most unfavourable locations for a leak to occur: one in the evaporator enclosure and two in the condensing enclosure: one on top and one at the bottom.

All releases involved a jet at choked flow conditions, directed horizontally, to impinge against a nearby surface in order to remove momentum from the jet and thus to minimise mixing.

3.4.6.3. Selection of flowrates and mass of R290 to be released

The three mass flowrates considered were: 20g/min, 45g/min and 65g/min. 20g/min corresponds to the leak flowrate that might be obtained in case of defective bending, fatigue rupture or pipe icing, 45 g/min corresponds to the assumed low-side R290 leak rate within the draft amendment 61D/421/CD to IEC 60335-2-40 for enhanced tightness systems and 65g/min correspond to the highest leak flowrate, considering that electrical arc can be avoided by construction.

500g of R290 was released at each test. After the 500g were released, the R290 concentration records last for another couple of minutes.

3.4.6.4. Test conditions and test results

Table 4. test conditions and results obtained for indoor packaged air to water heat pump

Test no.	Release mass flow rate [g/min]	Release location	Orifice height [m]	R290 concentration reached during the test surrounding the product – zone C
1	40	Evaporating enclosure	1.5	Lower than 50% of LFL
2	20	Condensing enclosure: bottom	0.8	Higher than LFL
3	40	Evaporating enclosure	1.5	Lower than 50% of LFL
4	65	Evaporating enclosure	1.5	52% of LFL was reached
5	20	Evaporating enclosure	1.5	Lower than 50% of LFL
6	20	Condensing enclosure: bottom	0.8	Lower than 50% of LFL
7	45	Condensing enclosure: bottom	0.8	Lower than 50% of LFL
8	65	Condensing enclosure: bottom	0.8	Lower than 50% of LFL
9	20	Condensing enclosure: top	0.95	Lower than 50% of LFL
10	65	Condensing enclosure: top	0.95	Lower than 50% of LFL

Test 1 and 2 were performed on a heat pump designed for R410A. When released in the evaporating enclosure, the concentration of R290 in zone C remains lower than 50% of LFL. However, when released in the condensing enclosure, R290 concentration get higher than LFL in zone C.

Starting from test 3, all tests were performed on a heat pump specifically designed for R290.

During test 3, 4 and 5; R290 was released in the evaporating enclosure. When released at 65g/min, the concentration of R290 reaches 52% of the LFL in zone C. The 50% LFL criteria is not strictly met; however, at this phase of the project it was decided to go on with the test. When released in the evaporating enclosure, R290 concentration remains lower than 52% of LFL surrounding the product, however, it has been observed that the higher is the flowrate, the higher the R290 concentration gets surrounding the heat pump.

From test 6 to test 8, R290 was released at the bottom of the condensing enclosure. Whatever is the released mass flowrate, 20g/min, 45g/min or 65g/min, the concentration of R290 in zone C remained below 50% of LFL.

Results obtained when R290 was released at the top of the condensing enclosure, test 9 and 10, gave very similar results as to the ones obtained over tests 6, 7 and 8.

From the eight tests performed on the heat pump specifically designed for R290, one can conclude that the indoor packaged air to water design is sufficient to avoid creating an explosive atmosphere around the product. However, some adjustments would be needed as a little more than 50% LFL is reached where R290 is released in the evaporating enclosure.

4. Conclusion

The LIFE FRONT project aims to remove barriers posed by standards for flammable refrigerants in refrigeration, air conditioning and heat pump applications. It strives to improve system design to address flammability risk and thereby encourage wider uptake of climate-friendly alternatives to fluorinated gases.

In the scope of the LIFE FRONT project, two heat pump prototypes designed to operate with R290 were built and tested. The objective of the tests was to evaluate the efficiency of the prototype design in limiting R290 concentration at 50% of LFL surrounding the heat pump and in parts of the heat pump where an ignition source can be present, in the event of a leak is occurring within the refrigerating circuit. Note that during the tests, the compressor was off, thus, the impact the air temperature within the refrigeration enclosure may have on the R290 flow was not evaluated.

The two major outcomes of the tests performed are the following:

- Mitigation measures can be implemented that permits the use of R290 in larger quantities than those imposed by the safety standards without compromising safety. The tests demonstrate that it was possible to limit the concentration surrounding the product and in heat pump parts containing potential ignition sources below 50% of the LFL.
- A suitable test method, described in section 3.4.1, has been developed and evaluated that permits the evaluation of the efficiency of the mitigation measures. The test method assesses whether the heat pump can generate an uncontrolled explosive atmosphere surrounding the heat pump in the event of a refrigerant leak.

According to the current safety standards, residential indoor packaged air to water heat pumps and ground source heat pumps containing more than 150g of flammable refrigerant cannot without difficulty be placed on the European market. However, the tests performed within the LIFE FRONT project on a residential indoor packaged air to water heat pump and on a ground source heat pump show that appropriate mitigation measures can guarantee that the flammable refrigerant concentration surrounding the heat pump and in any part of the heat pump that may contain potential ignition source remains lower than 50% of the LFL. The tests demonstrate that substantially more than 150g of flammable refrigerant can be used in indoor heat pumps without compromising safety.

As an outcome of the work done, we would like to suggest that the safety standards, EN378 and EN/IEC 60335-2-40, are revised in a way that offers several possible approaches, at least a “simple” approach, based on existing requirement: 150g as a maximum charge size, and an “advanced” approach that would imply that the manufacturer performs the test as described in the above section.

Analysis of the mixture refrigerant R600/R245fa using in high temperature heat pump

Xiaohui Yu*, Chang Xu

School of Energy and Environment Engineering, Hebei University of Technology, Tianjin 300401, PR China

Abstract

High temperature heat pump (HTHP) is an effective equipment to recovery industrial waste heat and it has a wide application potential. The choice of refrigerant has important influence on the efficiency of HTHP. In this paper, the performance parameters of the mixture refrigerant R600/R245fa using in HTHP were tested. Compared with the R245fa, the mixture refrigerant R600/R245fa has higher heating capacity and lower COP. But the COP of the HTHP system also can maintain above 3.0 when the temperature of condenser outlet water is at 100 ℃ and 35 ℃ temperature lift. Analysis shows that R600/R245fa is suitable for HTHPs with higher condenser outlet water temperature and heating capacity demand. And its low GWP also has good environmental benefits.

Keywords: mixture refrigerant; High temperature heat pump; cycle performance

Nomenclature		**Greek symbols**	
COP	coefficient of performance	η	efficiency (%)
C_p	specific heat capacity (kJ/(kg.K))	Subscripts	
HTHP	high temperature heat pump	1,2,3,...,6	state point
GWP	global warming potential	a	available

1. Introduction

The problem of energy and environment has become a serious problem facing all countries in the world. The environmental pollution caused by energy consumption has become an important obstacle to global

* Corresponding author. Tel: +86 15102282362
E-mail address: 2018133@ hebut.edu.cn

economic growth and social progress. Industrial energy consumption accounts for nearly half of the world's total energy consumption [1]. Many industrial processes produce a large amount of waste heat and directly discharge to the environment, resulting in energy waste and environmental pollution. Therefore, waste heat utilization is an effective way to energy saving. On the one hand, the utilization of waste heat can reduce the thermal pollution. On the other hand, it can reduce the consumption of high-grade energy and achieve multiple purposes. HTHP is one of the reliable waste heat recovery devices. It can improve the quality of low-grade heat energy to higher quality by producing high temperature water or steam. Metallurgy, chemical industry, food, paper and other industries have a large demand for 100-130℃ hot water [2]. Therefore, HTHP has a good application prospect and has some new researches in recent years.

The research on refrigerant selection was also widely carried out, which lays a solid foundation for the selection of HTHP working medium. Guido et al. [3] conducted extensive screening on the working medium of steam compression high temperature heat pump, there were 27 kinds of preliminary selection under the environmental protection requirements and technical restrictions. Bobelin et al. [4] verified that a new mixed refrigerant ECO3 and it could effectively raise the outlet water temperature of HTHP to 125 ℃ . Chamoun et al. [5] designed and tested a new type of heat pump which raised the outlet water temperature to 130~140 ℃ when using R718 as refrigerant. Bamigbetan et al. [6] proposed that pasteurization process, drying, distillation and so on all need the working temperature of 100-125 ℃. After screening, R600 and R1233zd(E) have better performance and basically suitable for the mainstream compressor. In addition to the pure substance, the research of mixed refrigerant has gradually become another direction. Yu et al. [7] conducted a binary near-azeotropic mixture named BY- 4. The COP was 2.8-3.6 when the temperature of outlet water was 90-110 ℃ and 40 ℃ temperature rose. Guo et al. [8] analyzed a series zoetropic mixture, proposed that N-hexane/propene and R4310mee/R32 are superior alternative to CO2 heat pump.

R245fa has been theoretically calculated or experimentally verified in some literatures to show that it is a kind of HTHP refrigerant with good performance, safety and stability [9],[10]. R245fa is widely used because of its high COP, low compressor discharge temperature and discharge pressure. The obvious disadvantage of R245fa is that its volumetric heating capacity is lower compared with the conventional heat pump refrigerant [11]. R600 is a recognized refrigerant which is suitable for HTHP, but its application is greatly restricted due to its inflammable and explosive characteristics [12]. R1234ze(Z) and R1233zd(E) are considered as potential substitutes for R245fa in some studies from the perspective of pure refrigerant [13]. In this paper, from the perspective of mixture refrigerant, a binary mixture substance R600/R245fa is proposed to provide more refrigerant choices for users of HTHPs. Most studies on the refrigerants of HTHP adopt the method of theoretical calculation, while in this study, the mixture refrigerant R600/R245 is tested on the experimental platform. For comparison, pure refrigerant R245fa with the same injection mass is also tested at the corresponding working conditions. According to the research of Zhou et al. [14], the theoretical cycle calculation results show that the mixture refrigerant prepared on R245fa has a higher COP when the mass ratio of R245fa is 0.5-0.7. Therefore, the ratio of R600/R245fa is defines as 0.3/0.7 in this experiment. The experimental results show that the two refrigerants R600 and R245fa can complement each other. After the two constitute a mixture refrigerant, the COP of the HTHP system decreases and the heating capacity increases. Compared with pure refrigerant R245fa, the compressor discharge temperature and discharge pressure of mixture refrigerant increases, the compression ratio decreases obviously. The GWP of the mixture refrigerant decreases compared with the pure refrigerant R245fa due to the low GWP of R600. The inflammable and explosive properties of R600 are also weakened because of its low proportion in the composition. The experiment setup are presented in Section 2. The thermodynamic analysis methods are described in Section 3. The results and discussions are arranged for Section 4. Conclusions are summarized in the last section.

2. Experiment setup

A HTHP system was designed and built for testing the performance of the proposed mixture refrigerant R245fa/R600. The schematic diagram of the HTHP system is shown in Fig. 1. The main equipment of the system is evaporator, condenser, electronic expansion valve and scroll compressor. A vapor-liquid separator is installed between the evaporator and the compressor to prevent the refrigerant liquid from entering the compressor and causing liquid hammer. The electronic expansion valve and the condenser are equipped with dry filter and liquid storage tank. Some other accessories together with the main equipment constitute the whole HTHP system. The heat source of the system is an adjustable electric heating tank. The temperature in the heating water tank can be maintained constant through the control cabinet to satisfy the requirements of

the evaporator's stable inlet temperature. The heat sink side of the system uses the fan-coil unit to discharge heat to outdoor air and maintain the heat balance of the system.

