Simulation results for each case, along with the original SSHP and VCHP simulations, are compared in Table 15. By replacing the original VCHP performance curves (while keeping all other simulation settings the same), annual heating energy use was reduced by between 6% and 12%, primarily driven by higher COPs between outdoor air temperatures from -10°C to +5°C. The *VCHP From SSHP* case is particularly interesting, as it demonstrates the isolated impact of adding variable capacity technology to a single stage heat pump (a reduction in heating energy use of 9%). Given the significant development work in the field of variable speed drives and heat pump technologies, it is likely that the performance benefits of variable capacity units will continue to grow in the coming years, and may even be underestimated in the current analysis.

Table 15 Sensitivity analysis for VCHP systems in Edmonton

End Use	SSHP	VCHP	VCHP Lit.	VCHP From SSHP
Total Heating (kWh)	10,600	10,340	9,110	9,680
Heat Pump	6,190	8,060	6,780	5,390
Aux: Duct Heater	4,410	2,280	2,330	4,290

7. Conclusions

This study has examined the techno-economic potential of three market available heat pump technologies in new construction Canadian housing. Using an improved, data-driven component model, single stage, variable capacity, and cold climate variable capacity systems were simulated over a full year in the Canadian cities of Montreal, Edmonton, and Vancouver. Cold climate heat pumps offered the strongest energy savings in all three regions, with heating/cooling energy use reductions ranging from 31% in Montreal to 68% in Vancouver. Despite these energy savings, higher capital costs and low natural gas rates made it difficult to achieve lifecycle cost savings for heat pumps in all regions except Montreal. An assessment of the distribution of HVAC electrical demand showed the potential of cold climate systems to reduce electrical loads by mitigating auxiliary energy use, but also highlighted the critical importance of appropriately considering the interaction between the heat pump and any auxiliary heating systems, and the value of more sophisticated controls. While the information presented in this study offers insight into the Canadian market, it is important to be aware of the sensitivity of the results to the economic parameters and performance characteristics used. Future work will explore the economics and grid impacts of these systems in other Canadian regions and housing vintages, and obtain additional test data to more accurately represent the heat pump technologies presented in this study.

Replicable Water Source Heat pumps for A Zero Carbon Future

Nicky Jason Cowan[a*]

[a]Star Renewable Energy, Thornliebank, G46 8JW, Scotland

Abstract

The United Kingdom (UK) is beginning to invest heavily in the construction of district heating networks as it recognises their potential for decarbonisation. Unfortunately, the vast majority of these are designed around burning fuel in one form or another, but with the undeniable effects of climate change being constantly reported and the surge in public awareness, alternative technologies are being sought after, primarily, heat pumps.

Although there is huge success in European countries regarding heat pump projects, the UK is still hesitant in deploying the technology even though the majority of large towns and cities are built on the backs of rivers.

By analysing the key sections required to deliver a successful water source heat pump (WSHP) for large urban district heating networks, a simplified methodology for repeating similar projects has been developed. Based on the learnings gathered from designing Scotland's largest, hottest WHSP being installed in Clydebank, utilising the river Clyde as a source, real examples of design and technology will be detailed.

Keywords: Water source heat pump, Design, District Heating

1. Introduction

Time is running out for every country to fulfill the agreements and pledges signed on 22nd April 2016: The Paris Agreement [1]. Some countries have went further declaring climate emergences [2], however little to no real progress has been made. With so many technologies confusing the pathway to decarbonising the UK it is not surprising that most towns and cities end up either doing nothing or "quick wins" which see a small impact made on the overall challenge. It is time to start taking large chucks out of our carbon footprint and this paper will describe how, by utilising a natural resource that almost every town and city has, we can achieve this.

2. Heat Pump Sections

An unavoidable fact about water source heat pump (WSHP) projects is that every location is different therefore we must look to simplify, where possible, the methodology to approaching each project and equipment selections. A WSHP heat pump project can be split into its basic constituent sections that can be further refined.

2.1. Section 1: The Water Source

Every river that flows through a town or city is unique but there are some basic questions that help begin selections:

1. Is the river fresh water or salt water?
   This determines pipework and heat exchanger materials and selections on the source water side.
2. Is the river tidal or controlled through weirs?
   Determines filtration equipment location and pipe routes, helps determine abstraction pump style.
3. River depth at abstraction location?
   Determines abstraction location and pump style.
4. Is there information relating to the flora and fauna of the water abstraction area?
   This has knock on effects to the filtration requirements. Eels and Mussels can impact on pre filtration quite significantly and so can migrating Salmon if this happens to be at the same time you intend to disrupt the water course.
5. Yearly water temperature profile?
   Allows more accurate heat pump performance data to be calculated.
6. Annual river flowrate profile?
   Determines the amount of available water for abstraction.

Engagement with the environmental agency is crucial at as early a stage as possible for any project as they will have their own requirements to follow such as; Allowable water volume than can be abstracted (based on Q95 or Q50 value etc.), temperature change allowed on the water, velocity at discharge location.

A decision will have to made about the handling of the source water side. There are different techniques being put forward for this such as:

1. Glycol pipework loop in the river.
2. A hydraulic break loop: River water is abstracted and fed to a heat exchanger where it transfers its heat to a glycol loop. The glycol loop is then sent to the heat pump evaporator.
3. Open loop: The river water is sent directly to the heat pump evaporator.

As the focus is on multi MW district heating, the glycol loop can be discarded as the size and amount of pipework would not be viable. A hydraulic break loop is considered to be a sound option however the inclusion of one has multiple negative effects such as extra installation costs, additional running cost (glycol pump circuit) and a negative effect on the heat pumps performance (heat transfer required across the break loop heat exchanger which results in a lower evaporating temperature at the heat pump). Pumping river water direct into the evaporator is viewed as risky but with the right technology installed this risk can be contained.

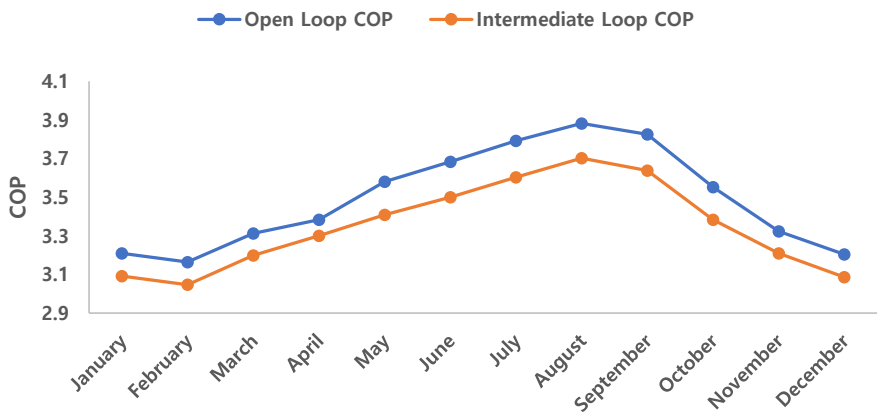

Fig. 1. COP performance graph of open loop style abstraction Vs including a hydraulic break loop

When looking at an open loop style system, there are multiple methodologies for achieving water abstraction:

1. Cutting away a section of the riverbank and inserting an abstraction chamber.
2. Floating a pipe out with concrete sections and sinking it to a desired depth.
3. Laying a pipe along the bottom and upturning the end.
4. Design a building to sit on a pontoon or floating barge where the abstraction pumps sit directly above the water. If made big enough you could house the entire abstraction system inside.

For the Clydebank heat pump project, the abstraction chamber will sit at the edge of the basin where pipework will vertically enter the water. The following basic layout describes the source side of the heat pump system

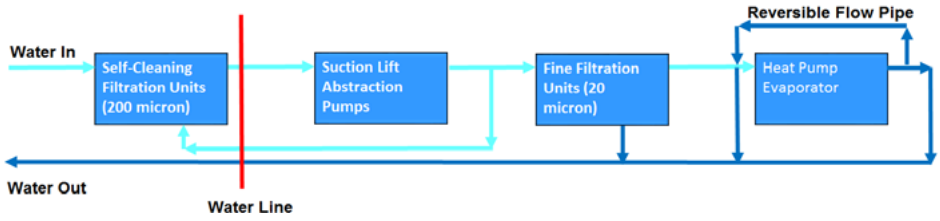

Fig. 2. Abstraction Layout

Due to the location of the project three major challenges had to be overcome: Salt water, extreme tidal fluctuations and mussels being present.

Challenge 1 – Salt Water:
The heat pump is an open loop style, so the river water from the Clyde enters directly into the heat pump evaporator. To overcome the issues of salinity in the heat exchanger a Spray Chiller Evaporator style was selected with Titanium tubes, titanium coated tube plates and super duplex end boxes. The evaporator itself is self-cleaning as explained in challenge 3.

Challenge 2 – High Tidal Fluctuations:
At the abstraction location the river can vary in height from over 4m to under 1m during the course of the tides. To ensure abstraction can continue the filters are placed under the minimum height expected from the lowest tide. A second problem was foreseen due to the abstraction point being in a manmade basin where silt could build up if the filters were placed on the river bed. To avoid this the filters are held 300mm off the river bed.

Challenge 3 – Silt and Mussels:
The river Clyde has mussels which means there are mussel seeds. These seeds are around 20 microns in size so very fine filtration is required. There are three types of filtration on the source water side to help combat this. First there are self-cleaning backwash style filters in the river. These are made self-cleaning as a small portion of the water being delivered to the heat pump, is sent back to the filters where a rotating bar with nozzles ejects the water back through the mesh. The second piece of filtration is a bank of spinning disk style units which are sized to stop the mussel seeds from progressing in the system.

The final piece of filtration is on the spray chiller evaporators. Each evaporator contains 770 tubes which are externally and internally enhanced as per figure 3. Each tube is fitted with a brush (figure 4) and a cage on both sides to catch the brush as it travels through the tube (figure 5).

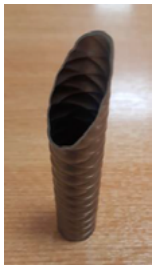

Fig. 3. Spray Chiller Enhanced Tube

Fig. 4. Spray Chiller Brushes [3]

Fig. 5. Spray Chiller Cages

As water flows through each tube, the brushes settle at one side of the evaporator. Silt and other fouling can accumulate in the tubes, leading to a negative effect on heat transfer. To use the brushes a series of valves and pipework reverse the flow allowing the brushes to be pushed to the other end of the evaporator, dislodging any fouling that has accumulate. The water is then discharged back to the river.

.

Fig. 6. Flow Reversal Pipework On the Side of the Spray Chiller Evaporator

2.2. Section 2: The Heat Pump

The heat pump while complicated in its own right, is by far the simplest piece of equipment to put together in this type of project. Its working conditions are preset on one side by nature and the other by desiring a calculated outcome.

To narrow in on a design, there are always three initial questions for the selection of any water source heat pump:

1. Source water: flow and return temperature (°C)?
2. Heating network: flow and return temperature (°C)?
3. Capacity required (MW)?

Advanced selection criteria that can influence the design of the heat pump are:

4. Refrigerant Type?
5. Electric Voltage?
6. Variable Speed Required?
7. Source Water and style of abstraction?
8. Source Side and Hot Side fluids?
9. Does COP meet project requirements?

Using Clydebank as an example

1. Source water: Varies from 4°C in winter to 18°C in Summer. Based around conversations with SEPA we are allowed a 3K ΔT.
2. Heating network: 80°C/60°C then dropping to 75°C to 45°C
3. Capacity required: 5.2MW
4. R717 as refrigerant (GWP<1, ODP 0)
5. 690V electric motor
6. Salt water, open loop abstraction and treated water for the district heating loop.
7. Average COP of >3

Fig. 7. 2-off 2.6MW Water Source Heat Pumps for Clydebank

Each heat pump at Clydebank consists of a positive displacement, oil injection, twin screw compressor with the rotation provide from an air cooled electric motor. Once the ammonia is compressed, the oil and ammonia mix is sent to an oil separator where the ammonia carried on to a desuperheater, condenser, subcooler, expansion valve and evaporator before being drawn back into the compressor. The oil is sent from the oil separator to an oil cooler, filters, oil pump and finally re-injected back into the compressor.

The district heating water is fed into the heat pump where it is split so that some water goes to the oil cooler and the rest passes through the subcooler, condenser and the desuperheater. The water from the oil cooler and desuperheater are then joined back together and returns to the district heating network.

The source water is as per fig. 2.