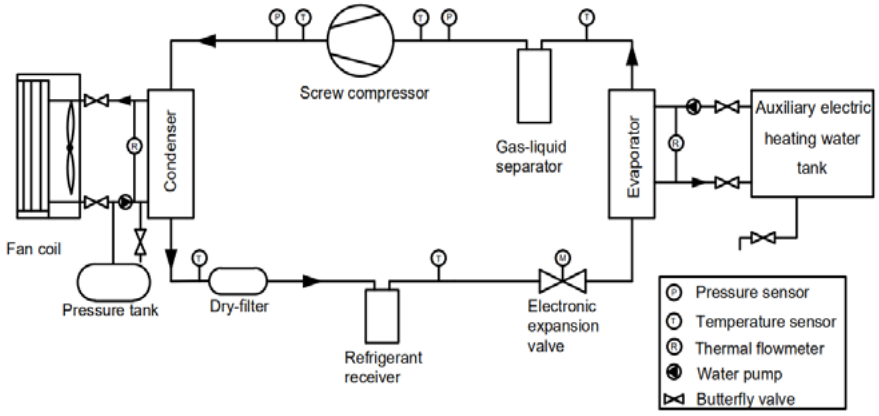

Fig. 1. Schematic diagram of the HTHP system

The detailed parameters of main equipment of HTHP are listed in Table 1. And the information of measuring instruments are listed in Table 2. Some parameters of the refrigerants are listed in Table 3.

Table 1. The main equipment parameters of the HTHP

Equipment	Type	Specification
Evaporator	EB12P3823	Heat transfer rate: 13.3 kW
Condenser	CB12P3823	Heat transfer rate: 14.7 kW
Electronic expansion valve	DPF(Q01)2.4	Diameter: 2.4 mm
Screw compressor	HRH049U4LP6	Rated power: 4.04 kW Nominal refrigeration capacity: 12110 W
Water pump	PUM200	Rated flow: 2.5 m^3/s; Pump head: 12 m; Power: 0.25 kW.
Fan coil	KFR-35GW/MHAB1	Specification: 1280×195×295 mm
Auxiliary electric heating water tank	SX-1000	Volume: 1 m^3

Table 2. The information of measuring instruments

Name	Type	Accuracy grade

Pressure transmitter	MIK- P50- 2 (low- pressure side) MIK- P100- 8 (high- pressure side)	± 0.5% FS included nonlinearity hysteresis and temperature drift
Digital power meter	RK9900N	± 0.5% FS
Turbine flow meter	LWY-25	± 1.0L
Pressure gauge	YTZ-150	± 1.5% FS
Temperature sensor	PT1000	A

Table 3. Some parameters of the refrigerants

Substance	Molar mass (g/mol)	Tb (℃)	Tc (℃)	Pc (MPa)	ODP	GWP (100yr)

R245fa	134.05	15.14	154.01	3.651	0	858
R600/R245fa (3:7)	96.31	/	132.74	3.557	0	/

3. Analysis method

The circulating principle of high temperature heat pump is reverse Carnot cycle, as shown in Fig. 2. The blue and red lines represent the temperature changes of the circulating water in the evaporator and the condenser respectively. The whole refrigerant cycle includes four thermodynamic processes: endothermic process (5-1) , compression process (1-2) , condensation process (2-4) , throttling process (4-5) . In order to simplify the calculation, the following assumptions are made as follows.

(1) All components of the system are operated under steady- states and steady- flow conditions.

(2) The changes in kinetic energy and potential energy of the refrigerant are ignored.

(3) The temperature loss and pressure loss of the refrigerant during pipeline circulation are ignored.

(4) The evaporation and condensation processes are isobaric.

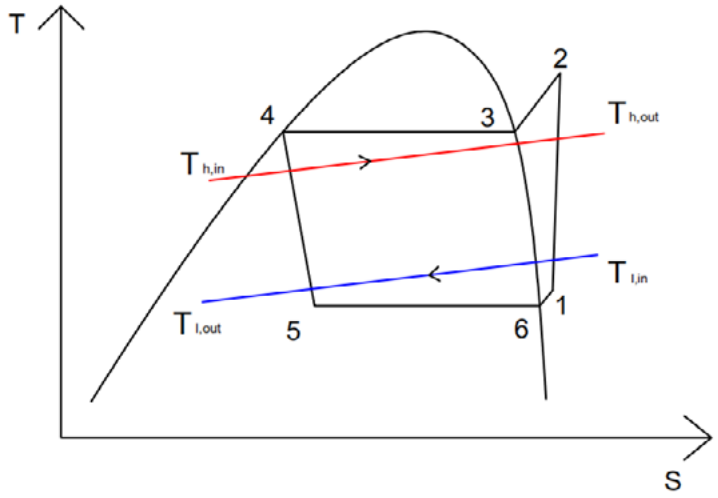

Fig. 2. T-s diagram of the HTHP

The energy equation of some components of the system, based on the first law of thermodynamics, can be calculated as follows.

(1) Condenser

The heating release of the refrigerant in the condenser can be calculated as follows：

$$Q_{con} = m_r(h_2 - h_4) = m_{hw}C_{p,hw}(T_{h,in} - T_{h,out}) \quad (1)$$

Where h2 is the enthalpy of the refrigerant at the condenser inlet, h4 is the enthalpy of the refrigerant at the condenser outlet, mr is the mass flow rate of the refrigerant, mhw is the mass flow rate of the high temperature water passing through the condenser, Th,in is the temperature of high temperature water at the condenser inlet, Th,out is the temperature of high temperature water at the condenser outlet, Cp,hw is the constant pressure specific heat capacity of the high temperature water.

(2) Scroll compressor

Scroll compressor is suitable for small units because of its high efficiency and strong stability. The efficiency of compressor can be calculated as follows:

$$\eta = \frac{P_a}{P_{in}} \quad (2)$$

Where η is the compression efficiency, Pin is the input power of the compressor which can be measured directly, Pa is the available power which can be expressed as:

$$P_a = m_r(h_2 - h_1) \quad (3)$$

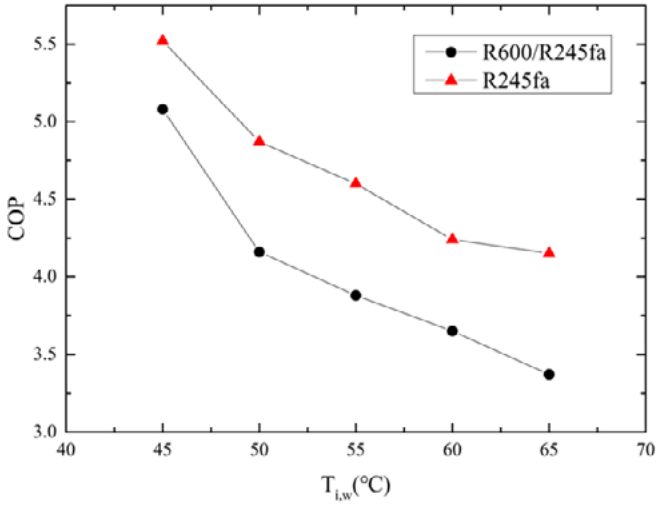
Where h1 is the enthalpy of refrigerant at the evaporator outlet.

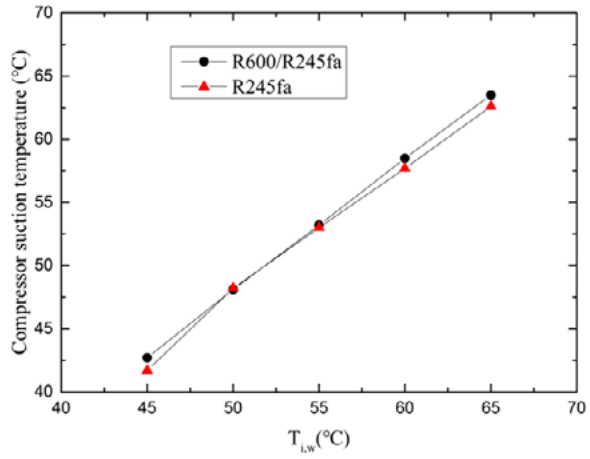
In conclusion, the COP of the system can be calculated as follows:

$$COP = \frac{Q_{con}}{P_{in}} \tag{4}$$

4. Results and discussions

The evaporator inlet water temperature of the experiment ranged from 45 ℃ to 65 ℃ and the temperature interval is 5 ℃ . The temperature lift between evaporator inlet water and condenser outlet water remains constant at 35 ℃ . When the operating condition is stable, the HTHP performance is tested and investigated under different operating conditions. For the convenience of the following description, R600/R245fa is denoted by R1 and R245fa is denoted by R2.





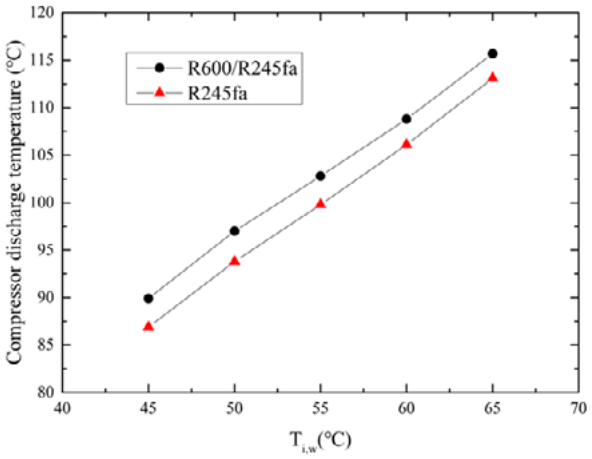


Fig. 3. The COP of HTHP varied with different inlet water temperature of the evaporator

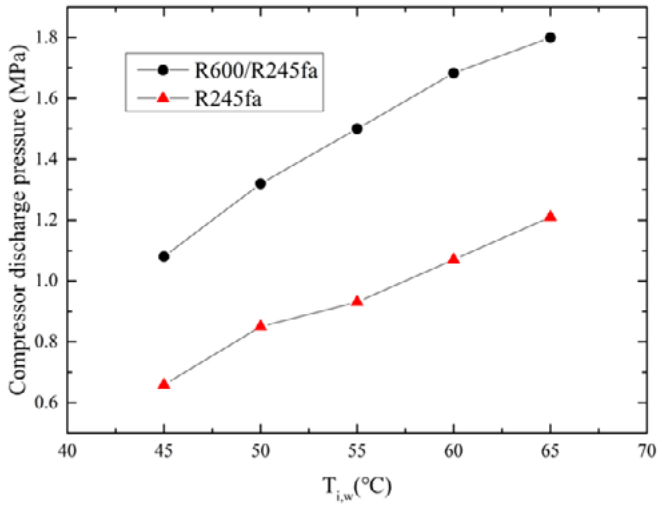
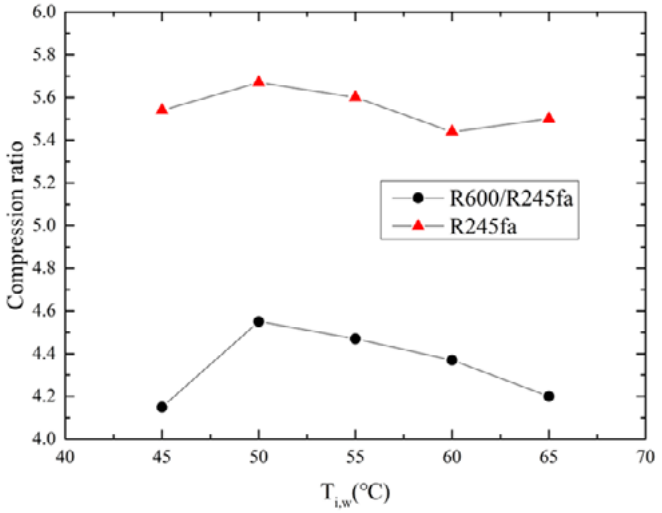
As shown in Fig. 3, the COP of R1 and R2 decreases gradually with the increase of evaporator inlet water temperature. When the inlet water temperature increased from 45 ℃ to 65 ℃ , the COP of HTHP using R1 and R2 decreases by 1.71, 1.37 respectively. It means that the COP of the HTHP system decreases by 1.68 % and 1.24% on average with the evaporator inlet water temperature increased by 1 ℃ . Among them, the COP decreases faster in the temperature interval 45-50 ℃ , and the other temperature intervals decrease evenly. The average COP of using R1 decreases about 13.9% compared with R2. Considering the experimental error, the R1 also can maintain the average COP not less than 3.0 when the water temperature lift is 35 ℃ and the outlet water temperature at 100 ℃.



(a) The compressor suction temperature changed with different inlet water temperature of the evaporator



(b) The compressor discharge temperature changed with different inlet water temperature of the evaporator

Fig. 4. The compressor suction temperature and discharge temperature changed with different working conditions

As shown in Fig. 4 (a), the compressor suction temperature varies with different inlet water temperature of the evaporator. R1 has a slightly higher compressor suction temperature than R2 in this experiment. The compressor suction temperature is lower than the evaporator inlet water temperature, which may be due to a little amount of liquid refrigerant evaporates and absorbs heating at the inlet of the compressor. The Fig. 4 (b) shows the change of compressor discharge temperature under different evaporator inlet water temperatures. The compressor discharge temperature corresponding to R1 is significantly higher than that to R2, and the average temperature overshoot is 2.9 ℃. The difference between the compressor suction temperature and the discharge temperature will rise with the increase of the evaporator inlet water temperature in this experiment.

(a)

(b)

Fig. 5. The variation of the discharge pressure of the compressor (a) and compression ratio (b) changed with different inlet water temperature of the evaporator

Fig. 5 shows the variation of the compressor discharge pressure and compression ratio under different working conditions. As shown in Fig. 5(a) , the compressor discharge pressure of R1 is 0.533MPa higher than R2 on average. The maximum of the difference between the two pressures occurs when Ti,w is 60 ℃ and the value is 0.613 MPa. Despite the higher compressor discharge pressure of the R1, it can been seen from Fig. 8

5(b) that the compression ratio is lower. The average compression ratio of R1 is 4.35 and the average compression ratio of R2 is 5.55. The different of the mean value is 1.2. It seems that R1 may be suitable for higher heating temperatures form the trend. In general, R1 is superior to R2 in term of compression ratio.

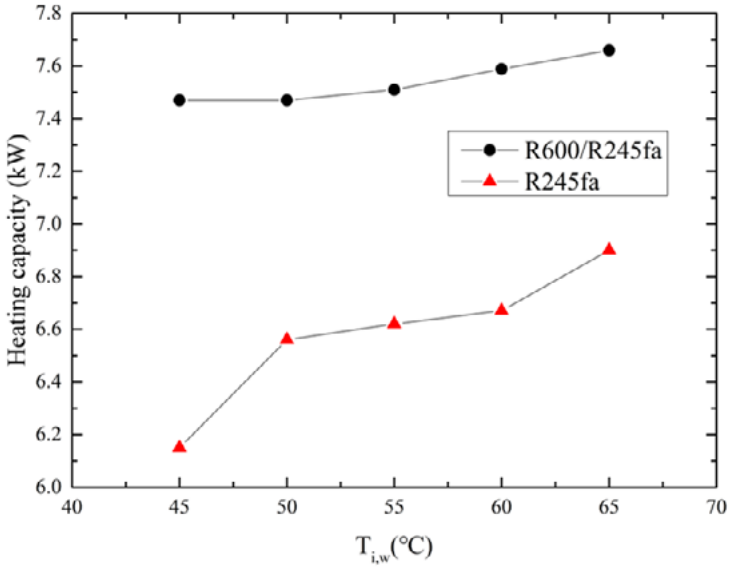


Fig. 6. The heating capacity of HTHP varied with different inlet water temperature of the evaporator

As shown in Fig. 6, the heating capacity of the HTHP using R1 as refrigerant is significantly higher than that of R2. The value of using R1 is on average 14.7% higher than that of R2. This suggests that R1 is better suited to higher heating capacity requirements of HTHPs than R2. The heating capacity of the HTHP is negatively correlated with the compression ratio. In this experiment, with the increase of the evaporator inlet water temperature, the compression ratio of the two refrigerant decreases gradually. It makes the compressor volume efficiency lift, resulting in the increase of the actual compressor gas transmitting volume. Meanwhile the volumetric heating capacity decreases with the rise of condensation temperature, but the product of volumetric heating capacity and refrigerant steam volume at the outlet of the compressor will still increase, that is, the heating capacity of the HTHP will continue to increase.

5. Conclusion

The operating performance of the HTHP system using R600/R245fa and R245fa as refrigerant are obtained by experimental test under different running conditions. We analyzed these data and reach the following conclusions:

1. From the point of the COP, the mixture refrigerant R600/R245fa is less than R245fa and the COP dropped by an average of 13.9%. But the mixed refrigerant R600/R245fa can keep the COP at least 3.0 when the temperature lift is 35 ℃ and outlet water temperature at 100 ℃. Therefore, this kind mixture refrigerant can be accepted for HTHPs.

2. The compressor discharge temperature and compressor discharge pressure of HTHP using R600/R245fa will be higher than that of R245fa. However, R600/R245fa has advantages in terms of compression ratio and heating capacity, in which the compression ratio decreases 1.2 on average and the heating capacity increases 14.7% on average.

3. Compared with the R245fa, the mixture refrigerant R600/R245fa is more suitable for HTHPs with higher heating capacity demand and higher temperature working conditions.

4. The mixture refrigerant R600/R245fa has lower GWP than the R245fa, which has certain advantages in environmental protection.

Abstract

For protecting the global environment, low GWP refrigerants are to be incorporated in air conditioning systems and refrigerating devices, such as refrigerated display cabinets (RDCs) commonly used in convenience stores and supermarkets. R290 (propane), as a natural refrigerant, has been receiving attention as a potential working fluid alternative but poses safety issues due to its flammable characteristic. As the demand for safe refrigeration systems with easy maintenance is increasing, this study evaluated the utilization of HFO-1234yf for RDCs, and its performance was compared to R290 and other commonly used refrigerants. Simulations were conducted based on actual ambient temperature data from a convenience store. Results showed that the COP of HFO-1234yf was slightly lower than those of R290 and R134a, but higher than those of R410A, R32, and R744. The annual power consumption and the annual performance factor of HFO-1234yf were very similar to those of R290. Hence, it is expected that RDCs using HFO-1234yf will perform as efficiently as those using R290.

Keywords: Showcase; Performance Evaluation; Refrigerants; HFO-1234yf; Simulation

1. Introduction

Recent trends in global warming prevention have been revised by the Kigali Amendment in the Montreal Protocol [1], and an obligation was established to reduce HFCs by 85% by 2036. Therefore, to achieve the reduction obligation by 2029, before the amount of HFCs becomes severe in Japan, refrigeration equipment using low GWP refrigerant and reduction of refrigerant leakage is to be developed. However, if a low GWP refrigerant is used without preliminary evaluation of the equipment performance, then it can result in (1) inefficient operation, and (2) increased energy required for manufacturing.

Apart from the proper selection of the working fluid focused on natural refrigerants to lessen direct CO2 emissions, systems that utilize these refrigerants must work efficiently to avoid over power consumption that results in indirect CO2 emissions. As of March 2019, 58,000 convenience stores operate in Japan, with annual sales exceeding 10 trillion yen [2]. Most of the energy consumption at convenience stores is due to lighting, air conditioning, and refrigeration equipment [3]. There is a high demand for refrigerated display cabinets (RDCs) as one of the commonly used refrigeration equipment to hold and preserve perishable goods while offering ease of accessibility to the customers. There are two types of RDCs: “built-in type” and “separate type.” In the former, a condensing unit, with mechanical parts such as a compressor and a condenser, is integrated with a device for displaying and cooling the product, while the latter features the separation of the evaporating and condensing units at the indoor and outdoor, respectively. Convenience stores often use built-in RDCs because they can easily accommodate changes in store layout and restrictions on the location of condensing units. Convenience store owners are also keen on the operational safety of the refrigerated display cabinets.

In this study, a simulator was built and used to evaluate alternative working fluids that can conform to the environmental standards, operational safety, and system efficiency, particularly for built-in type RDCs. The results can be used for benchmarking and preliminary assessment of the performance before manufacturing and utilization of the systems. In particular, this study evaluated the potentiality of HFO-1234yf refrigerant as a low GWP refrigerant to replace commonly used high GWP refrigerants, such as R134a, R410A, and R32. Furthermore, the performance of HFO-1234yf was compared to that of R290, as the latter has received attention for possible usage despite its high flammability that poses safety issues.

2. Methods

The annual energy performance of RDCs using various refrigerants was evaluated. Here, an annual performance evaluation simulator for RDCs was constructed based on the annual interior conditions at a store in Japan. Furthermore, the simulator evaluated the annual performance by changing the refrigerant. This feature makes it easy to assess the performance of a variety of refrigerants without incorporating them in actual equipment.

2.1. Simulator Overview

The annual performance simulator was input with specifications and conditions of the RDCs, and the store interior temperature conditions (in case of the built-in type) and the outdoor temperature conditions (in case of the separate type). The simulator provided the annual performance as output. For analyzing the applicability of low GWP refrigerants to RDCs, the annual performance of showcases was evaluated. Therefore, the annual power consumption of the RDCs, the annual average COP, and the time-series data of the operating state such as compressor discharge temperature, were obtained as output. Fig. 1 shows the input/output relationship of the annual performance simulator. The annual performance was calculated by the simulator that used the thermodynamic cycle analysis. This simulator applied pinch temperature analysis as its calculation principle [4]. For subcritical cycle refrigerants, the pinch temperature was applied at the condenser refrigerant outlet. The subcooled condition was determined by the temperature difference between the condensation temperature and ambient temperature, and the pinch temperature. In the case of R744 (CO_2), the pinch temperature was used at the gas cooler refrigerant outlet.