Currently the United Kingdom (UK) offers the Renewable Heat Incentive (RHI) to compliant heat pump systems. This is a tariff paid over 20 years for every kWh of heat generated renewably and the heat pump must conform to certain requirements such as an average COP of 2.5. This has been put in place to not only help stimulate the marked but offset against the cost of cheap gas and expensive electricity (known in the UK as the spark gap). The cut off point for projects is that they must be installed and commissioned by March 2021.

2.3. Section 3: The District Heating Network

District heating networks come in all different shapes, sizes and most importantly for the heat pump, temperature ranges. The temperature ranges are often referred to as Generations [4], with the flow temperature of the 3rd generation being (<100°C) and 4th (≤70°C). There are other styles being examined such as ambient loops however as detailed in section 2.4. this does not provide the least intrusive method for the consumer in a retrofit procedure.

Project networks can be devised into several categories:

1. Existing networks: These are already in place, delivering heat to existing building stock where the heat is generated, typically, by the burning of fossil fuel. This a very challenging case for heat pumps to fit into due to the networks predominantly being on a high flow and return temperature, typically with a poor ΔT. The high temperature is normally a function of reducing end consumer impact (changing building internals)
2. New networks for existing buildings. This is the most challenging case to make heat pumps fit in as typically in the UK, each building has its own gas boiler connected to the gas network. Finding ways to encourage people to move away from cheap gas to what is seen as a new methodology for delivering heat (district heating) can be very complicated.
3. New network for new buildings: Network temperature is designed specifically for the heat pump from the beginning and so are the consumers building internals (radiators, heat interface units etc).
4. New network serving new builds and existing stock: The heat pump will be deployed to serve existing building stock while new builds come online. Existing buildings will transition to a lower network temperature and wider ΔT. Careful consideration needs to be given to heat pump heat exchanger design as flowrates can half so extra passes may have to be designed in.

The Clydebank project falls under point 4. Currently existing stock to be included in the district heating project is the West College Scotland Clydebank campus and the Clydebank leisure center (The pink section of Figure 2. The red section is for all the new builds: 1063 dwellings, 80 bed care home, NHS medical center, a hotel, food store and various other retail and commercial facilities.

Fig. 8. Clydebank Project Sections.

Due to the Clydebank project looking to secure RHI, the heat pumps are going to be installed before the majority of the site has been completed which leads to some complications.

5. Stage one of the project is to send heat to the college and leisure center while waiting for the new development to bring buildings online. The college and leisure center will be retrofitted to work on the lower district heating network temperature however the heat pumps will begin operating on 80°C flow and 60°C return before this work is carried out.
6. When the network comes online the college and leisure center will be retrofitted and the whole system will operate on 75°C flow and 45°C return. This has two positive impacts on the heat pump as the output temperature has been lowered and the ΔT has been increased, allowing for more subcooling on the units. See section 3 for more details.

In reality if water source heat pumps are going to tackle dense urban city centers then projects fall under point 1 or 2. If we look at point 2 and take Glasgow city center as an example, how can you roll out district heating when each building is currently served off the gas grid, operates individually and has no incentive to switch. The main schools of thought are around providing concession areas for district heating companies and setting air quality limits (which are within Scotland's devolved powers).

2.4. Section 4: The Secondary Network (The Consumer)

There are several examples of what to expect when faced with a consumers internal building network

1. Currently existing with no plans to retrofit.
2. Currently existing with plans to retrofit.
3. New build where a desired temperature can be installed form the start.

Ultimately, the temperature required on the consumer's network is what sets the district heating network flow and return temperature and to decarbonise a city center, the major challenge will be changing customers with the mindset of point 1 to point 2 especially if the intent is to run the network from heat pumps.

Customers who fall under point 1 have the biggest detrimental effect to the heat pumps performance. They will typically be served by a gas boiler and have an internal network of 82°C flow and 71°C return. Most buildings do not even achieve this ΔT and it can be as little as 1 or 2K.

A key starting point to minimise disruption would be to survey the buildings internals and calculate if the equipment installed can operate on lower temperatures (was it over sized when it was installed?).

If the network serves multiple different consumers and for example one of them is an industrial heat consumer and requires very high temperature heat., instead of designing the network based on that one consumer's requirements, design for the majority at a lower temperature and look at installing a booster heat pump at the client's location to deliver site specific requirements. This could allow the industrial consumer heat up to 150°C if required.

Ambient loop networks are being discussed as a solution instead of district heating. Similar in concept to a district heating network except the water sent to each building is around 15°C, this water is then used as the source to an individual heat pump placed in each building. Each building takes a bit of heat out of the loop and the loop is cooled. A large heat pump would be required to balance out the ambient loop. Ideally buildings would equally be heating and cooling to self-balance the loop, however in Winter there is little cooling demand. A drawback for this style of system in a city center is where you want to minimise end consumer building internal changes as everything is a function of cost. The individual heat pumps placed at each building will be small capacity and so limited in outlet temperature (around 65°C) so a full retrofit will probably be required and unlikely given the scale of existing building stock.

3. Heat Pump Performance

Although heat pumps can achieve reliably 85°C/90°C for district heating, they generate the best performance at lower temperatures on the hot side and higher temperatures on the cold side. In this instance the cold side is the river and although this is variable throughout the year, it is a fixed point that cannot be altered. This leaves manipulating the hot side where possible to increase performance. There are two areas to strive for improvement:

1. Reduction of the network temperature
2. Increasing the network ΔT

Figure 9 below shows a yearly trend for COP based on a typical river profile for 3 different heating scenarios.

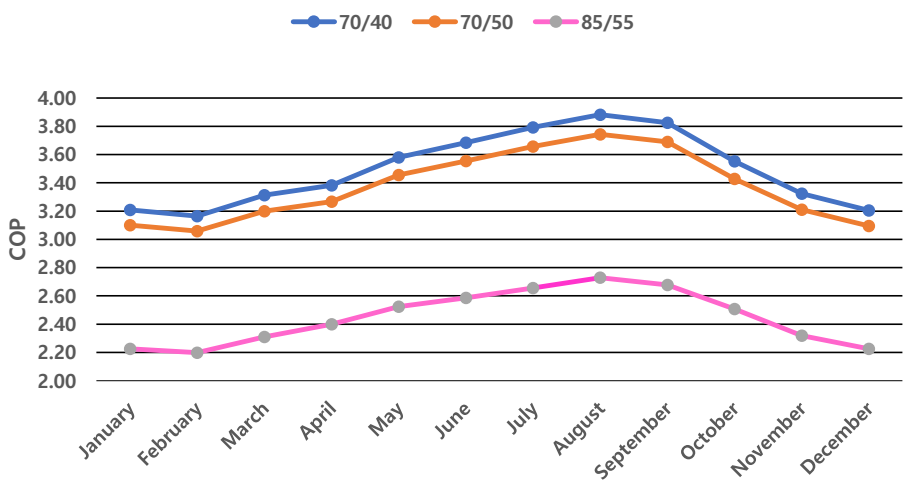

Fig. 9. COP variations for changing Network temperature and the network ΔT

4. Advanced Thinking

Like many types of projects there are ways to further optimise a system. With a heat pump led district heating network the following areas can greatly enhance the viability and efficiency of a system:

1. Thermal storage.
2. Flexible electricity tariff (half hourly).
3. Off-peak/ surplus electricity consumption.
4. Incorporate the cooling generated by the heat pump.
5. Lower the network temperature.
6. Reduce network heat losses.

Points 1, 2 and 3 work together as heat consumption from a district heating network is not constant. Low periods of heat consumption generally coincide with lower electricity prices, so if you are on a flexible tariff, instead of operating the heat pumps at 50%, run them at 100% (achieving the best COP), consuming the cheap electricity to fill a thermal store. You have then developed a buffer that if sized correctly could allow the heat pumps to be switched off at peak network consumption, avoiding expensive electricity charges. The same point applies to the electricity grid if it is being supplied with more electricity than it requires. Heat pumps could be switched on to fill thermal stores, avoiding the constraint payments wind farms are paid to switch off during over production.

Point 4 highlights the fact that to generate heating on one side of the heat pump you have created a cold source that can either be returned to the river or sent to a process that requires cooling. If the heat pumps are strategically placed this cooling can be sent to a data center or a hospital for example, offsetting their own electrical consumption and increasing the heat pumps overall COP. This can form another revenue stream for the district energy company making project more viable.

5. Environmental

The pathway to decarbonising the UK, can at best be described as complex. With so many technologies on the market providing quick wins in reducing carbon (but not fully decarbonising) or providing the illusion of decarbonising while having a negative impact as the grid decarbonises (Gas CHP) it has never been more confusing to pick a solution that is right. Mix in the vested interests from major oil and gas companies that would push the introduction of hydrogen into the gas grid or a full relaying of the pipework to have 100% hydrogen sent to homes it is not surprising that very few projects begin.

Heat pumps operate by consuming electricity so their carbon footprint is inherently tied to that of the electricity grid feeding them. If a heat pump has a COP of 3 then you take the electrical grids carbon content per kWh and divide by 3 to obtain each unit of heats carbon footprint. If your grid is 0gCO_2/kWh, then so is your heat. This make heat pumps one of the only scalable zero carbon methods for generating heat.

Even though the UK has made great strides to decarbonise its electrical grid, unfortunately documentation in the building sector is lacking in supporting the deployment of heat pumps. New projects have to use documentation published in 2012 which states the electrical grid has a footprint 519gCO_2/kWh [5] even though planned updates in 2016 (showed grid at 398gCO_2/kWh) [6], 2018 (Showed grid at 233gCO_2/kWh) [7] and now 2019 (Shows grid at 136gCO_2/kWh) [8]; all of which, have yet to be implemented.

6. Conclusion

With cities such as Glasgow and Edinburgh setting a target of net zero carbon by 2030 [9],[10], Scotland by 2045 and the rest of the UK by 2050 drastic changes have to be taken now if there is any hope at succeeding.

The main barriers that often block project conception range from a lack of understanding though to the complexity of aligning all the appropriate project partners. There any many companies that can assist local authorities in how to get projects moving and can even take on the whole project scope leaving the local authority in charge on the network at the end.

Although challenging, water source heat pumps provide a real way to decarbonise a cities carbon footprint now and every day that projects like these are delayed in conception, another day is lost in preventing further climate change.

In-situ analysis of a centralized wastewater heat pump for a complex of high energy standard buildings

Simon Callegari*, Fleury de Oliveira, Pierre Hollmuller, Carolina Fraga

Energy Systems Group, University of Geneva, 66 Bd Carl Vogt, 1211 Genève, Switzerland

Abstract

While heat pump systems combined with district heating could reduce the CO_2 emissions of Geneva's heating sector, it is crucial to know and control their performance in real condition of use. This paper concerns detailed monitoring (hourly data, entire year) of a new low energy multifamily buildings complex, with centralized heat pump on wastewater (200 kW) and complementary gas boiler (600 kW). Heat production is covered at 45% by the heat pump (SPF: 3.03), with 55% complement by the gas boiler (85% efficiency). At the level of the buildings, domestic hot water supply (39.5 kWh/m^2) accounts for 59% of the demand, against 41% for space heating (27.3 kWh/m^2). For space heating, the gap between measured and climate corrected design values can be explained by operation conditions which differ from the norm (indoor temperatures, window openings), but remains quite lower than benchmark values on the recent building stock. Domestic hot water supply is also above the normed value, but coherent with a benchmark on other buildings. Finally, we highlight some issues and recommendations for optimized system integration and control concerning this type of innovative solution.

Keywords: wastewater heat recovery ; district heating ; multi-family buildings ; in-situ monitoring ; performance gap

1. Introduction

Nomenclature

DH	district heating
DH1	district heating network with the 4 studied buildings
DH2	district heating network with the last 3 buildings under construction
DHW	domestic hot water
HEX	substation heat exchanger
HP	heat pump
MFB	multifamily building
SH	space heating
SPF	seasonal performance factor (annual or seasonal value)
VHR	ventilation heat recovery by dual flow
WW	wastewater
WW-HX	wastewater heat exchanger

1.1. Context and issues

In Geneva, the heat demand is mainly covered by fossil fuels, with individual gas or heating oil boilers. One of the most realistic and expected option for renewable heat integration in this dense urban area is the development of district heating (DH), along with integration of centralized or individual heat pumps (HP) [1].

The potential and performance of HP systems is however linked to the temperature range of available heat sources such as ground, ground water, lake water or air, and its adequacy to the related heat demand in terms of quantity and temperature level [2]. A further key point for HP integration in heating systems is its eventual combination with other resources, typically fossil boilers, which requires carful system design planning and regulation [3].

Moreover, on the heat demand side, actual values of energy demand usually turn out to be higher than project values, as well for retrofit of old buildings [4], as for new buildings with high energy standards [5]. Concerning new buildings, the heat demand for domestic hot water (DHW) production represents a growing share compared to the space heating (SH), and becomes a key point for HP integration, as it requires relatively high temperatures levels.

In this context, in particular in the case of innovative systems, it is important to understand real conditions of use and operating constraints through system monitoring, which is also an opportunity to highlight optimization issues and possibilities.

1.2. Objectives

This paper concerns a new low energy MFB complex located in Geneva, whose heat is produced by a centralized 200 kW_{th} HP on wastewater (WW) with a complementary 600 kW_{th} gas boiler, and distributed via a local DH network.

Based on detailed hourly monitoring over an entire year of operation, we derive the annual energy balance of the entire system and analyze the annual daily dynamic of heat production and demand. We then display daily heat production temperatures, and highlight their impact on operating constraints, especially for the HP. Finally, we focus on the performance gap of SH and DHW supply, as compared to project values.

2. Case study

2.1. Buildings and system layout

Situated in Geneva, the case study concerns the first 4 buildings of a complex of 7 new MFB, built according to the *Minergie* low energy demand standard. The studied buildings have a total heated area of 17'400 m^2, of which 16'150 m^2 for housing and the rest for extracurricular activities for school kids. Note that the 4 buildings have an identical heated surface area (4'350 m^2), structure and form (9 storeys), as well as thermal envelope.

The simplified schematic of the heat production and distribution system is depicted in Figure 1. Base load production is supplied by way of a 200 kW_{th} wastewater HP, which is connected to a centralized wastewater tank with immerged heat exchanger system (WW-HX) [6]. On condenser side, the HP delivers its heat to a 20m^3 buffer. Complementary peak load is supplied by a 600 kW_{th} gas boiler.

Heat distribution to the buildings is provided by way of 2 local DH networks, one for the 4 buildings of the case study (DH1), the second for the 3 buildings still under construction (DH2). At the level of each building, supply is delivered by way of a heat exchanger (HEX) on a secondary circuit, which supplies a DHW storage tank (in priority) and the SH floor heating circuit (connected to the outlet of the DHW supply).

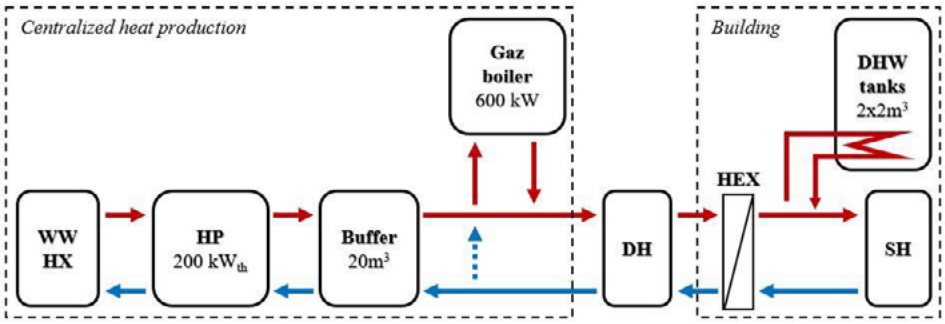

Fig. 1. Simplified schematic of heat production and distribution

2.2. Monitoring

The main data in 20 min time step is collected from the centralized control system, and aggregated in hourly and daily values. In terms of energy flows, it concerns: i) electricity for the HP and related circulation pumps; ii) heat production of HP and gas boiler; iii) in each building, heat supply for DHW (at storage inlet) and for SH. The associated temperatures, as well as the wastewater temperatures (tank inlet and outlet, evaporator in and outlet) are also collected.

As a complement: i) spot monitoring of the mechanical ventilation system (temperatures and air flows) allows to characterize the corresponding heat recovery and loss; ii) weekly reading of the gas consumption is used to determine the boiler efficiency.

3. Results

The results presented in this paper concern the first year of operation (2018) with complete hourly data on centralized heat production and heat demand of the 4 buildings under consideration (DH1).

3.1. Annual heat production and demand

The annual heat production and demand flows are depicted in following Sankey diagram (Figure 2).

The HP production (613 MWh) accounts for 45% of the total production, with a seasonal performance factor (SPF) of 3.03, including ancillary electricity of circulation pumps on evaporator and condenser side. This SPF can be related to an annual energy weighted average temperature of 56°C (at condenser outlet) and 7°C (at evaporator inlet), corresponding to 45% of the Carnot performance factor. The 55% complement by the gas boiler (761 MWh) is produced with an 85% efficiency (on higher heat value).

The produced heat is mainly distributed to the 4 buildings under consideration (DH1), while the remaining part goes for the last 3 buildings, which were already partially heated while under construction (DH2), and for storage and distribution losses.

At the level of the 4 buildings, DHW supply (687 MWh) accounts for 59% of the total, against 41% for SH (474 MWh). As a complement to direct SH, ventilation heat recovery by dual flow (VHR) with a measured 80% efficiency, contributes with 420 MWh to compensation of heat losses through the building envelope.

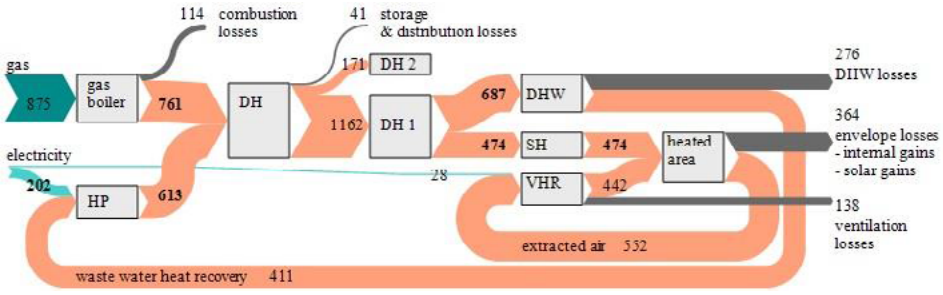

Fig. 2. Sankey diagram, 2018 (unit: MWh; bold font: completely monitored values; normal font: derived values and/or spot monitoring)

3.2. Seasonal dynamic

The seasonal dynamic of heat production and demand is presented in Figure 3. In summer the HP is able to fully furnish the DHW supply, except for a weekly temperature rise of 1 h, for legionella prevention, done by the gas boiler. The HP production slightly drops during winter, and is complemented by a high heat fraction from the gas boiler. Unlike what could be understood at first sight, winter HP production actually doesn't cover the DHW supply, but rather part of the SH supply at lower temperatures, as clarified below.

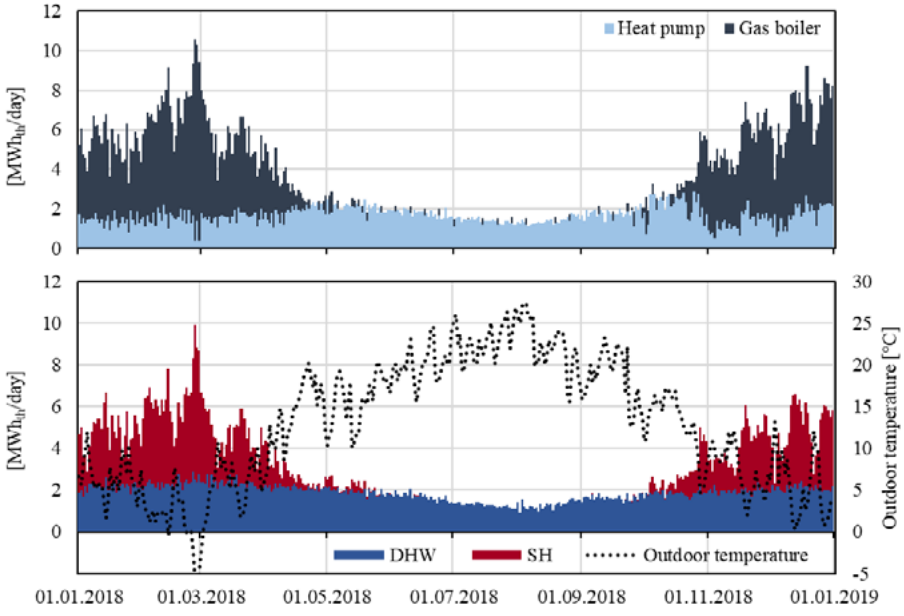

Fig. 3. Heat production (top) and demand (bottom), Jan – Dec 2018 (daily values)

The related dynamic of the daily average heat production temperatures is presented in Figure 4, which highlights differentiated operation modes and set points between summer and winter. During the summer, the HP production is set to its maximum at 63°C, which is sufficient for DHW supply (except during the above-mentioned anti-legionella treatment at 75°C by the gas boiler). During winter, the HP production temperature varies between 45 and 55°C, according to the upper and lower buffer set points, while the gas boiler produces at an average of 65°C (including the 1h anti-legionella treatment).

On the cold source side, we notice a relatively stable temperature at wastewater tank inlet (in the range of 20-25°C), while the evaporator inlet as well as tank outlet are quite lower (5-10°C). This surprising drop is

possibly linked with recurrent fouling of the wastewater heat recovery system, an issue which is still under investigation.

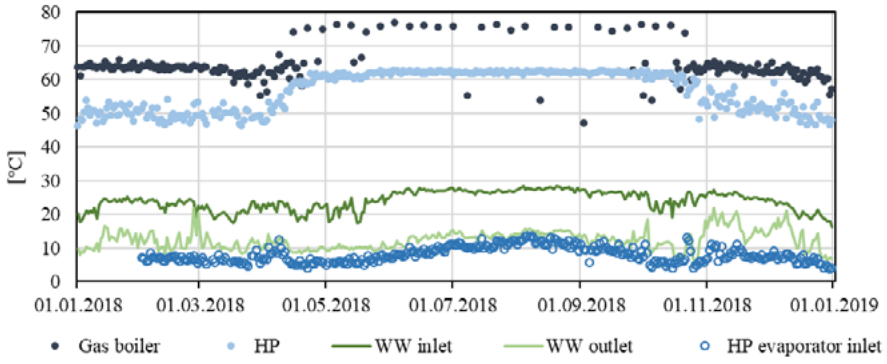

Fig. 4. Heat production temperatures, Jan – Dec 2018 (daily values)

3.3. Heat production issues

The above described differentiated summer/winter operation mode induces a distinct use of the HP and gas boiler, as explained (but not depicted) hereafter. In winter, due to the lower HP production set point, it can no longer cover the DHW supply. Latter is hence produced by the gas boiler, which induces return temperatures higher than those of the HP buffer. As a consequence, to avoid heating of the HP buffer with the gas boiler, the HP and its buffer are isolated from the DH distribution. Once the DHW storage tanks of all the buildings are fully charged, the DH drops to a SH supply temperature of around 35°C, which is again compatible with the HP and buffer temperatures.

Note that the differentiated winter operation mode was planned for SPF optimization reasons, with the objective to take advantage of the lower SH temperatures. However, it does in fact limit the operation duration of the HP to short periods, between DHW supply cycles. As a result, the HP share is lower than expected. In this regard, it could be worth using the same set points and operation mode as in summer, which would probably induce a higher share of HP production. Despite a possible drop in SPF, latter could actually lead to a better system performance in terms of CO_2 emissions, when takin into account the related reduction in gas consumption. This issue is currently being tackled by way of numerical simulation.

3.4. Heat demand issues

Figure 5 shows the disaggregated SH and DHW supply by building. We observe a strong variability, despite identical heated surface areas and thermal envelopes (note: as a unique difference, the ground floor of building no 3 has apartments instead of extracurricular activities). This variability, as well as the discrepancy with the projected and available benchmark values, will be discussed here after.

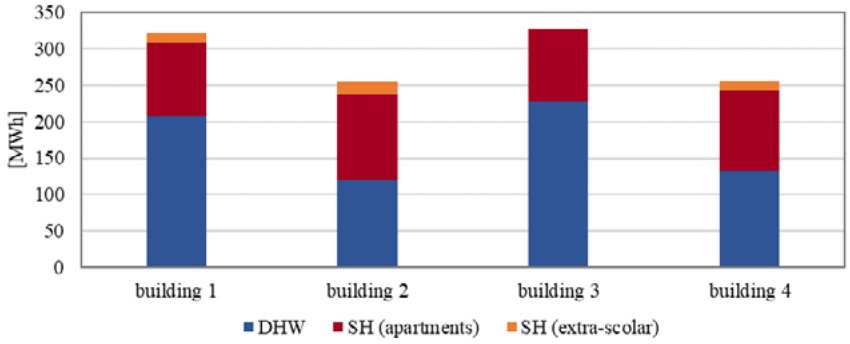

Fig. 5. Disaggregated heat demand by building, 2018

SH supply and performance gap are analyzed by way of a sensitivity analysis carried out with the Lesosai thermal balance calculation tool [7], with following scenarios (Table 1):

1. *Project*, simulated with the project design values, taking into account standard weather data, as well as normed indoor temperature and ventilation rates (without heat recovery).
2. *Real weather*, simulated with the actual weather data of 2018.
3. *Real weather & indoor temperature*, simulated with actual weather data of 2018, as well as actual indoor temperatures (as measured on the exhaust air of the ventilation system of each building).
4. *Measured*, simulated with actual weather and indoor temperatures, as well as adjusted ventilation rates, so as to reproduce the actual monitored SH of 2018.