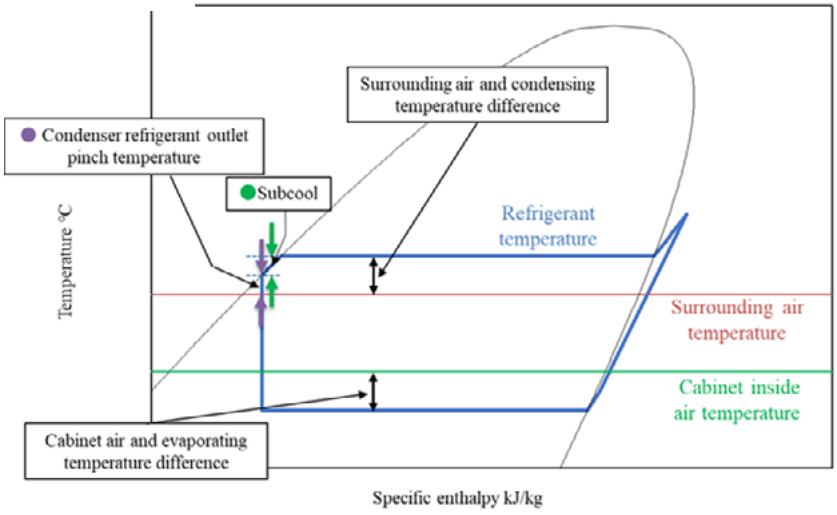

Fig. 1. Temperature-enthalpy diagram

2.2. Calculation prerequisites

The performance of RDC systems using various refrigerants can be compared in the thermodynamic cycle. Table 1 shows the computational elements used for the performance calculation.

Table 1 Computational elements

Computational elements
Difference between the evaporating temperature and the surrounding air temperature
Evaporator outlet superheat
Difference between the condensing temperature and the surrounding air temperature
Compressor adiabatic efficiency
Isenthalpic process at the expansion valve

The procedure to determine the cycle is as follows:

1. Determine the evaporation temperature from the cabinet air temperature.
2. Determine the condenser temperature from the surrounding air temperature and the refrigerant outlet pinch temperature.
3. Determine the refrigerant properties of the compressor suction considering the evaporator superheat.
4. Determine the refrigerant properties at the compressor outlet considering compressor adiabatic efficiency.

A fixed temperature difference between the heat exchanger and the ambient temperature was employed, where the difference in heat transfer performance and pressure loss due to the physical properties of the refrigerant was not considered. This is because the thermal resistance on the air side is dominant and there is no significant difference in the temperature difference between refrigerants.

3. Results and Discussion

3.1. Annual exterior and interior temperatures at an actual store

Various measurement data obtained at an actual convenience store were examined to conduct the simulation under conditions that represent those in an actual store. Fig. 2 shows the exterior and interior store temperatures measured for one year in an actual store. This data was measured at one-hour intervals between June 1, 2017, and May 31, 2018. However, there are some missing data.

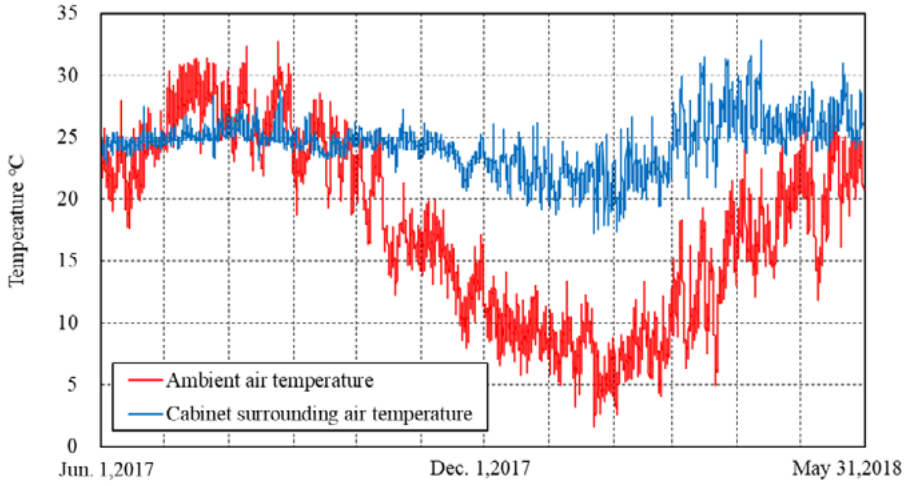

Fig. 2. Indoor and outdoor air temperature of an actual store

The simulator used the physical properties of the refrigerants based on the data from the NIST REFPROP [5]. Tables 2 and 3 list the physical properties, GWP, and the safety classifications of the refrigerants considered in the study.

Table 2 Physical properties, GWP, and safety class of various refrigerants (1/2)

Refrigerant	GWP [6]	Critical temperature °C	Critical pressure MPa	Safety class
R134a	1430	101.06	4.059	A1
R1234yf	< 1	94.70	3.382	A2L
R290	3.3	96.74	4.251	A3
R410A	2088	71.34	4.901	A1
R32	675	78.11	5.783	A2L
R744	1	30.98	7.377	A1

Table 3 Physical properties of various refrigerants (2/2)

Refrigerant	Condensing pressure MPa	Evaporating pressure MPa	COP	Volume capacity kJ/m^3	Suction density kg/m^3	Capacity kJ/kg Refrigerant
R134a	0.887	0.243	4.01	1865	11.780	158.30
R1234yf	0.895	0.266	3.89	1806	14.556	124.05
R290	1.218	0.406	3.96	2597	8.686	298.99
R410A	2.144	0.678	3.78	4440	25.111	176.80
R32	2.190	0.691	3.84	4815	18.176	264.93
R744	8.019	3.046	2.66	12446	79.064	157.42

Table 4 lists the preconditions of the RDC set for the calculation. These input conditions do not necessarily reflect actual machine data, but by maintaining these uniform conditions, a calculation can be performed to an approximate refrigeration system in accordance with the physical properties of various refrigerants. As the condensation temperature of R744 cannot be defined under the calculation conditions shown in Table 4, the pinch temperature of the gas cooler outlet temperature sets the pressure at which the COP is maximum as the high operating pressure [7].

Fig. 3 shows COP calculation results of various refrigerants. In terms of the COP, the results confirm that R1234yf is slightly inferior to R134a and R290, equivalent to R32, and superior to R410A and R744.

Table 4 Specifications of the calculation

Condition	Value
Difference between condensing temperature and the surrounding air temperature °C	10
Cabinet temperature °C	25
Surrounding air temperature °C	5
Difference between evaporating temperature and the surrounding air temperature °C	10
Evaporating temperature °C	-5
Evaporator outlet superheat °C	5
Compressor adiabatic efficiency	0.7

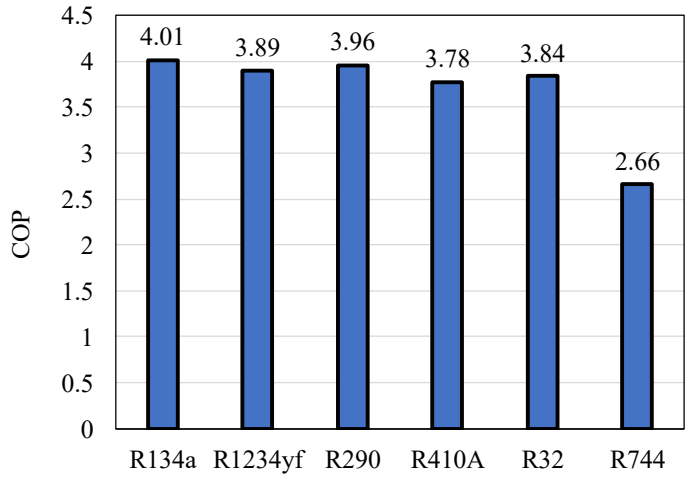

Fig. 3. COP calculation results of various refrigerants

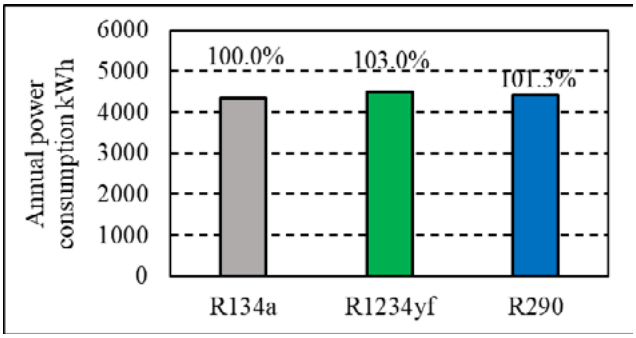

3.2. Annual performance evaluation with fixed heat load

The performance of RDC systems were evaluated from two sets of simulations: with fixed heat load and with heat load variation when the type of refrigerant was changed based on the indoor temperature and the inside of cabinet temperature data measured at an actual store. The result for one year was calculated at hourly intervals. For the cabinet temperature of the refrigerated showcase, the actual average value of one-minute interval data per day for each season was considered, because there were no hourly data throughout the year.

At first, we simulated the performance of RDC systems with fixed heat load. The heat load was fixed at 2 kW. Linear interpolation was applied to account for some missing time-series data. The comparisons were focused mainly on R1234yf and R290 with R134a as the baseline, as these refrigerants have shown better COP values compared to the other working fluids presented in the previous section. Additionally, these three refrigerants exhibit similar critical temperatures and properties. Fig. 4 shows the ratio of the annual power consumption of R1234yf and R290 with respect to R134a, and Fig. 5 shows the annual average COP obtained by dividing the annual total refrigeration load by the power consumption. Table 5 shows the assumed specifications of the RDC set.

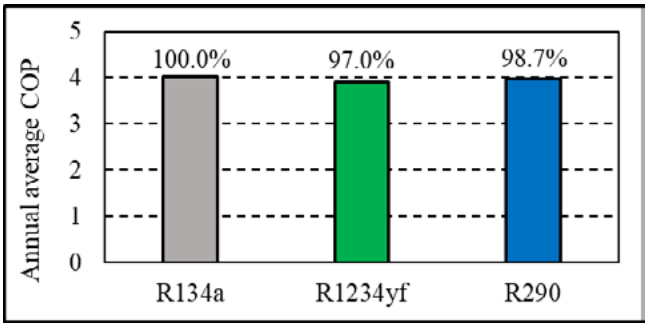

Table 5. Specifications of the RDC set

Specifications	
Rated refrigeration load	2 kW
Type	Built-in type
Physical size	Standard size (specific size is not considered)

Refrigerant	Annual power consumption (kWh)
R134a	4343
R1234yf	4475
R290	4400

Fig. 4. Annual power consumption calculation results for three refrigerants at 2kW heat load

Refrigerant	Annual average COP
R134a	4.03
R1234yf	3.92
R290	3.98

Fig. 5. Annual average COP calculation results for three refrigerants at 2kW heat load

Fig. 6 shows the results of calculating the hourly change in the COP of three refrigerants for one year. From Fig. 4–6, it is evident that the performance of R1234yf is similar to that of R290.