Note that for the sake of simplicity and coherence, this analysis only concerns SH related to apartments (and not the one for extracurricular activities).

Table 1 Main input parameters for SH performance gap analysis

Scenario	Meteorological year	Indoor temperature [°C]	Air flow [m³/h/m²]
Project	Standard	20.0	0.7
Real weather	2018	20.0	0.7
Real weather & indoor temperature	2018	[22.3 - 22.7][1]	0.7
Measured	2018	[22.3 - 22.7][1]	[0.9 - 1.3][2]

[1] Based on extracted air temperature measurements [per building]
[2] Adjusted air flow to reach the measured heat demand [per building]

The results are depicted in Figure 6 and yield following comments. As 2018 was warmer than the standard weather (2'347 instead of 2'894 heating degree days), the SH demand for the *Real weather* scenario turns out around 20% lower than for *Project*. The demand however rises when taking into account the actual indoor temperature. Finally, reproduction of the actual monitored SH implies to adjust the ventilation rate to 0.9 - 1.3 $m^3/h.m^2$ (instead of the normed value of 0.7 $m^3/h.m^2$, without heat recovery). Latter adjustment could be related to window openings. In this regard, of the average adjusted value of 1.1 $m^3/h.m^2$, 0.2 $m^3/h.m^2$ actually correspond to mechanical ventilation (i.e. 1.0 $m^3/h.m^2$ subject to 80% heat recovery efficiency). The remaining 0.9 $m^3/h.m^2$ is equivalent to 9 constantly open windows of 1x1m per building (as given by a standardized airflow chart). So as to corroborate the plausibility of such window openings, we conducted an infrared photography campaign of the total 768 windows, at a rate of 289 pictures per day over a typical winter week. As a result, we observed an average per building of 3.5 open windows, 8.4 partially open windows and 5.9 open windows behind shutters (i.e. an order of magnitude which could explain the gap between *Measured* and *Real weather & indoor temperature* scenarios).

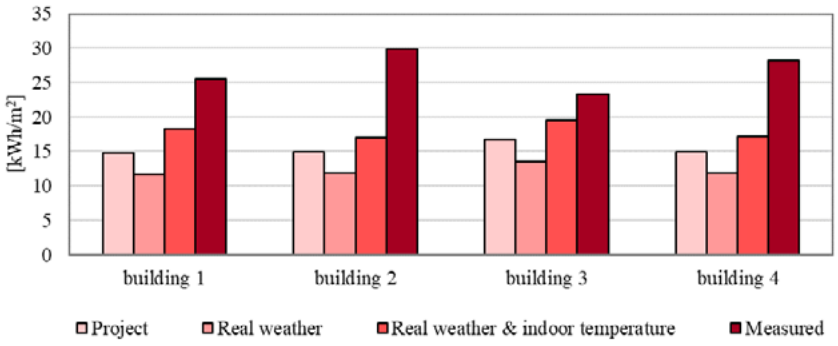

Fig. 6. SH demand, calculated and monitored values

Preceding results lead to following remarks:

- The ratio between *Measured* and *Real weather* (1.7 - 2.5, depending on the building) can in principle be explained by: i) higher indoor temperatures than the ones given by the norm; ii) window openings which over-compensate heat recovery by the mechanical ventilation.
- While this performance gap may seem relatively important, it is in the order of magnitude of other monitored buildings [5]. Furthermore, despite this gap, the actual SH demand (27.3 kWh/m^2) is quite lower than the 68 kWh/m^2 average value of Geneva's MFB stock constructed between 2001 and 2010 [4].

Finally (Figure 7), the measured DHW supply is compared to normed values concerning as well supply to the storage [8], as end use at taps [9]. The measured average (39.5 kWh/m^2) is above the normed supply value (32 kWh/m^2), but in between the median and 3rd quartile of a benchmark on 61 sub-station of Geneva's main DH network [10]. Also note that the important discrepancy between the 4 buildings, which cannot be explained by distinct number of inhabitants, still is in the dispersion range of latter benchmark.

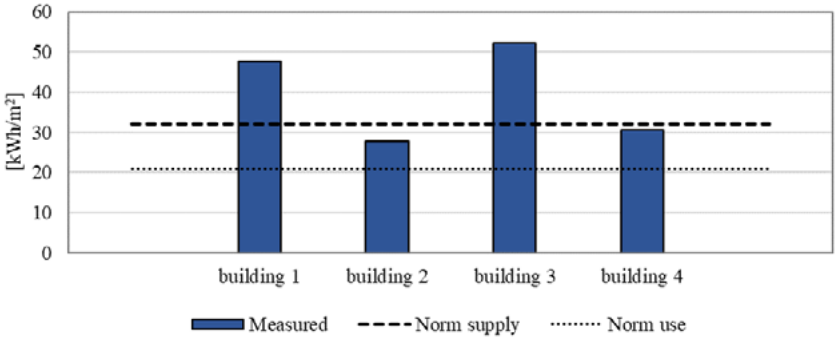

Fig. 7. DHW supply: measured and normed values

4. Conclusions

This paper concerns a new low energy MFB complex in Geneva, whose heat is produced by a centralized HP on wastewater with a complementary gas boiler, and distributed via a local DH network. Detailed hourly monitoring over an entire year of operation yields following main results.

At production level:

- The HP production accounts for 45% of the total production, with a seasonal performance factor of 3.03, including ancillary electricity of circulation pumps on evaporator and condenser side.
- The dynamic and annual energy balance of the system show a lower HP production than expected, especially during winter. This is due to operational constraints linked to distinct temperatures set points between summer and winter, as well as to high return temperature from the gas boiler. Note that this issue is currently being tackled by way of numerical simulation.
- While the wastewater resource temperature is relatively high all year round (20-25°C), the evaporator inlet temperatures is quite lower (5-10°C). Such is possibly linked to recurrent fouling of the wastewater heat recovery system, an issue which is still under investigation.

At demand level:

- At the level of the buildings, DHW supply (39.5 kWh/m^2) accounts for 59% of the total, against 41% for SH (27.3 kWh/m^2).
- As a complement to direct SH, ventilation heat recovery by dual flow, with a measured 80% efficiency, contributes by 24.1 kWh/m^2 to compensation of heat losses through the building envelope.
- The ratio between measured and climate corrected design values (1.7 - 2.5) can in principle be explained by: i) higher indoor temperatures than the ones given by the norm; ii) window openings which over-compensate heat recovery by the mechanical ventilation. While this performance gap may seem relatively important, it is in the order of magnitude of other monitored buildings, and the actual SH demand is quite lower than the average for Geneva's multifamily buildings constructed between 2001 and 2010.
- Finally, the measured DHW supply is above the normed supply value, but in between the median and 3rd quartile of a benchmark on 61 sub-station of Geneva's main DH network.

As a conclusion of this case-study, centralized HP systems on wastewater can play a substantial role for the combined SH and DHW heat production of low-energy multifamily buildings. Implementation and operation however need adequate system integration, control and commissioning.

Air-to-water heat pumps as a substitution of oil-boiler in a non-retrofitted multi-family building of the 70's. In-situ monitoring, actual energy balance and performance.

Omar Montero D., Carolina Fraga, Simon Callegari*, Pierre Hollmuller

Energy Systems Group, University of Geneva, 66 Bd Carl Vogt, 1211 Genève, Switzerland

Abstract

In Geneva, CO_2 emissions are mainly related to the heat supply in the residential sector, in particular in multifamily buildings (MFB). In this context, air-source heat pumps (HP) could help to reduce emissions and replace fossil-based heating systems, especially in dense existing urban areas where air is the only available renewable energy source. This study concerns the analysis of an existing non-retrofitted MF building of 1972 (4´047 m^2 heated area), whose original fossil heat supply was recently replaced by two industrial air-to-water HPs (2 x 140 = 280 kW). Based on a detailed monitoring campaign covering 15 months of operation, the main findings show that the HP system was able to cover the entire heat demand, except for a short breakdown. Thanks to optimizations in the system regulation and the choice to use only one HP in summer, the COP_{sys} increased from 1.3 in the early stage, up to 3.4 during the last summer. Based on the latter performances, we estimated that the SPF could reach an annual value of 2.3 (instead of the measured value of 1.9).

Keywords: air-to-water heat pump, multi-family building, retrofit, in-situ monitoring, energy balance, performance gap.

1. Introduction

Nomenclature

COP_{HP}	coefficient of performance of the heat pump
COP_{sys}	coefficient of performance of system, including related auxiliary electricity
DHW	domestic hot water
E_{HP}	electricity consumption of heat pump
E_{sys}	electricity consumption of heat pump and auxiliary electricity
HP	heat pump
MFB	multifamily building
Q_{HP}	heat production of heat pump
SH	space heating
SPF	seasonal performance factor (annual or seasonal value)
ΔT_{HP}	Differential temperature between HP heat source and sink temperatures

1.1. Context and issues

In Geneva, the CO_2 emissions related to the energy sector represent 4.2 ton of emitted CO_2 per capita, of which 2.2 emitted by the heating sector, 1.1 by the transport sector (not including the airport) and 0.8 by the electricity sector [1]. Consequently, the main CO_2 emissions reduction potential lies in the heating sector, which represents about half of the final energy consumption in Geneva.

* Corresponding author. Tel.: +41 22 379 0646.
E-mail address: simon.callegari@unige.ch.

Even though multifamily buildings (MFB) only constitute 27% of the Geneva building stock, they represent almost half of the heated floor area of the canton, namely 19.3 out of 40.9 million m^2 [2]. About half of these MFB, which were built between 1946 and 1980, are nowadays in need of retrofit and possess a strong energy saving potential. In parallel to reducing of the heat demand of the building stock, in particular by way of retrofit, reducing of the CO_2 emissions can also be achieved by replacing fossil fuels by renewable energies, in particular via heat pump (HP) systems.

However, although the market share of HPs in the Swiss residential sector grew from nearly zero in the 1990s to about 50% today, only 10% corresponds to MFB [3]. This can be explained by the fact that the implementation of HP systems in MFB is more complex than in single family buildings [4], especially because of: i) multiple households, with diluted decision power and related problems of governance; ii) buildings often located in highly dense urban areas, with limited access to renewable heat sources other than air; iii) if not threated carefully, noise emissions can easily become a barrier; iv) higher shares of domestic hot water (DHW) in overall heat demand and related high temperature, which can affect the HP performance.

1.2. éco21- HP program for multifamily buildings

Within this context, the local public utility Services Industriels de Genève (SIG) is developing a series of pilot projects concerning the replacement of fossil-based heating systems by air to water HP in MFB. These projects, which are developed under SIG's portfolio éco21, are implemented in the form of energy contracting [4].

Feasibility studies revealed the difficulties of the task: solar is not technically possible (due to complicated old roof, building being under historical heritage protection, no place available for water storage), geothermal energy and often wood and biomass are not authorized by law (due to water and air protection regulations). Air to water HPs are therefore the only solution for integrating renewable energy supply into the buildings. The challenge is important: buildings are old, there is little space, the heat distribution systems within the buildings are old, and investment costs are high [4]. Due to the age of the buildings and the restrictions to insulate the buildings envelope, the distribution temperatures are not always compatible with the ones needed for the high efficiency of the air to water HPs.

One of the major technical challenges is related to unavailability of air to water HPs specially designed for MFB. Most of the residential HPs currently have a capacity below 30 kW and are suited for single-family houses, while industrial HPs with higher capacities are not specifically designed for integration in residential buildings, specifically on noise aspects.

1.3. Objective

This paper aims to analyze one of the pilot projects of the éco21 program, in actual conditions of use. After description of the considered case study, we analyze the results of a detailed monitoring campaign covering 15 months of operation (July 2018 – Sep 2019). A particular focus is set on the diverse optimizations which had to be done so as to reach an acceptable system performance. Basing on the results obtained by way of this optimization process, we finally estimate an optimized SPF over an entire year of operation.

2. Case study

Located in Geneva and built in 1972, the MFB under consideration has a total heated surface of 4´047 m^2 (114 residents). While its envelope has not undergone any retrofit, the existing oil boiler (319 kW) was replaced by two industrial air-source heat pumps (312 kW). Each one has a heating capacity of 156 kW and COP of 3.42 (7°C evaporator and 45/40°C condenser side) as well as four scroll compressors offering four capacity stages in response to the load or source temperature [5]. Before system replacement, the climate corrected oil consumption (final energy) for production of space heating (SH) and domestic hot water (DHW) was 158 kWh/m^2 per year.

Fig. 1. Studied collective multifamily building (left) and industrial air-source heat pumps (right)

The oil boiler was kept as backup for the first years of operation but will eventually be dismantled. The distribution includes two storage tanks in parallel for DHW (500 L each) and one for SH tank (1000 L).

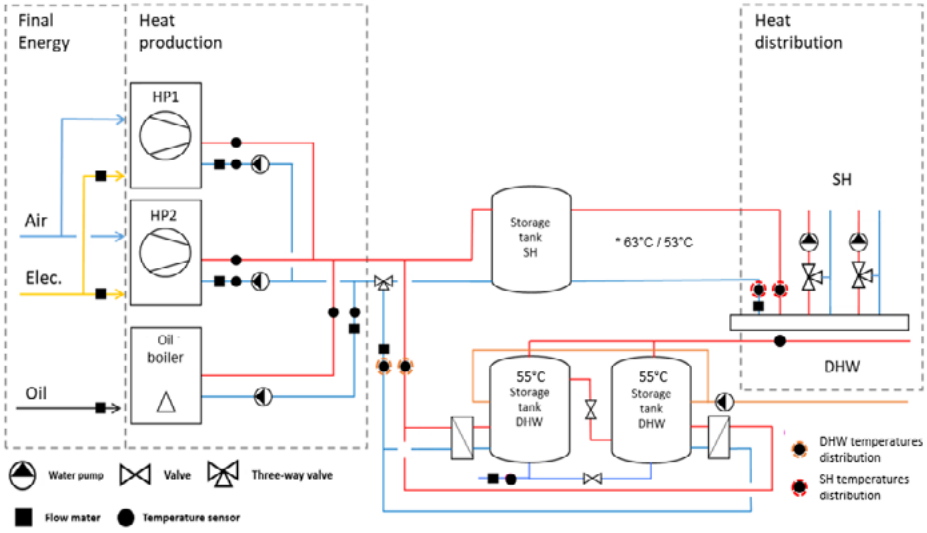

Fig. 2. Heating system (simplified diagram). * Defined at an outdoor temperature of -7°C

3. Monitoring

Instrumentation of the system is depicted in Figure 2. The monitored data are: i) electricity of each HP, including auxiliary electricity of the circulation pump on condenser side; ii) heat production of each HP; iii) heat distribution for SH (before the three-way mixing valve) and for DHW (at storage inlet); iv) DHW consumption (storage outlet).

The monitoring campaigned started in July 2018 for a period of 15 months (until December 2019). Data is acquired in 5 min time step, and aggregated in hourly and daily values.

4. Results and discussion

4.1. Building demand

The annual demand is 125 kWh/m^2 (Sep 2018 – Aug 2019), of which 47% for DHW (58 kWh/m^2) and 53% for SH (67 kWh/m^2). Latter DHW demand corresponds to the highest benchmarked values on Geneva's MFB stock [6]. On the other hand, despite the envelope not having been retrofitted, SH is well below Geneva's average for buildings from the 70's (101 kWh/m^2) and rather matches the average of the decade of 2000s [7].

The energy signature of the entire bundling shows a non-heating temperature of 17°C and SH rises to 20 W/m^2 at an outdoor temperature of 0°C (Figure 3).

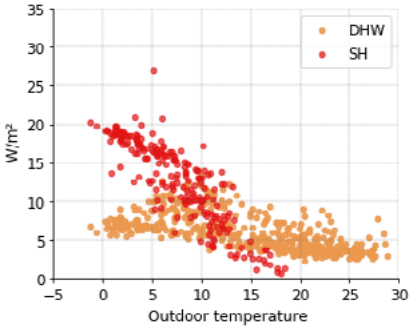

Fig. 3. Daily heat demand vs the outdoor temperature

The peak daily demand is around 25 W/m^2 (Figure 4). In daily average, DHW varies between 3 and 12 W/m^2 (summer vs winter), with an unexplained increase from February 2019 onwards.

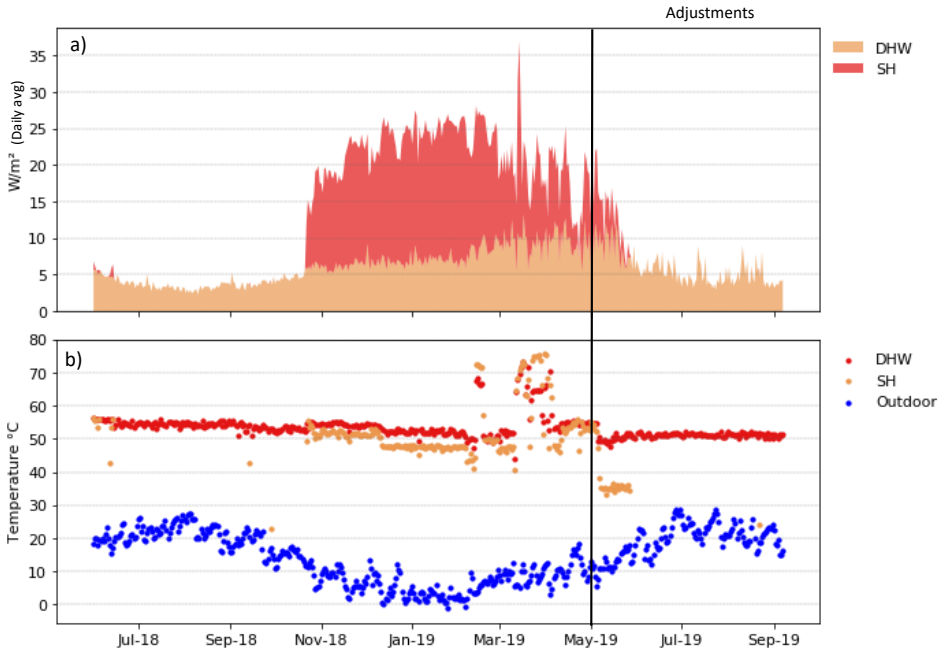

Fig. 4. Daily heat demand (a) and daily distribution temperatures (b)

Daily distribution temperatures are also depicted in Figure 4. The DHW temperature (at storage inlet) has a constant value of 50 – 55°C (except during HP breakdown in Feb and Mar 2019, see further down). Up to May 2019, the SH temperature (before the mixing valve) was relatively constant and similar to DHW. This was due to internal HP setpoints not taking into account the heating curve defined at the level of the centralized automation. This problem could finally be identified and resolved at the end of the heating season (May 2019), with a SH temperature dropping to 35°C (for an outdoor temperature above 10°C).

4.2. Heat production

The daily heat production is depicted in Figure 5. The heat production was entirely covered by both HPs, except during the HP breakdown (Feb and March 2019) when the oil boiler had to be turned on. During the first summer (up to Sep 2018), both HPs were run in parallel. From there on, priority was given to HP2 (master), with HP1 turned on for loads above approximately 15 W/m^2. During the adjustments of May 2019, priority was given to HP1, and HP2 was completely switched off for the summer period (for electricity savings on unnecessary standby mode).

Note that the HP breakdown could have been handled faster if the local technicians were used to/trained for this type of heating systems and had available spare changes, which underlines the importance of professional training.

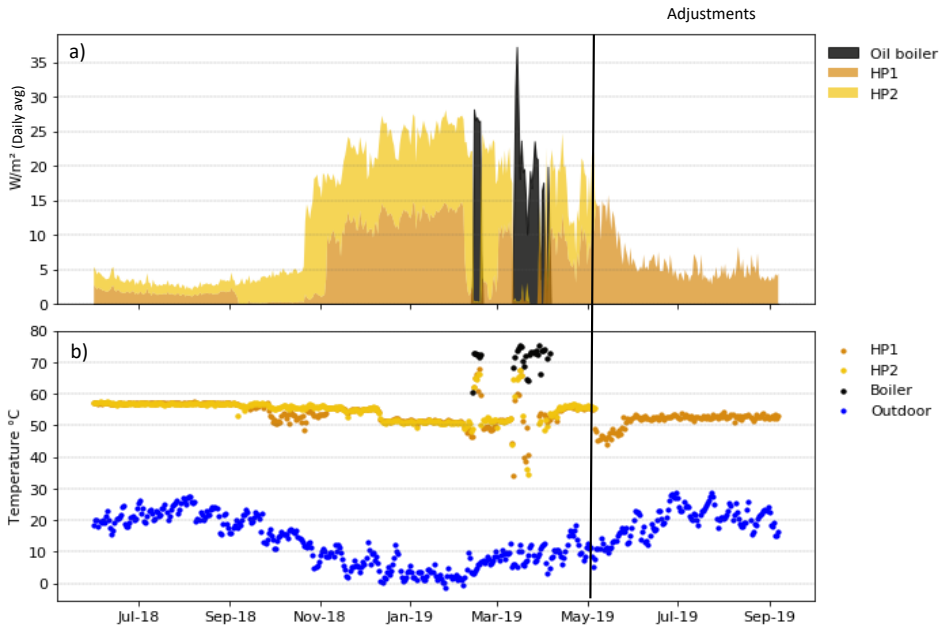

Fig. 5. Daily heat production (a) and production temperatures (b)

As pointed out before, the HP production temperature is relatively constant until the adjustments in May 2019 (Figure 5). Afterwards a short drop is observed due to the adjustments SH heating curve, followed by the DHW production during summer. During the HP breakdown, the oil boiler production temperature raised to 70°C, which is standard for this type of technology.

4.3. HP performance

For the purpose of this section, the HP performance indicators are based on the HP heat production and electricity use, and they are defined as follows:

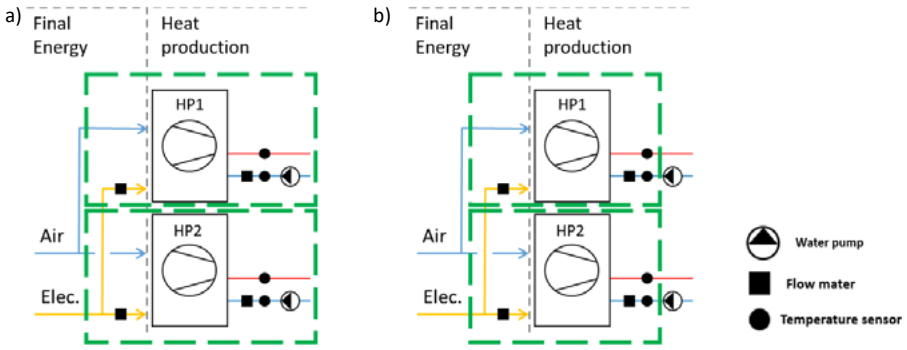

Fig. 6. Boundaries of the system performance (a) and heat pump performance (without water pump) (b)

- HP performance (Figure 6 - b) : Ratio between heat production and electric consumption of the heat pump, without auxiliary electricity consumptions, for short time periods (hourly or daily):

$$COP_{HP} = \frac{Q_{HP}}{E_{HP}} \quad (1)$$

- HP system performance (Figure 6-a) : Ratio between heat production and electric consumption of the heat pump and its circulation pump on condenser side, for short time periods (hourly or daily):

$$COP_{sys} = \frac{Q_{HP}}{E_{sys}} \quad (2)$$

- Ratio between heat production and electricity consumption of the heat pump and the circulation pump for a given period (annual or seasonal):

$$SPF = \frac{\sum Q_{HP}}{\sum E_{sys}} \quad (3)$$

Note: As temperature sensors used to calculate Q_{HP} are close to the HP, distribution losses are included in the heat production.

4.4. System performance

The evolution of the HP system performance during the monitored period is depicted in Figure 7, along with different adjustments. Summer 2018 has the lowest COP_{sys}, below 1.5, despite high air temperatures. This is due to a constant activation of the HP1 circulation pump (condenser side), even when the HP was off. An increase in performance is observed from Oct 2018 onwards when the constant flowrate is adjusted to follow the heat production, but COP_{sys} remains mostly below 2, due to constant SH temperature distribution and HP standby mode. After May 2019, the COP_{sys} increased significantly (2.4 - 3.4) due to the adjustment of the SH production temperature, the variable flowrate, high summer outdoor temperatures, as well as the choice to switch off the second HP during the summer period.