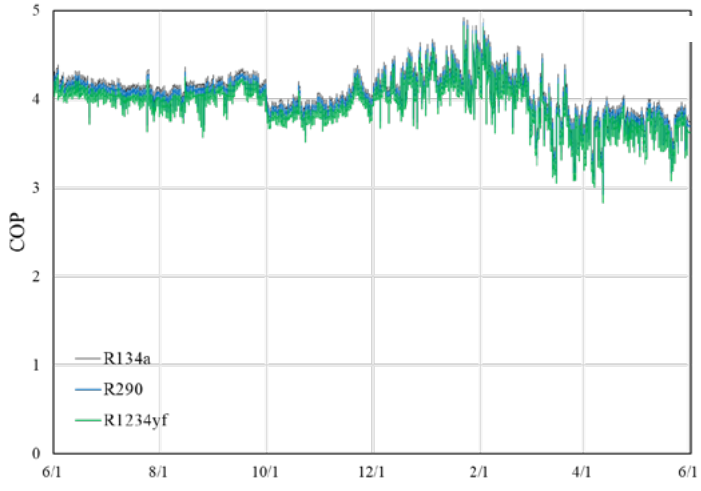

Fig. 6. Hourly COP for one year for three refrigerants at 2kW heat load

3.3. Annual performance evaluation with varying heat load

Next, we simulated the performance of RDC systems with varying heat load. This is because the surrounding air temperature at RDC changes in the case of an open refrigerated display cabinet. The heat load is assumed to change due to cold air leaks from the RDC while an outside air infiltrates [8]. Varying the heat load was obtained from the correlation between the difference of the inside and surrounding air temperature of RDC, and the heat load calculated from the experimental values. The experimental measurements were taken using the actual machine during three periods with varying temperatures at the surrounding environment of the RDC: summer, mid-term, and winter, and the heat load was calculated from the evaporator inlet/outlet temperature and airflow rate.

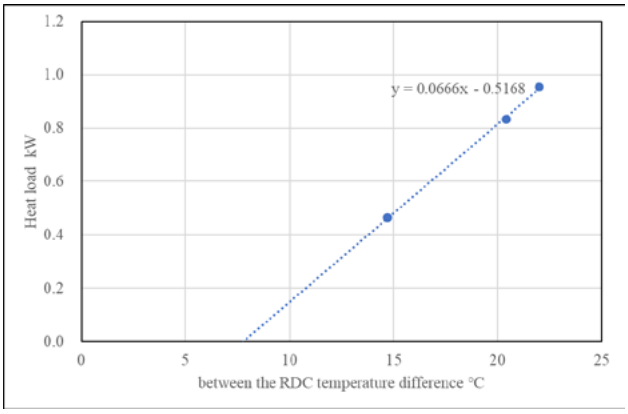
Table 6 shows the results of the heat load during the three periods. The calculated heat load from the experimental values was linearly approximated.

Fig.7 presents the results of the correlation for the difference between the surrounding air and inside temperature of the RDC, against the heat load.

As observed from Fig. 7, the heat load of the target RDCs was less than 1kW.

Table 6. Calculated heat load during the three periods

	Summer	Mid-term	Winter
RDC surrounding air temperature ℃	27	25	19.3
RDC inside temperature ℃	5	4.6	4.6
Heat Load kW	0.953	0.831	0.464



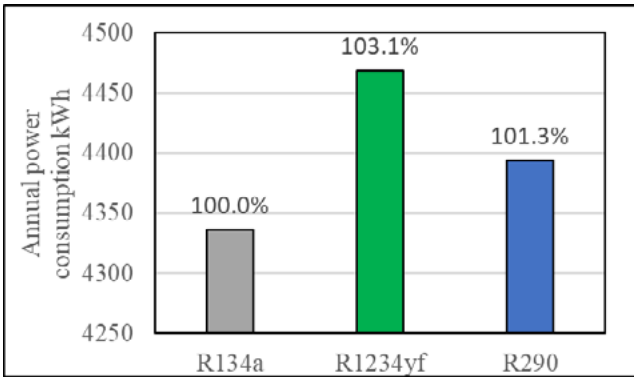


Fig. 7. Correlation between the RDC temperature difference and heat load

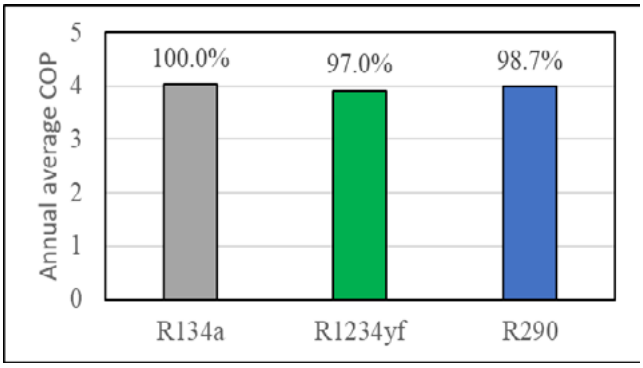

To compare the annual power consumption and annual average COP for fixed and variable loads, the correlation equation shown in Fig. 7 was scaled up so that the average heat load conforms to 2 kW. The results are shown in Fig. 8 and Fig. 9. Furthermore, the correlation equation between the heat load and heat exchange temperature difference does not apply because it varies with the geometry of each equipment and refrigerant, hence the set of preconditions of the RDC from Table 4 was used for the calculation.

Fig. 8 shows the ratio of the annual power consumption of R1234yf and R290 with respect to R134a, while Fig. 9 shows the annual average COP.

Refrigerant	Annual power consumption (kWh)
R134a	4336
R1234yf	4468
R290	4394

Fig. 8. Annual power consumption calculation results for three refrigerants with varying heat load

Refrigerant	Annual average COP
R134a	4.04
R1234yf	3.92
R290	3.98

Fig. 9. Annual average COP calculation results for three refrigerants with varying heat load

Table 7 shows the calculated values for the annual power consumption and the average annual COP for fixed and variable heat load. The results show that the error in the average annual power consumption figure is about 0.15%, and the average annual COP changed insignificantly.

Table 7 Comparison of annual energy consumption and annual average COP at fixed and variable heat loads

Refrigerant	Heat load fixed		Heat Load Variation	
	Annual energy consumption	Annual average COP	Annual energy consumption	Annual average COP
R134a	4343	4.03	4336	4.04
R1234yf	4475	3.92	4468	3.92
R290	4400	3.98	4394	3.98

Fig. 10 shows the results of calculating the hourly change in the COP of three refrigerants for one year. As in the case of fixed heat load, the performance of R1234yf is similar to that of R290.

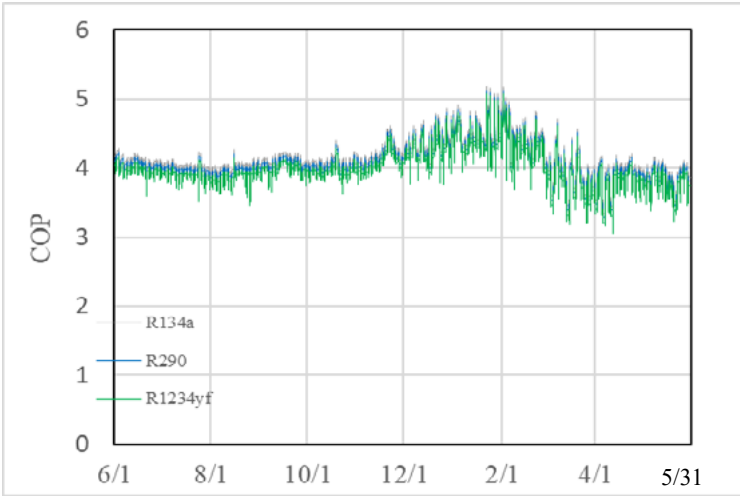

Fig. 10. Hourly COP for one year for three refrigerants with varying heat load

These results show that the annual power consumption and the average annual COP for fixed and variable heat loads are almost the same. One of the reasons for this is that the surrounding air temperature at RDC does not change much because the target is built-in RDCs, and the heat load does not consequently change much throughout the year.

3.4. Parameter study

A simulation calculation was performed to examine the effect of varying the cabinet temperature of the RDC on the annual power consumption and annual average COP. This simulation was performed with a fixed heat load of 2kW. Table 7 and Table 8 list the calculation results of annual power consumption and annual average COP, respectively.

Table 7 Annual power consumption (kwh)

Refrigerant	Cabinet temperature		
	4 ℃	5 ℃	6 ℃
R134a	4388	4271	4151
R1234yf	4522	4398	4271
R290	4445	4328	4207

Table 8. Annual average COP

Refrigerant	Cabinet temperature		
	4 ℃	5 ℃	6 ℃
R134a	3.99	4.10	4.22
R1234yf	3.87	3.98	4.10
R290	3.94	4.05	4.16

It is evident from Table 7 that when the cabinet temperature is lowered by 1 °C, the annual power consumption increases, and annual average COP decreases by approximately 3%. Table 7 and Table 8 indicate that the power consumption of R1234yf increases by approximately 1–2% compared to that of R290, and annual average COP decreases by 1–2%. Thus, it can be concluded that the performance of R1234yf is closely equivalent to that of

R290.

4. Conclusion

Simulations were performed to compare the performance of HFO-1234yf refrigerant to those of various refrigerants when used for refrigerated display cabinets. The COP of HFO-1234yf refrigerant was slightly lower than R134a and R290, but higher than conventionally used high GWP refrigerants such as R410A, and even R32. HFO-1234yf also outperformed R744 (CO_2). Based on the annual power consumption and annual average COP results, and it was confirmed that HFO-1234yf performed as efficiently as R290. Therefore, RDCs using HFO-1234yf are expected to exhibit a system performance that is as efficient as those using R290. Owing to the safety desired from integrated RDCs installed in stores and supermarkets, the low GWP refrigerant, R1234yf, is considered to be more suitable than R290.

In the future, as the built-in type refrigerated display cabinet was considered in this study, the separated type will be considered. Furthermore, to verify the accuracy of the simulation results, we plan to conduct more experiments to evaluate the performance with actual machines.

A Techno-Economic Assessment of Air-Source Heat Pumping Technologies in the Canadian Residential Sector

Justin Tamasauskas[a,*], Stéphanie Breton[a], Martin Kegel[a]

[a]CanmetENERGY in Varennes, Natural Resources Canada, 1615 Lionel Boulet Blvd, Varennes, Quebec, Canada, J3X 1P7

Abstract

While heat pump systems have strong potential to reduce energy use in the Canadian residential sector, the optimal system type and configuration can vary greatly depending on local climate and economic conditions. This paper applies techno-economic analysis to compare three market available air-to-air heat pumps (single stage, conventional variable capacity, and cold climate variable capacity) and examine their relative potential under different climate and utility rate structures. Using an improved, data-driven heat pump model, the economic and energy performance of each system is assessed for new construction housing in three Canadian regions. Results demonstrate the energy savings benefit of cold climate heat pumps in harsher winter climates, and the challenging economic context faced by heat pumps under current low natural gas rates in some Canadian regions. Key design concepts, including the sensitivity of the results to changes in estimated operating COP, and the strong link between peak loads and the combined control of the heat pump and auxiliary systems, are also discussed in order to promote an improved integration of heat pumps in Canada.

Keywords: Variable capacity heat pumps; Cold climate heat pumps; Techno-economic analysis; Canadian residential sector

1. Introduction

As the world transitions towards a decarbonized economy and infrastructure, efficient renewable energy technologies are of great importance. In recognition of this context, the Government of Canada has developed a Market Transformation Roadmap [1], which presents a framework for an increased adoption of the high efficiency mechanical systems needed to drive decarbonisation of the built environment. Heat pumps play an important role within the Roadmap, responding to key aspirational goals regarding future high efficiency space heating systems (Target energy performance[1] >100%) and the integration of renewable energy. However, to fully capitalize on this strong potential, appropriate heat pump system selection is of critical importance.

The Canadian context represents a particularly challenging set of circumstances for heat pump integration. Significant variations in both climate (mild maritime to extreme cold) and utility rate structures (vast differences in natural gas vs. electricity rates) often mean that the optimal system choice is highly dependent on local climate and economic conditions. Selection can be further complicated when considering the peak load impacts of heat pumps, an aspect of growing importance given the increasing electrification of building systems and more widespread heat pump adoption.

The current Canadian residential heat pump market is dominated by air-source (air-to-air) heat pumps, driven by their lower costs and relative ease of installation [2]. However, traditional single stage systems suffer significant performance degradations at colder temperatures while cycling frequently at milder conditions, making it difficult to meet comfort needs in Canadian climates. The last decade has seen important technological advances in the market, including the increased availability of inverter-driven variable speed compressors, and the introduction of cold climate air-source heat pumps, which combine variable capacity

[1] Energy performance here refers to how efficiently a selected technology delivers space heating, quantified using the COP and Heating Season Performance Factor (HSPF) (heat pumps) or annual fuel utilization efficiency (AFUE) (gas and oil-fired equipment) [1]. These targets provide important motivation for increased heat pump adoption in Canada.

technology with larger outdoor coils and other cycle improvements such as vapour injection [3,4]. These advancements allow the heat pump to provide increased heating capacities at lower ambient temperatures, while still efficiently modulating at milder conditions. While previous studies have examined the energy performance of these systems and their economics in isolation [5,6], there is little information available regarding when the added investment for cold climate and variable capacity technologies is most appropriate, or how the economics of different air-source heat pump technologies compare across Canada.

This paper presents a simulation-based approach, driven by extensive testing and measured data, to assess the relative benefits of three types of market available air-source heat pumps: conventional single speed systems, conventional variable capacity units, and cold climate (variable capacity) heat pumps. A new data-driven heat pump model, capable of appropriately capturing the unique performance characteristics of variable capacity heat pumps, is used as a base for system assessment. Each heat pump integration is examined for newly constructed housing in three Canadian regions (Montreal, Edmonton, and Vancouver) to identify the potential for energy and lifecycle cost savings. A grid interaction analysis is also performed to more fully understand the implications of a given system selection.

2. Development of Base Case Housing Models

Climate, utility rate structure, and the type of heat pump integration (ducted or ductless) can vary greatly across Canada. In order to highlight these effects, three Canadian regions were selected, each representing a unique set of boundary conditions. Key climate parameters for each region are provided in Table 1 [7].

Table 1 Summary of climate characteristics

Characteristic	Montreal	Edmonton	Vancouver
Heating Design Temperature (°C)	-23	-30	-7
Heating Degree Days Below 18°C	4,200	5,120	2,825
Climate Type	Cold & Humid	Cold & Dry	Cool & Humid

Housing models used in the analysis were selected to be representative of typical single family housing, with building geometry based on the Canadian Centre for Housing Technology (CCHT) test homes located in Ottawa, Canada [8]. The modelled home included two above ground floors and a finished basement, with a total heated floor area of 284 m^2. The building envelope was modified to represent new construction housing in each region using National Building Code of Canada (NBC) minimum requirements for the appropriate climate zone [7]. Building mechanical systems were based on typical configurations in each region, and included both centrally ducted systems (Edmonton, Vancouver) and non-ducted configurations (Montreal). It is important to note that Montreal does include small flexible ducting to distribute a low volume (65 CFM) of ventilation air from the HRV, with a small electric duct heater used to ensure a suitable ventilation supply air temperature. A summary of key housing characteristics for each base case is provided in Table 2, with further details available in Kegel *et al.* [9].

Table 2 Key housing characteristics for base case models

Characteristic	Montreal	Edmonton	Vancouver
Central Air Distribution	No	Yes	Yes
Primary Heat Fuel & System	Electric Baseboard Heaters	Natural Gas Forced Air Furnace	Natural Gas Forced Air Furnace
Heating Efficiency	100%	92%	92%
Space Cooling System	Split AC Unit COP = 3.3*	Central AC COP = 3.5*	Central AC COP = 3.5*
DHW Fuel	Electric	Natural Gas	Natural Gas
Heat Recovery Ventilator (HRV)	Yes	Yes	Yes

*At AHRI rating conditions

3. Heat Pump System Integrations

Each base case model serves as a platform to assess three different heat pump technologies:

I. Conventional Single Stage Air-Source Heat Pump (**SSHP**)
II. Conventional Variable Capacity Air-Source Heat Pump (**VCHP**)
III. Cold Climate (Variable Capacity) Air-Source Heat Pump (**CCHP**)

It is important to note that the method of heat distribution within the home can vary depending on whether central ducting is available. As such, for each system type listed above (SSHP, VCHP, CCHP), both ducted and non-ducted configurations were examined. For locations with existing central ducting (Edmonton, Vancouver), a ducted heat pump configuration is proposed, with the indoor coil of the heat pump integrated into a central air handling unit. For homes without central ducting (Montreal), a ductless configuration is proposed, with a wall mounted indoor unit located in the stairwell connecting the first and second floors of the home. In this configuration, the basement is heated only using electric baseboards, as per the base case.

For all heat pump cases, system sizing was chosen to match the capacity used in the CCHP analysis. This decision was made to provide a common base of comparison for all systems, and to avoid cross-effects from different sizing methodologies. System sizing for the CCHP case was based on the heat pump acting as the primary source of heating for the building, supplemented by limited auxiliary heating operations if needed.

System sizing in Montreal is limited to 1.5 tons, the largest market available system size for the ductless CCHP *used in the simulations*. As outlined later in this paper, the simulation model for this heat pump was based on extensive test data, with the tested model not available in sizes > 1.5 tons. This limitation is better understood by noting the type of ductless system used: A single-split (one indoor unit, one outdoor unit) ductless configuration. Although a multi-split unit (multiple indoor units, one outdoor unit) is a more likely choice given the size of the home in this study, the single-split unit is modelled due to the availability of extensive performance data derived from detailed testing at the CanmetENERGY facility. Given that similar data was not available for multi-split systems, the single-split was used instead to avoid employing additional modelling assumptions, while more closely representing as-installed performance.

Single Stage Air-Source Heat Pump

The single stage heat pump represents the most basic system available in the current market, and is included in the analysis to provide a point of reference for the other technologies.

Single stage heat pumps encounter two significant challenges when operating in many Canadian climates:

I. Heating capacity drops drastically at colder ambient temperatures, increasing auxiliary energy use
II. Available capacity at milder conditions is often far greater than the building heating load, leading to frequent and inefficient on/off cycling.

Given the reduced heating performance at colder ambient temperatures, fully sized auxiliary systems (sized to meet the peak heating loads) are required. For ductless configurations, auxiliary heating is achieved using electric baseboards located in each thermal zone, while for centrally ducted configurations, an electric duct heater is used to supplement heat pump operations as required. Key SSHP parameters are provided in Table 3.

Table 3 Performance characteristics for single stage heat pump

	Montreal	**Edmonton**	**Vancouver**
HP Size	1.5 Ton	3 Ton	2 Ton
HP Configuration	Ductless	Ducted	Ducted
Heating COP*	3.2	3.7	3.7

Min. Outdoor Operating Temperature, Heating Mode (°C)	-8	-20	-20
% of Rated Capacity @ Cut-Off	62%	27%	27%

*At AHRI Rating Conditions

Conventional Variable Capacity Air-Source Heat Pump

Variable capacity units account for a growing share of the Canadian market, driven by increased energy savings resulting from the ability to efficiently modulate the capacity of the unit to match heating or cooling demand. However, variable capacity technology alone does not necessarily constitute a cold climate heat pump: Many market available units provide less than 50% of rated capacity at outdoor air temperatures of -20°C or -25°C. This integration examines these more conventional variable capacity systems in each region.

Variable capacity heat pumps are defined both by their full capacity at maximum speed, and their ability to modulate to meet reduced loads. Fig. 1 presents the heating capacity and COP as a function of outdoor air temperature for a representative ducted variable capacity heat pump [10]. Capacity curves are normalized based on AHRI rating conditions (i.e. capacity at 47°F (8.3°C)). It is important to note the increase in COP at lower compressor speeds, which allows this type of heat pump to operate at improved efficiencies during times of lower heating demand while also limiting on/off cycling.

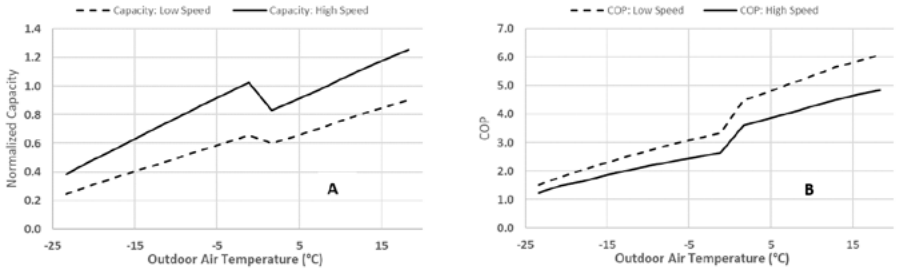

Fig. 1. Variation of (A) heating capacity and (B) COP at minimum and maximum capacity for a typical VCHP [10]

A summary of key variable speed heat pump parameters for each region is provided in Table 4.

Table 4 Key performance characteristics for variable capacity (non-cold climate) heat pumps

% Capacity at Cut-Off Temperature (Max Speed)	51%	38%	38%
Average Min: Max Capacity Ratio	0.32	0.30	0.30

*At AHRI Rating Conditions

Cold Climate Variable Capacity Air-Source Heat Pump

Cold climate heat pumps combine variable capacity technologies with other cycle improvements (e.g., larger outdoor coils, vapour injection cycles) to maintain a larger portion of heating capacity at low outdoor air temperatures. While several definitions for cold climate heat pumps are available in the literature [11,12], in this study they have been classified based on an ability to operate to a minimum outdoor air temperature of -25°C, while still maintaining over 65% of their rated capacity. These performance characteristics make cold climate units well suited to space heating in many Canadian regions, albeit at added initial investment.

Fig. 2 (A) shows a representative normalized heating curve for a ducted cold climate heat pump at minimum and maximum speed [13]. A representative curve for a non-cold climate variable capacity unit at maximum speed is also presented. It is clear that the cold climate unit is able to maintain a far greater percentage of its heating capacity, reducing the amount of auxiliary energy input required. Fig. 2(B) shows the COP of the same representative cold climate unit over its range of operating conditions.