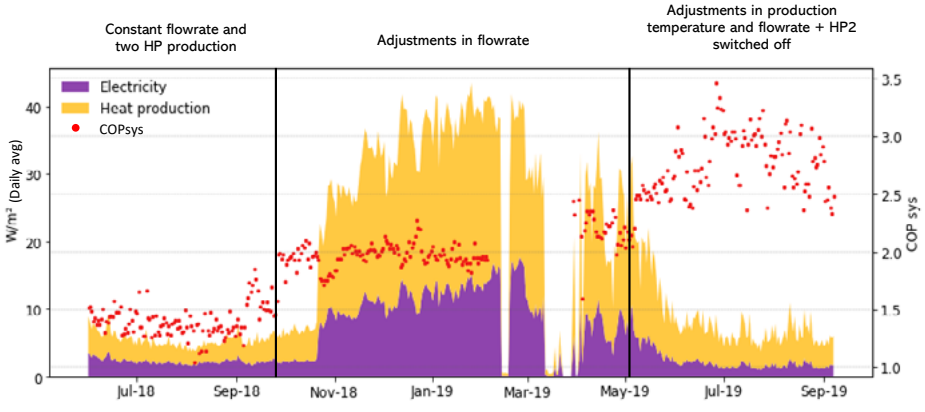

Fig. 7. Daily heat production and electricity consumption of the two HP as well as COP system performance (note: performance during the breakdown period is not considered).

The daily COP_{sys} decreases with the increase of the ΔT_{HP} as show in Figure 8. For the winter 2018-2019 and summer 2019, the COP_{sys} ranges between 3.7 to 1.8 for a ΔT_{HP} of 20 and 50 K, respectively. Note the lower performance during summer 2018 is due to the high electricity consumption induced by the constant flowrates, unrelated to temperature levels.

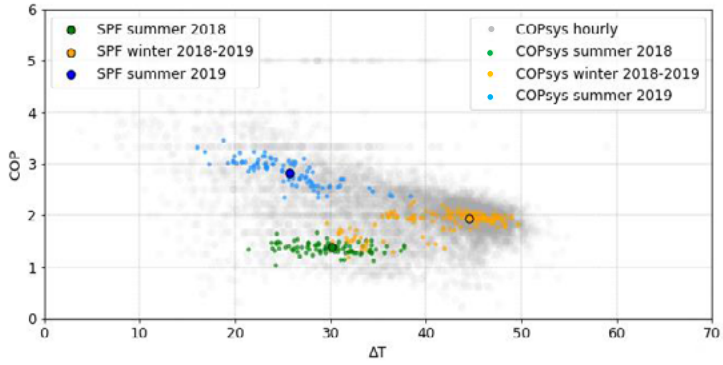

Fig. 8. COPsys and SPF as a function of ΔT_{HP}, for each season (Summer: 1st June - 31st Aug; Winter: 1st Sep - 31st Jan).

4.5. Heat pump performance

In this section, the monitored performance is compared to the one announced by the manufacturer, which is done at HP level. In the case of the manufacturer values, the COP_{HP} is given for continuous HP operation, at full power capacity (four compressors) and without auxiliary electricity consumptions. In order to approach these conditions, the hourly monitored data was filtered to identify the hours when the HP worked at least 30 minutes (note: in the case of summer 2018, the filter was reduced to 18 min, due to the higher power capacity of the two HP set-up which induced shorter durations of heat production). Furthermore, the electricity consumption of the circulation pumps (estimated to approx. 3 kW each) was deducted from the monitored electricity consumption, according to the type of flow rate of each period (constant / variable).

As a result, COP_{HP} (Figure 9) has higher values than COP_{sys} (Figure 8). In addition, the values of summer 2018 are now aligned with the ones of following periods, which highlights the fact that the poor COP_{sys} of that period was due to constant operation of the circulation pumps. Finally, a monitored COP_{HP} has the same trend as the one by the manufacture, with slightly lower values as is frequently observed difference between in situ

monitored versus lab measured values [8, 9, and 10]. In conclusion, the low COP_{sys} observed was not due to a deficiency in the HP machine but to a non-optimal system operation.

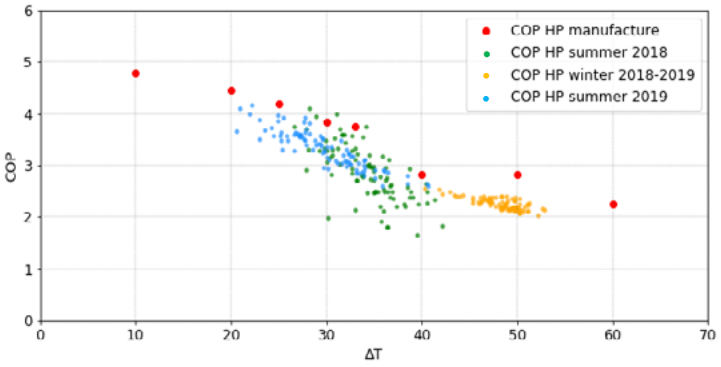

Fig. 9. Daily COP_{HP} filtered for each season and COP manufacture as a function of the ΔT_{HP}.

This analysis further suggests that HP systems should have a dedicated electrical energy meter for the HP (without auxiliary electricity), in order to verify the proper performance according to the manufacture values and help identify auxiliary electricity issues.

4.6. Optimized system performance

As observed above, the system optimizations in May 2019 lead to a clear increase of the COP_{sys} (Figure 7). Given this increase, we finally estimate an optimized SPF over an entire year of operation (Sep 2018 – Aug 2019), based on daily values, with the following hypotheses:

- The heat production is supplied by the HPs year-round (no HP breakdown).
- The daily COP_{sys} is estimated by way of the quadratic regression in Figure 10, on the optimized period, which allows to calculate the related daily electricity consumption.
- Throughout the year, as the ΔT varies between 20 and 55 K, the regression is only applied to this range. The temperature difference outside of this range are not considered.

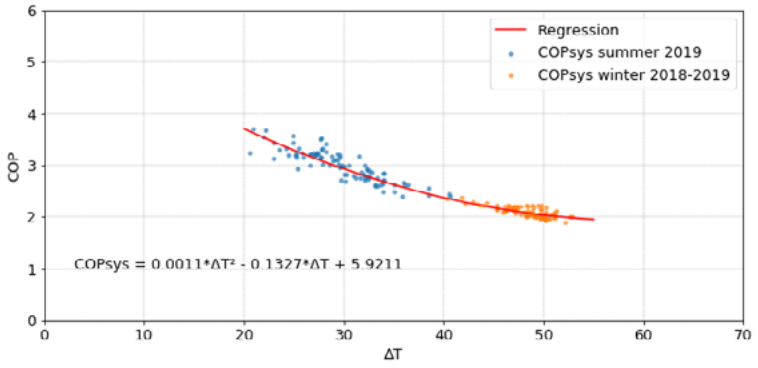

Fig. 10. Quadratic regression of the COP_{sys} as a function of the ΔT_{HP} on the optimized period (Nov 2018 - Aug 2019).

As a result, Figure 11 shows a slightly decrease of the electricity consumption (54.7 to 54.3 kWh/m^2). Note that latter still is a conservative value, because it does not include the adjustment of the SH production temperature. The total heat production increases to replace the breakdown period (HPs production year-round). It shows that a SPF of 2.3 could potentially be achieved (instead of a measured value of 1.9).

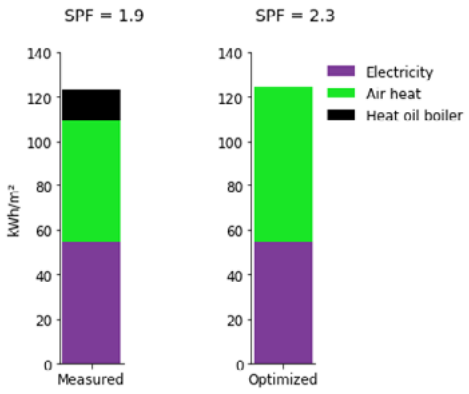

Fig. 11. Measured and optimized HP system electricity and absorbed heat (Sep 2018 – Aug 2019)

5. Conclusions

This paper focuses one a pilot project of the local public utility, concerning the replacement of fossil-based heating systems by air to water heat pumps in multifamily buildings. In the building under consideration (4´047 m^2), heat production by way of a centralized oil boiler was replaced by two industrial air-source heat pumps (2 x 156 kW = 312 kW).

A detailed monitoring campaign covering 15 months of operation (July 2018 – Sep 2019) shows that even in an existing and non-retrofitted building, a fossil boiler can be replaced by an industrial air-source HP system, without decrease of the thermal comfort for the tenants. However, based on the monitored data, improvements in the control system were implemented to improve the overall performance of the system, including:

i) Avoid constantly running of HP circulation pump in absence of production as they have a significant power consumption.
ii) Guarantee that HP set points take into account the heating curve defined at the level of the centralized automation.
iii) Turning off the second heat pump if a single HP is able to cover the entire demand, in order to improve the remaining HP's load factor.

As far as electrical consumption and related SPF is concerned, implementation of such systems however still needs adequate professional training, as well as careful commissioning. Future work will focus on exploring possible optimizations in the hydraulic and control system using numerical simulations.

Acknowledgements

The authors would like to thank SIG for financing of this study and handing over of the main monitoring data, as well as the diverse stakeholders (building owner, engineers, technicians, HP manufacturer) for participating in the follow-up group in turn of this case-study.

Abstract

Cascade multi-functional heat pumps have gained much attention in recent times due to their ability to simultaneously meet the cooling, heating and hot water demands of residential buildings. However, the effect of heat source and sink temperature on the performance of cascade multi-functional heat pumps is lacking in open literature. This study experimentally analyzed the performance characteristics of a water-to-water cascade multi-functional heat pump operating in cooling-hot water mode according to variation of indoor heat exchanger entering water temperature (ID EWT), outdoor heat exchanger entering water temperature (OD EWT) and hot water heat exchanger entering water temperature (HW EWT). Capacity of the cooling cycle was affected by variation in ID EWT and OD EWT while capacity of the hot water cycle was affected significantly by variation in OD EWT and HW EWT. Furthermore, system COP decreased with increase in HW EWT and OD EWT, and increased with increase in ID EWT.

Keywords: Cascade multi-functional heat pump, Cooling-hot water mode, Entering water temperature, Capacity, COP

1. Introduction

Heat pumps have been identified as energy efficient systems for space cooling, space heating and hot water generation [1]. While space cooling and heating are needed during summer and winter seasons respectively, hot water is needed all year round. A single heat pump that can simultaneously provide cooling/heating and hot water is of great importance in the aspect of cost, energy savings and efficient space utilization especially in apartment and high rising residential buildings. Multi-functional heat pumps have therefore been developed over the years for this purpose [2, 3]. However, most of the studies done on multi-functional heat pumps have focused on single stage heat pumps with few works on cascade multi-functional heat pumps. Performance characteristics of cascade multi-functional heat pumps is therefore lacking in open literature. This study analyzes the performance characteristics of water-to-water cascade multi-functional heat pump according to variation in secondary fluid temperature. This will provide pathway for the design and control of energy efficient cascade multi-functional heat pumps.

2. Experimental condition and test procedure

The study was done to analyze the performance characteristics of cascade multi-functional heat pump with variation in entering water temperature (EWT) in cooling-hot water mode. The experimental setup used in the study is a multi-functional water-to-water cascade heat pump consisting of a single stage cycle connected in

E-mail address: jmchoi@hanbat.ac.kr.

parallel with the low stage (LS) side of a cascade heat pump cycle as shown in Fig. 1. The single stage cycle was used for cooling, and generally consisted of the outdoor heat exchanger (OD HX), compressor, indoor heat exchanger (ID HX) and expansion device. The cascade cycle consisted of low stage (LS) side and high stage (HS) side interconnected by cascade heat exchanger, which acted as condenser to the LS side and evaporator to the HS side. Brine with ethylene glycol of 40% concentration was used as secondary fluid, with constant temperature water bath and magnetic pump used to simulate the secondary fluid flow loop.

When in operation, refrigerant from LS compressor divides into two and go through the cascade HX and the OD HX. The divided refrigerant combine, after expansion, and go through the ID HX for cooling. Also, HS refrigerant gains heat from LS refrigerant in the cascade HX, gets compressed and goes into HW HX for hot water generation. Refrigerant from HW HX is then expanded into the cascade HX for the cycle to continue. Different refrigerants were used in the LS and HS cycles due to their different critical pressure and temperature properties.

Test was conducted by varying the outdoor heat exchanger entering water temperature (OD EWT), indoor heat exchanger entering water temperature (ID EWT) and hot water heat exchanger entering water temperature at reference secondary fluid flow rates as shown in Table 1. Sensors were installed in the test rig to measure the performance parameters of the cascade multi-functional heat pump. Capacity of the cooling cycle (Q_C) and capacity of the hot water cycle (Q_{HW}) were calculated using mass flow rate of secondary fluid ($\dot{m}$), leaving water temperature (LWT) and EWT across the ID HX and HW HX respectively as shown in Eq. (1), while COP of the cascade multi-functional heat pump was calculated using Q_C, Q_{HW} and power consumption of LS (W_{LS}) and HS (W_{HS}) as shown in Eq. 2.

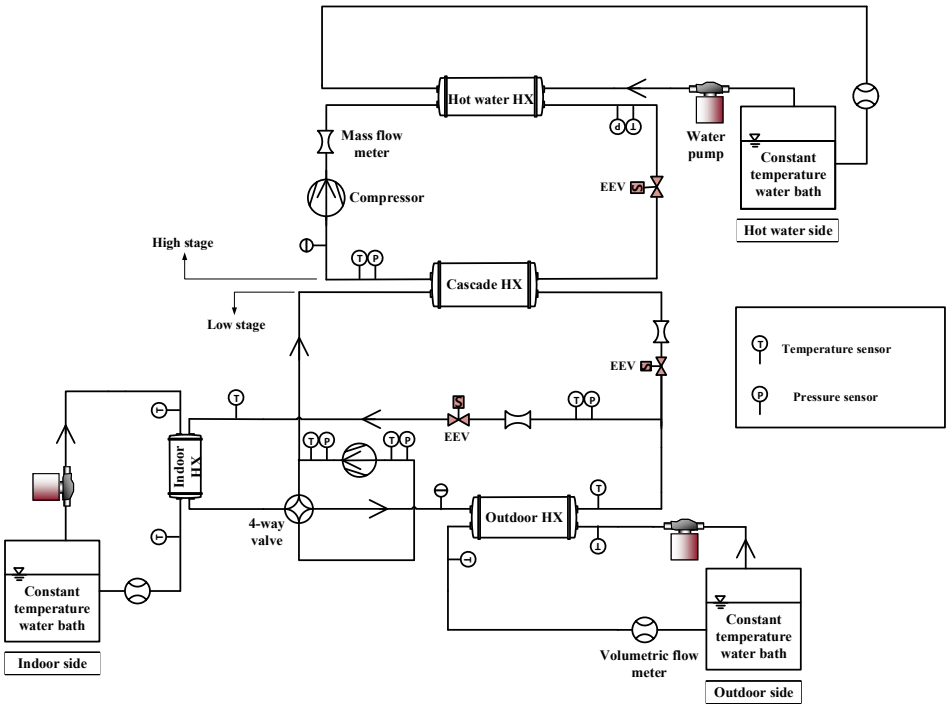

Fig. 1. Schematic diagram of experimental setup

$$Q_C/Q_{HW} = \dot{m} \cdot |LWT - EWT| \quad (1)$$

$$COP = \frac{Q_C + Q_{HW}}{W_{LS} + W_{HS}} \quad (2)$$

Table 1 Test conditions for cooling-hot water mode

Parameter	Unit	Low stage	High stage
Refrigerant	**	R410A	R134a
Optimum charge amount	g	4700	2300
OD EWT	℃	20, 25, 30, 35	-
ID EWT	℃	2, 7, 12, 17	-
HW EWT	℃	-	40, 50, 55, 60, 65
ODHX flow rate	LPM	10	-
IDHX flow rate	LPM	8	-
HWHX flow rate	LPM	-	6
EEV opening	%	Adjusted	Adjusted

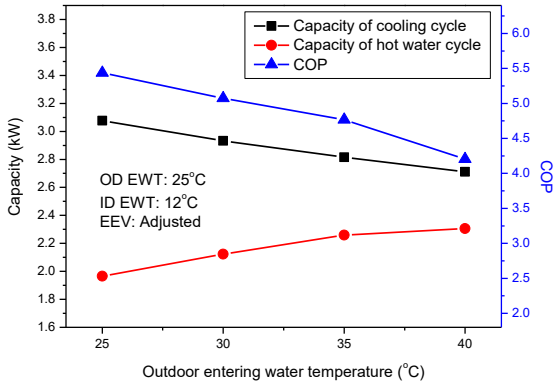

Fig. 2. Capacity and COP variation according to OD EWT

3. Results and discussion

3.1. Performance characteristics according to OD EWT variation

Figure 2 shows capacity and COP variation of the cascade multi-functional heat pump according to OD EWT. Capacity of the cooling cycle decreased with increase in OD EWT due to decrease in heat transfer rate in the evaporator. Capacity of the hot water cycle increased as OD EWT increased due to increase in LS condensing temperature and heat transfer from the LS to the HS while COP of the cascade multi-functional heat pump decreased with increase in OD EWT due to great increase in LS power consumption. Cooling capacity and COP decreased by 13.5% and 29.3% respectively, while capacity of the hot water cycle increased by 14.8% as OD EWT increased from 25℃ to 40℃.

3.2. Performance characteristics according to ID EWT variation

Figure 3 shows variation of capacity and COP according to ID EWT. Capacity of the cooling cycle increased with increase in ID EWT due to increase in refrigerant mass flow rate in the ID HX while COP of the cascade multi-functional heat pump increased with increase in ID EWT due mainly to increase in capacity of the cooling cycle and slight decrease in power consumption of the HS cycle. Furthermore, capacity of the heating cycle was slightly affected by variation in ID EWT. Capacity of the cooling cycle and COP increased up to 27.9% and 26% respectively as ID EWT increased from 2℃ to 17℃.

3.3. Performance characteristics according to HW EWT variation

Capacity and COP variation of the cascade multi-functional heat pump according to HW EWT is shown in Fig 4. Capacity of the cooling cycle was not affected by HW EWT variation. However, capacity of the hot water cycle decreased with increase in HW EWT due to decrease in heat transfer to secondary fluid in the HW HX. Furthermore, COP of the system decreased due to decrease in capacity of the hot water cycle and increase in HS power consumption. Capacity of the hot water cycle and COP decreased up to 15.9% and 28.4% respectively, as HW EWT increased from 40℃ to 65℃.

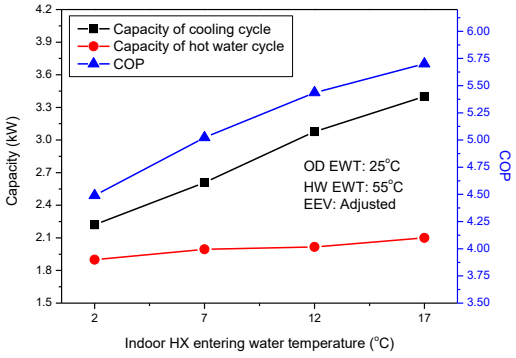

Fig. 3. Capacity and COP variation according to ID EWT

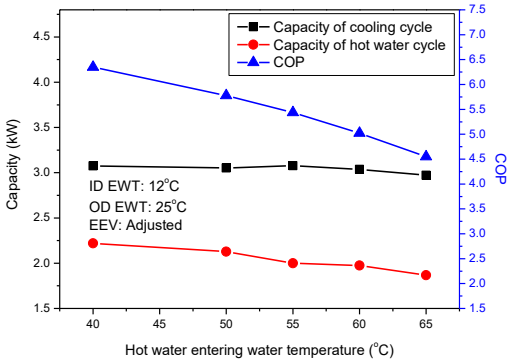

Fig. 4. Capacity and COP variation according to HW EWT

4. Conclusion

This study analyzed the performance characteristics of cascade multi-functional heat pump according to variation of OD EWT, ID EWT and HW EWT in cooling-hot water mode. Heating capacity of hot water cycle increased by 14.8% while cooling capacity and system COP decreased by 13.5% and 29.3% respectively, as OD EWT increased by 15℃ of the standard value. Furthermore, cooling capacity decreased by 27.9% while system COP increased by 27% as ID EWT decreased by 10℃ of the standard value. Capacity of the hot water cycle and system COP decreased by 15.9% and 28.4% respectively as HW EWT increased from 40℃ to 65℃. However, variation of ID EWT and HW EWT had insignificant effect on capacity of the hot water cycle and performance of the cooling cycle respectively.

Abstract

Progressive fault such as refrigerant leakage in a heat pump system is difficult to diagnose at an early stage. If the faulty system is operated for a long time, it may lead to serious fault such as compressor break down as well as performance deterioration. If the dynamic characteristics of the system caused by refrigerant leakage can be predicted, it is possible to prevent the progress of faults and to reduce maintenance cost by early fault detection. This study presents a dynamic model to analyze the dynamic characteristics of the heat pump system. Experiments were conducted by varying the operating conditions such as indoor and outdoor air temperatures, cooling load, and refrigerant charge amount. The developed model can predict the temperature variations of the condenser and evaporator and the dynamic characteristics of the system due to load change under normal or faulty operating conditions. It is expected that the control performance of the system can be enhanced, and refrigerant leakage can be quantitatively diagnosed by predicting the dynamic characteristics using developed model in this study.

Keywords: Heat Pump, Refrigerant charge amount, Dynamic characteristics, Dynamic model, Fault detection;

1. Introduction

Recent advances in variable-speed compressor opened new possibilities in improving system performance and energy efficiency. The compressor speed can be continuously changed to meet the target capacity, and the expansion valve opening is adjusted to maintain the optimized system efficiency. [1]

Various researches for capacity and optimum control of a heat pump system have been carried out. Shah et al. [2] developed a novel controller based on system identification in which a simulation model for a practical air-handling system was developed. He et al. [3] reported on the use of MIMO control of a vapor compression cycle that had multiple actuators and sensors for regulating multiple outputs. They used a low-order dynamic model of the vapor compression cycle that produced a physical meaning to model order reduction.

Faults of heat pump system can be divided into two categories; hard failures and soft failures.[4] Hard failures occur abruptly and cause the system to stop functioning such as compressor and electrical faults. These kinds of faults can be easily detected and diagnosed by electrical on/off relay and alarm signals. However, soft failure such as improper refrigerant charge is more difficult to detect and diagnose. Even though soft faults do not stop a system from working, they lead to decrease in energy efficiency and finally, a fatal failure of the system.[5]

It is required to adopt control methods considering dynamic characteristics of the system models for overall operating region. And, it is needed to develop new control algorithm, which can discriminate dynamic characteristics of heat pump system and indoor load and fault detection. In this study dynamic characteristics of heat pump system and fault detection study were carried out and performed sensitivity analysis of fault detection for improper refrigerant charge of heat pump system.

2. Test apparatus and conditions

Figure 1 shows the inverter type heat pump system. Rated cooling and heating capacity of the heat pump system is 3.5 kW and 4.0 kW, respectively. The heat pump system has an outdoor unit and an indoor unit with fin-tube type heat exchangers and variable speed rotary type compressor using R410A refrigerant. Fin-tube type heat exchanger of the outdoor unit consists of wavy fin and smooth tube. Fin-tube type heat exchanger of an indoor unit is consisted of strip fin and smooth tube. Figure 2 shows schematic diagram of test equipment for the heat pump system. Heat pump system was installed in 3RT capacity of environmental chambers. 16 temperatures, 3 pressures, relative humidity and refrigerant flow rate were measured.

Table 1 shows test conditions for obtaining dynamic characteristics of the heat pump system using central composite design method. 25 test conditions were selected by varying outdoor and indoor air temperature, compressor speed and indoor fan speed.

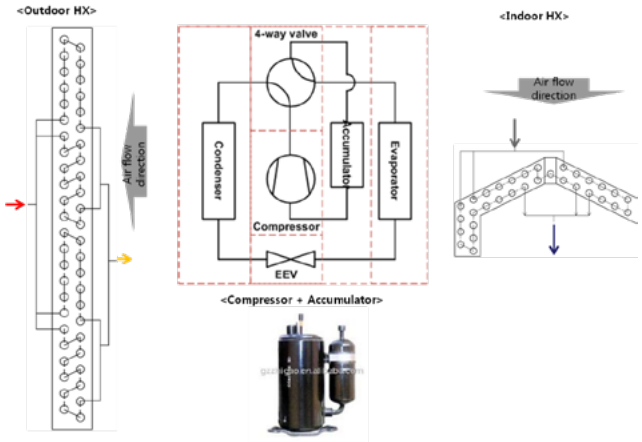

Fig. 1. Inverter type heat pump system.