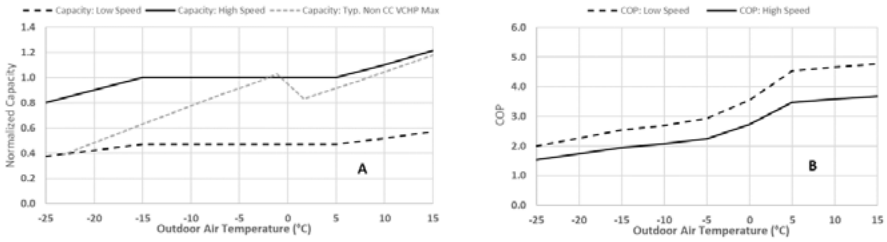

Fig. 2. Summary of (A) heating capacity and (B) COP for cold climate variable capacity heat pump [13]

A summary of key cold climate heat pump characteristics is provided below in Table 5.

Table 5 Key performance characteristics for cold climate variable capacity heat pumps

4. Heat Pump System Energy Models

Accurately modelling each heat pump system is critical in order to properly estimate the energy and economic benefits of each integration. In this study, all systems were modelled with TRNSYS v.17 using the appropriate Canadian Weather for Energy Calculations (CWEC) weather file. Each simulation was run with a time step of 2.5 minutes to better simulate the control logic of the heat pump and auxiliary systems.

Heat Pump Performance Modelling

One of the main strengths of TRNSYS is its ability to support the development and integration of custom components models for different HVAC equipment. This capability was leveraged to develop a new variable capacity heat pump model, Type 3255 [6], which was designed to more closely represent variable capacity performance in system level simulations. The component model is based on extensive experience with a heat pump test bench at the CanmetENERGY facility in Varennes, and integrates a number of new capabilities including performance variation with compressor speed, and short term characteristics such as defrost and compressor behaviour during start up. Further details regarding model development and capabilities can be found in Breton *et al.* [6].

Type 3255 uses a data driven approach to heat pump simulation, requiring the user to provide a detailed map of how capacity and power consumption vary with compressor speed. Wherever possible, systems simulated in this paper use experimental data to inform heat pump simulations. However, given the variety of systems examined in this study, certain models have been developed using manufacturer data at rated conditions, with performance at lower compressor speeds estimated using typical curves relating heat pump power to the ratio of delivered and rated heating capacities [14, 15]. A summary of the data sources used for each heat pump integration is summarized in Table 6.

Table 6 Summary of data sources for heat pump modelling

	Ductless Systems		Ducted Systems	
Heat Pump System	**Rated Performance**	**Part Load Performance**	**Rated Performance**	**Part Load Performance**
SSHP	Manufacturer [16]	Literature [15]	Manufacturer [17]	Literature [15]
VCHP	Manufacturer [18]	Literature [14]	Test [3]	Test [3]
CCHP	Test [19]	Test [19]	Manufacturer [13]	Literature [14]

Representing Heat Pump Control

Heat pump control was simulated using a PID controller, which estimated the required compressor frequency (or heat pump capacity, for SSHP) to maintain the desired temperature setpoint of 21°C in heating, or 23°C in cooling. Additional controls ensure that the heat pump only operates within its intended range of outdoor temperatures. Compressor frequency spikes to maximum during start up after a defrost or shutdown event when in heating mode, based on observations noted during testing at the CanmetENERGY facility.

Auxiliary heating elements (electric baseboards for ductless cases, electric duct heater for central systems) are a key component of each heat pump integration, and play an important role in defining the peak loads of the system. Auxiliary systems have three operating modes, depending on heat pump operations:

I. Heat pump is defrosting: For central systems, the auxiliary duct heater turns on at a constant, fixed, limited capacity to minimize occupant discomfort during defrost. No special control is used for the ductless system, as the system modelled is not equipped with internal heating elements. Defrost length is fixed at 5 minutes in the current model (future work will add varying defrost lengths).
II. Heat pump is operating: Auxiliary heaters operate with a slightly lower setpoint (20°C vs. 21°C for the heat pump) to ensure space temperatures are maintained within an acceptable range while still prioritizing heat pump operations. The heat pump and auxiliary system may operate in parallel.
III. Heat pump is unable to operate: When ambient temperatures are too cold for the heat pump to operate, auxiliary heating maintains the desired setpoint of 21°C.

5. Lifecycle Cost Analysis

In addition to examining energy performance, it is also important to understand the economics of each system to fully assess their potential in the Canadian market. With this in mind, each system integration has been assessed over a 20 year lifespan, with a focus on the associated capital, maintenance, and operational costs. No replacement costs are included. All lifecycle calculations were performed using an inflation rate of 1.8% and a discount rate of 3.3%, based on current Canadian financial markets.

System capital costs were estimated at the component level, and included all required equipment, controls, and ducting. A listing of all equipment included in the cost analysis is provided in Table 7.

Table 7 Summary of components included in capital cost calculations

Category	**Components**
Equipment	Heat Pump (Both Indoor & Outdoor Sections)
	Auxiliary Electric Baseboards (Ductless Cases)
	Auxiliary Electric Duct Heaters (Ducted Cases)
Controls	Thermostat
Distribution	Ductwork (Ducted Cases)

Component costs were derived from available suppliers [20-22], and RS Means [23], and included both material and labor. Wherever possible, prices were compared from the same source for all three system integrations to ensure that relative pricing between each remained consistent. Equipment and labour costs were adjusted for each region using factors presented in RS Means [23]. Capital costs for each integration and region are presented in Table 8, with values in Canadian Dollars. Annual maintenance includes typical tasks (inspection, coil & filter cleaning), but not replacement of major components (e.g. refrigerants or compressors).

Table 8 Summary of capital and maintenance costs for each system integration by region

System	Cost	Montreal	Edmonton	Vancouver
Base Case	System	$8,400	$12,300	$11,600
	Annual Maintenance	$114	$237	$225
SSHP	System	$8,500	$12,400	$10,900
	Annual Maintenance	$114	$123	$117
VCHP	System	$9,200	$17,200	$14,200
	Annual Maintenance	$114	$123	$117
CCHP	System	$10,100	$19,800	$16,000
	Annual Maintenance	$114	$123	$117

Utility rates used in the study were based on current rates and structures for each selected region [24-28]. This included all daily/monthly fixed charges, tiered rate structures, and appropriate rate riders. Energy escalation rates were estimated using information from the National Energy Board of Canada [29]. A summary of utility rates used in the analysis are provided in Table 9. Natural gas rates are not presented for Montreal, as this source of energy is not used in the base case or any heat pump integration.

Table 9 Summary of utility rate structures in each selected region [24-29]

Utility	Charge	Montreal	Edmonton	Vancouver
Electricity	Daily Charge	$0.4064/day	$0.8283/day	$0.205/day
	Energy Charge	$0.0591/kWh (First 36 kWh/day) $0.0912/kWh (> 36 kWh/day)	$0.1132/kWh	$0.0928/kWh (First 1,350 kWh/2 Month) $0.1392 (> 1,350 kWh/2 Month)
	Escalation Rate	0.1%	2.8%	0.3%
Nat. Gas	Daily Charge	--	$0.965/day	$0.409/day
	Energy Charge	--	$4.23/GJ ($0.015/kWh$_{Eq}$)	$7.36/GJ ($0.026/kWh$_{Eq}$)
	Escalation Rate	--	1.0%	0.2%

6. Results and Discussion

The developed models provide an important base to assess the energy and economic performance of each system, and to study the peak load implications of the three selected technologies.

Energy Performance

Table 10 summarizes the annual energy performance of each ductless heat pump integration in Montreal. Integrating a heat pump system results in a notable reduction in the energy used for heating and cooling, with savings ranging from 19% to 31%. While these savings represent an important reduction in energy use, the total energy required for heating still remains quite high in all cases. This can be attributed to the fact that, in the ductless system configuration, the heat pump only serves the first and second floors of the home, with the basement still heated using electric baseboards (Elec. BB). Comparing the energy used to heat the two above ground floors, each heat pump system is able to demonstrate heating energy use reductions of greater than 32%. The CCHP unit in particular demonstrates strong performance, reducing heating energy use for the first and second floors by nearly 50% while almost completely eliminating operations of the electric baseboards. Energy use reductions are more limited for the SSHP and VCHP cases, primarily due to reduced heating capacities and inefficient cycling of the SSHP at milder ambient conditions.

Readers may note the significant decrease in cooling energy use for the CCHP and VCHP cases, which can be attributed to the higher sensible heat factor (SHF) and the improved operating COPs of these two units in cooling. Given that cooling control in the model is based on the dry bulb space temperature, a system with a higher SHF is able to more rapidly reach the setpoint temperature, reducing system operations and energy use.

Table 10 Summary of annual energy performance for each ductless heat pump system in Montreal

End Use	Base Case	SSHP	VCHP	CCHP
Total Heating (kWh)	16,090	12,910	11,850	11,200
Heat Pump	--	2,500	3,960	4,790
Aux: Elec BB (1st, 2nd)	10,000	4,300	1,690	220
Other: Elec. BB Basement + HRV Elec. Duct Heater	6,090	6,110	6,200	6,190
Cooling (kWh)	1,050	1,030	630	600
Fans (kWh)	490	690	700	670
DHW (kWh)	4,270	4,270	4,270	4,270
Lighting/Equip. (kWh)	9,520	9,520	9,520	9,520
Total Energy Use (kWh)	31,420	28,420	26,970	26,260
Total Savings (kWh)	--	3,000	4,450	5,160
% Savings for Htg&Clg	--	19%	27%	31%
Seasonal Heating COP*	1.0	1.25	1.35	1.44

*Seasonal Heating COP for whole home. Seasonal COP higher when considering only zones served by HP

Table 11 summarizes the energy performance of the ducted heat pump systems in Edmonton and Vancouver. Energy savings are noticeably larger than in Montreal, given that each heat pump is now integrated into a ducting network serving all three levels of the home and sized to meet a larger portion of the heating load. In both cities, the CCHP offers the strongest energy savings, driven by greater available heating capacity at colder outdoor temperatures, and improved operating efficiencies over the most common winter temperatures (-10°C to +5°C). Cooling energy use is higher in all heat pump cases, as the selected heat pumps are able to provide cooling over a larger operating window (down to ambient temperatures of 18°C vs. 24°C for the base cases), a capability which is used primarily during the shoulder seasons.

Table 11 Annual energy performance for each ducted heat pump system in Edmonton and Vancouver

	Edmonton				Vancouver			
End Use	Base Case	SSHP	VCHP	CCHP	Base Case	SSHP	VCHP	CCHP
Total Heating (kWh)	19,310	10,600	10,340	8,590	12,690	4,500	4,740	3,830
Heat Pump	--	6,190	8,060	7,220	--	4,330	4,570	3,680
Aux: Elec. Duct Heater	--	4,410	2,280	1,370	--	170	170	140
Cooling (kWh)	280	370	320	320	260	350	320	340
Fans (kWh)	3,970	4,180	3,000	3,500	3,640	2,770	2,090	2,140
DHW (kWh)	7,490	7,490	7,490	7,490	5,870	5,870	5,870	5,870
Lighting/Equip. (kWh)	9,520	9,520	9,520	9,520	9,520	9,520	9,520	9,520
Total Energy Use (kWh)	40,570	32,160	30,670	29,420	31,980	23,010	22,540	21,700
Total Savings (kWh)	--	8,420	9,900	11,150	--	8,970	9,440	10,280
% Savings for Htg&Clg	--	44%	46%	55%	--	63%	61%	68%
Seasonal Heating COP	0.9	1.7	1.8	2.1	0.9	2.7	2.5	3.1

It is interesting to note that VCHP and SSHP performance is similar in both regions, with the VCHP actually consuming more energy for heating in Vancouver. This result is not related to the impact of variable capacity technology, but instead to the operating COP of the VCHP used in this analysis over the most common winter temperatures. To illustrate this point, Table 12 summarizes the operating COP of each heat pump integration by ambient temperature in Vancouver. Even when including cycling losses, the SSHP offers improved COPs for outdoor air temperatures from -10°C to +5°C in comparison to the VCHP. This result highlights the importance of examining not only the rated COP of the unit, but, wherever possible, the estimated operating COP at various points along the heating load line. Further details regarding the impact of these performance curves and operating COPs is presented later in this section.

Table 12: Operating COP of heat pump systems by temperature in Vancouver

Temperature Range	SSHP COP	VCHP COP	CCHP COP
-10°C to -5°C	2.8	2.0	2.6
-5°C to 0°C	2.9	2.3	2.9
0°C to 5°C	3.0	2.8	3.5
5°C to 10°C	3.0	3.5	4.6
10°C+	2.6	4.0	4.9

Techno-Economic Performance

Table 13 summarizes the economic performance of each system in Montreal. All three heat pump systems offer lifecycle utility and total cost reductions, with total lifecycle cost savings ranging from 8% for the SSHP to 11% for the CCHP unit. Results in Montreal are aided by (1) the fact that heat pumps are replacing a less efficient base case system using the same energy source, and (2) the relatively small incremental cost between ductless split system air-conditioners and heat pumps of the same capacity. Relatively low electricity costs and higher capital costs mean that the added energy savings provided by the CCHP yield marginal total cost savings vs. the VCHP, although both systems offer strong lifecycle cost reductions vs. the base and SSHP cases.

Table 13 Summary of lifecycle economic performance in Montreal

	Base	SSHP	VCHP	CCHP
Capital Cost	$8,350	$8,490	$9,240	$10,090
Lifecycle Utility Cost	$38,150	$34,120	$32,170	$31,220
Lifecycle Maintenance Cost	$1,670	$1,670	$1,670	$1,670
Total Lifecycle Cost	$48,170	$44,270	$43,080	$42,980

Table 14 summarizes the economic performance of each system in Edmonton and Vancouver. Results for these two regions are significantly different than those presented for Montreal, primarily because heat pumps are now replacing less expensive natural gas-based heating. Despite the much higher efficiency of the heat pumps in comparison to the furnaces used in the base cases, all heat pump cases still result in increases in total lifecycle utility costs. In Edmonton, for example, the ratio of electricity to natural gas rates (per unit of energy) is so high (> 7:1) that a seasonal COP of more than 7 is needed just to achieve *any* utility cost savings.

When comparing only the heat pump systems, it is evident that VCHP and CCHP systems are challenged by their higher capital costs. Although energy savings can significantly reduce annual electricity costs vs. the SSHP case (e.g., *annual* savings of over $300 CAD for the CCHP in Edmonton), this is not enough to outweigh the large increase in capital costs for these systems. Despite these currently challenging conditions, it is likely that increased market adoption of higher efficiency systems will gradually reduce initial costs and make these system integrations more financially viable in the coming years. The implementation of carbon pricing may also increase fuel-based utility costs, and further improve the economics of heat pumps systems.

Table 14 Summary of lifecycle economic performance in Edmonton and Vancouver

	Edmonton				Vancouver			
	Base	SSHP	VCHP	CCHP	Base	SSHP	VCHP	CCHP
Capital Cost	$12,290	$12,410	$17,220	$19,810	$11,630	$10,870	$14,170	$16,030
Lifecycle Utility Cost (incl. N.G & elec.)	$44,710	$63,520	$60,310	$57,610	$33,010	$35,750	$34,800	$33,040
Lifecycle Maintenance Cost	$3,450	$1,800	$1,800	$1,800	$3,280	$1,710	$1,710	$1,710
Total Lifecycle Cost	$60,450	$77,730	$79,330	$79,220	$47,920	$48,330	$50,680	$50,780

Grid Interaction

With increased adoption of onsite renewable energy generation and electrification of building systems, it is becoming important to assess not only energy and economic performance, but also the impact that each system integration can have on the local electricity grid. This is particularly important in many areas of Canada, where displacing current fossil fuel furnace systems with heat pumps can have significant peak demand implications.

In order to illustrate this aspect of system performance, the electrical load of the HVAC system (heat pump, auxiliary heaters, and fans) is examined for the first 60 days of the year (starting Jan. 1), representing the coldest winter conditions. Results are provided as a box plot in Fig. 3. The edges of each box denote the 25th and 75th percentiles, providing an idea of the variation in loading. The line across each box shows the median value. Whiskers in each plot show the maximum and minimum HVAC electrical load.

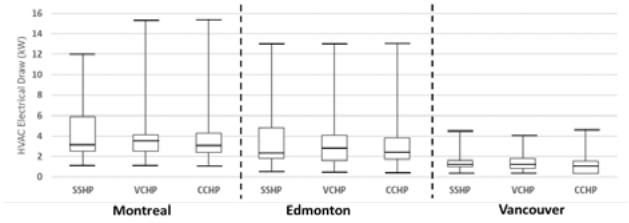

Fig. 3. Box plot of HVAC system power for each heat pump integration and region

An initial examination of the results shows median loads tend to be similar across all system types for a given region, which can be expected given the similar system sizing and operating efficiencies used in the study. However, a closer examination of the results by region reveals some key details regarding the impact of each heat pump configuration on the electricity grid. In Edmonton, the SSHP case shows a larger spread of data between the median and 75th percentile, meaning that this system spends a greater portion of time at a higher electrical draw in comparison to the other two heat pump systems. This increased draw is related to the reduced heating capacity of the SSHP at lower ambient temperatures in comparison to the CCHP, and the higher minimum operating temperature in comparison with the VCHP case (-20°C vs. -23°C). Maximum loads are identical for all three heat pumps, as these peak demands occur during the coldest winter days when outdoor air temperatures are below the minimum operating temperature of each heat pump.

Milder winter conditions in Vancouver present differing performance trends vs. the Edmonton case. These milder conditions result in similar HVAC electrical demands for all three heat pump systems, as the extra capacity and extended operating range of the CCHP and VCHP systems are not required. Peak loads in Vancouver are driven by the defrost process, when the auxiliary duct heaters (all sized identically) turn on to limit temperature drops in the conditioned space. Loading is reduced for the SSHP and VCHP cases due to their lower estimated heat pump power draws during this defrost process.

Results for Montreal underline important considerations regarding the control of the heat pump and auxiliary units. Similar to Edmonton, the SSHP shows greater variation between the median and 75th percentile, due to its reduced heating capacity and operating range. However, the VCHP and CCHP units actually have higher peak loads, due to the combined control of the heat pump and electric auxiliary.

The higher peaks for the VCHP and CCHP systems are best explained with the aid of Fig. 4, which shows several key performance criteria for the CCHP case over a four hour window starting at 3:00 AM Jan. 26th (day of maximum loading). Although the heat pump operates continuously until 5:20AM, its reduced capacity during this cold day means that it is unable to meet the setpoint temperature of 21°C. While auxiliary heating is still available during this portion of heat pump operations, the auxiliary system operates with a setpoint of 20°C to prioritize use of the heat pump. However, when outdoor air temperatures fall below the minimum cut-off for the heat pump (at 5:20 AM), the auxiliary then becomes the sole source of heating. Now operating with a new setpoint of 21°C, the auxiliary system attempts to rapidly raise the indoor temperature, causing the peak loads seen for the CCHP and VCHP cases. This behavior is not seen for the SSHP case due to its higher cut-off (i.e., minimum operating) temperature.

In addition to this peak loading, it is also interesting to note the potential issues caused by parallel heat pump/auxiliary operations. Just past 4:00 AM, the heat pump goes into defrost, cooling the space down to around 19.5°C. This translates into a strong increase in baseboard power demand, which, when combined with the heat pump operating at maximum frequency after the defrost event, also causes an unintendedly high peak power draw. In regions where the heat pump always operates above its minimum cut-off temperature, this behavior could become a major driver of peak electrical loading for the system, especially if backup baseboard temperatures setpoints are close to the temperature setpoint of the heat pump.

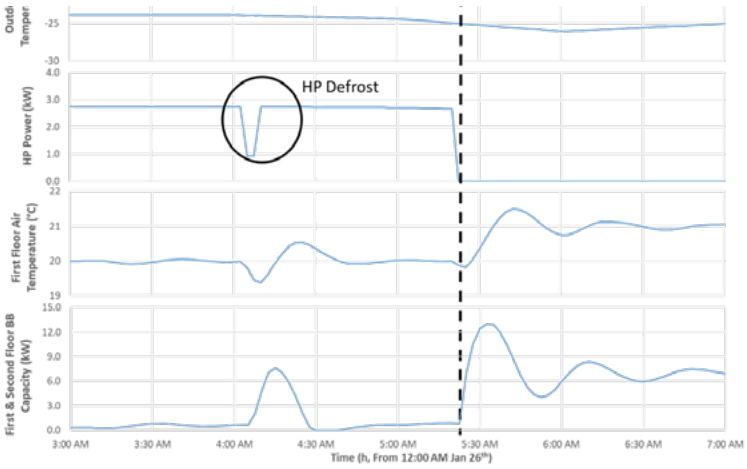

Fig. 4. Summary of key performance indicators for CCHP case in Montreal during peak load event

The importance of considering the interaction of the heat pump and auxiliary systems is clearly evident from the analysis. As demonstrated above, unforeseen operation of these two sub-systems can cause a significant increase in the peak electrical demand, and pose potential issues for the electrical grid in regions with more widespread heat pump adoption. Several simple workarounds can help facilitate a smoother interaction between these two system components, including limiting available auxiliary capacity to a reasonable amount when the heat pump is in operation (e.g., the difference between heat pump capacity and building load at the heat pump cut-off temperature), and using a ramped setpoint change when the system transitions from parallel heat pump/auxiliary operations to solely using auxiliary heating. In any case, more sophisticated controls should be carefully considered to optimize heat pump interaction with the grid. The integration of thermal storage could also afford an increased degree of flexibility by decoupling thermal supply and demand, allowing for peak shifting and demand reduction capabilities.

Sensitivity Analysis

While the above results show the potential of heat pump systems, it is clear that the conclusions are highly dependent on the performance data and control strategies used in the analysis. An appropriate selection of the heat pump is vital in order to maximize the energy savings potential of the system. In order to better illustrate this point, two additional cases were run in Edmonton:

(1) VCHP from Literature: A VCHP (with very similar SEER and HSPF ratings to the previously presented VCHP case) modelled using performance curves developed from manufacturer data [9]
(2) VCHP from SSHP: A variable capacity unit, with maximum performance derived from the ducted SSHP [17], and power consumption at lower compressor speeds estimated with typical part load equations for VCHPs [14]. Capacity modulation ratios were based on the original VCHP case.