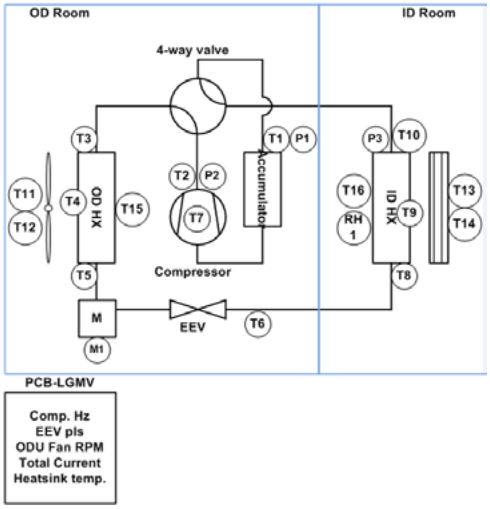

Fig. 2. Schematic diagram of the operation characteristics test equipment for the heat pump system

Table 1 Operation characteristics test condition using central composite design method

Parameter	+α	+1	0	-1	- α
OD temp. (DB/WB, ℃)	48/29	41/50%RH	35/24	28/50%RH	21/15
(ODU Fan speed (RPM))	(810)	(760)	(710)	(660)	(610)
ID temp. (DB/WB, ℃)	32/23	30/40%RH	27/19	24/40%RH	21/15
IDU Fan speed (mode)	Fast	Fast	Middle	Slow	Slow
Comp. Speed (Hz)			25 ~ 100		

Table 2 shows experimental condition for a development of fault-free reference model and for simulated fault mode of improper refrigerant charge. The rated refrigerant charge is 1000g, and the refrigerant charge is varied from 600g to 1100g at intervals of 100g and the experiment was conducted under various operation conditions.

Table 2 Experimental condition for a development of fault-free reference model

Parameter	Experimental condition
Outdoor air temperature (DB/WB)	21/15, 35/24, 48/29
Indoor air temperature (DB/WB)	21/15, 27/19, 32/23
Compressor Hz	Min~Max (5point)
Refrigerant charge	600, 700, 800, 900, 1100g

3. Development of the dynamic model of the system

In this study, the independent variable of the dynamic characteristic model is compressor speed and condensing and evaporating temperatures are considered as input variables that represent external influences on the system according to operating condition. The control variables include compressor discharge temperature, evaporating temperature, condensing temperature, and total current of heat pump system that show the effect of the system by the input variables.

Dynamic model that approximates dynamic characteristics of the system with compressor speed variation was developed using MATLAB. Figure 4 shows system response of four control variables such as compressor discharge temperature, condensing temperature, evaporating temperature and total current by compressor speed change. The dynamic characteristic of control variables was modelled and model outputs for four control variables are compared to actual responses in Fig. 4

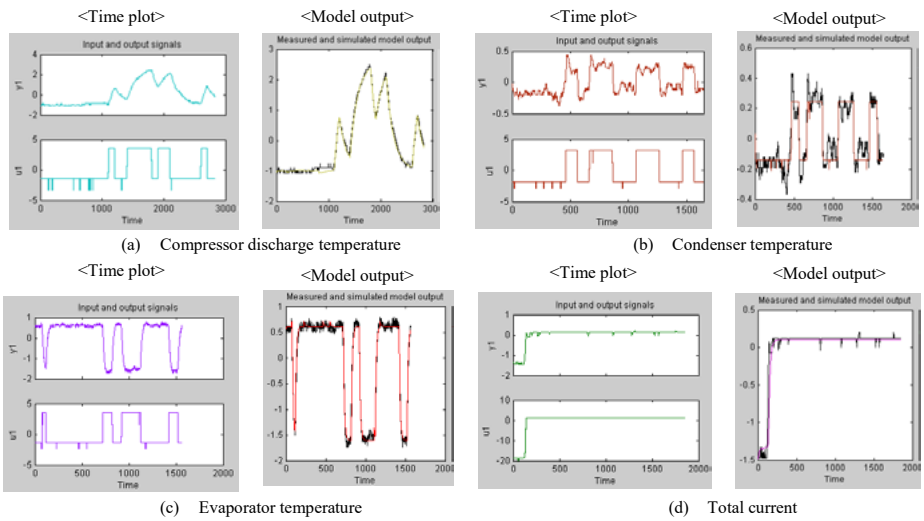

Fig. 3. Development of the dynamic characteristics model

4. Sensitivity analysis according to refrigerant charge

In this study, sensitivity analysis of fault detection was carried out with respect of fault progress. Figure 4 shows the variation of normalized distance according to refrigerant inventory of heat pump system. When refrigerant charge amount is normal, normalized distance is below 6. When fault progress increasingly, normalized distance is over 6 and built up. Fault detection using normalized distance method [6] proposed in this study predicts accurately failure mode for improper refrigerant charge.

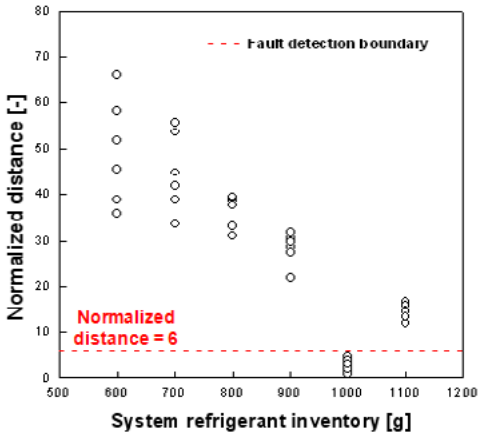

Fig. 4. Fault detection for a fault mode of refrigerant charge

5. Conclusion

In this study, a dynamic model was developed to analyze the dynamic characteristics of the heat pump system. The developed model can predict the temperature variations of the condenser and evaporator and the dynamic characteristics of the system due to load change under normal or faulty operating conditions. It is expected that the control performance of the system can be enhanced, and refrigerant leakage can be quantitatively diagnosed by predicting the dynamic characteristics using developed model.

Abstract

This paper presents the results of AHP (Air-controlled Heat Pump), a new concept of climate system for electric vehicle developed in order to overcome the disadvantages of conventional heat pump system to be applied to an electric vehicle for better efficiency. Unlike conventional heat pump system gets cooling and heating by change the refrigerant flow, AHP changes only the air flow path by door control to get cooling and heating functionality. The cooling performance of AHP at 45°C ambient temperature was a little better at high speed driving mode and much better at idle condition than current EV heat pump systems in spite of less power consumption. Also, heating performance at -20°C ambient was satisfied with reduction of power consumption which can achieve 15~27% EV driving range extension compared to electric heater system.

Keywords: Air-controlled Heat Pump System; Air Cooled Condenser; Water Cooled Condenser; Electric Vehicle;

1. Introduction

In recent years, market trends in automotive industry are changing to eco-friendly vehicles due to the lack of fossil fuel energy and global warming issues. The eco-friendly vehicles (Hybrid Vehicle, Plug-In-Hybrid and Battery Electric Vehicle) are being actively developed and rapidly spread out. Despite those wide spread trends, the EV(Electric Vehicle) has still remained technical issues - driving range, high cost and electric charging infra issues.[1] Among these issues, the driving range decrease caused by operating cooling and heating system in the EV cabin is the most pessimistic point to invigorate market.

The EV does not have a heating heat source from engine, unlike conventional internal combustion engine vehicles. It is common to solve the problem using a high voltage PTC electric heater. In this way, while minimizing changes in the existing air conditioning system, due to low efficiency, it has a big problem of reducing the driving range up to 50% in cold weather.[2]

Many vehicle makers and researchers on various types of heat pump system applied in a direction that compensates this non-efficiency with concept of heat recovery from ambient air or using vapor injection compression.[3-4] While the heat pump system is currently applied in vehicle products, the performance is significantly reduced in very cold (-10℃ or less) ambient conditions due to the characteristics of the R134a/R1234yf refrigerant, so it is common to correspond to the heating load with an additional high voltage PTC electric heater. Also heat pump system has frosting problem that happens in heating mode occurring system performance and driving distance decreases due to block of exterior heat exchanger. Some experimental study was conducted to solve the outside condenser frosting problem with various heat exchanger design.[5]

Another case of the heat pump system applied to vehicle products is as following; it is possible to operate the heat pump cycle at -20°C by applying a technology of utilizing the waste heat from vehicle power devices such as driving motors, inverters and so on. This technology can achieve a power reduction of

* Corresponding author. Tel.: +82-42-930-6641 ; fax: +82-42-930-6992 .
E-mail address: DHWANG@hanonsystems.com

battery more than 20% to 25% compared to the high voltage PTC heater only system. Despite the good efficiency of this heat recovery concept, system layout have to have a complex configuration of valves and piping to control the refrigerant path including additional high voltage electric heater and still have the problems caused by outside heat exchanger frosting.

In this study, we proposed an air-controlled heat pump system (AHP) concept to solve the complexity of conventional heat pump systems and improve heating performance with the feasible performance evaluation including vehicle test.

2. AHP System overview

2.1. Basic concept of AHP

There are various types of air conditioning systems for currently EV application which are shown in Fig.1. The first one, applying a high voltage PTC heater only system, has a simple configuration similar to the existing internal combustion engine vehicles. The general heat pump system, the second one, and heat recovery system from vehicle power system consist of a complex piping and a number of refrigerant path switching valves for getting advantages of heating power saving with the heat recovery from ambient air and sometimes waste heat from electric driving power system such as driving motor(s), inverter, etc.

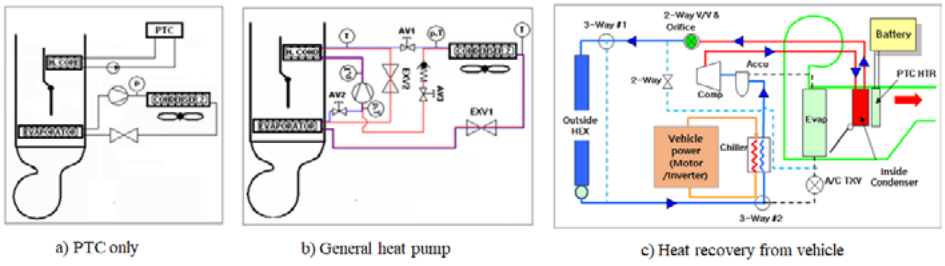

Fig. 1. Various type of electric vehicle air conditioning system

For more efficient and popular market trend, new concept of air conditioning systems for electric vehicles that can achieve weight savings by reducing the number of parts through simplifying the system configuration is required. The basic concept of the integrated air conditioning system "AHP (Air controlled Heat Pump)" developed for EV is the same as the concept of the air conditioning system since it uses hot air through the condenser as a heating heat source. Unlike the existing heat pump system changes the refrigerant flow path to implement the cooling and heating function, the refrigerant flow of AHP is always the same, while keeping the air flow into the cabin room according to the passenger's needs to implement the comfort of the cabin inside.

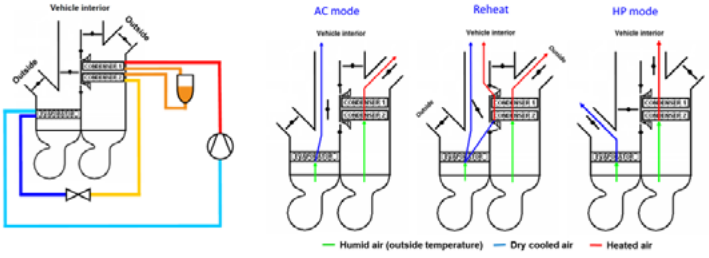

Fig. 2. Schematics and airflow path of AHP system

Fig.2 shows a schematics of AHP system and how it works. Unlike the conventional Heat Pump system as mentioned before, the refrigerant flow path is always in the same direction in cooling or heating mode. Only the airflow is changed depending on which mode user chooses. In A/C mode, cold air through evaporator goes in to the cabin room by control of door opening/closing and the warm air through the condenser is exhausted out to ambient. Vice versa in heating mode of cabin. Every valve is controlled in a HVAC system. For other mode as like dehumidifying function, it can be realized with another reheat door system.

The other word, AHP is an integrated air conditioning system by placing the condenser in one HVAC and make every function in cabin air conditioning with 1-directional and simple refrigerant system; So it can be called the integrated climate system module and is also referred to as the "Air controlled Heat Pump, AHP".

2.2. AHP system construction

For final target of this study, vehicle level performance and driving range extension evaluating, we try to apply the basic concepts of AHP system to electric vehicle. With this goal, the vehicle package and component capacity evaluating study with various type was done.

For better condensing performance and COP in A/C mode, the compact AHP model has a water-cooled condenser, while the air-cooled condenser is installed in HVAC for heating function for cabin. Fig.3 is a comparison of the AHP system in vehicle layout, and it shows the configuration of the actual system application. Depending on the location, the compressor may vary, but the overall refrigerant piping length is shorter and simpler configuration is possible.

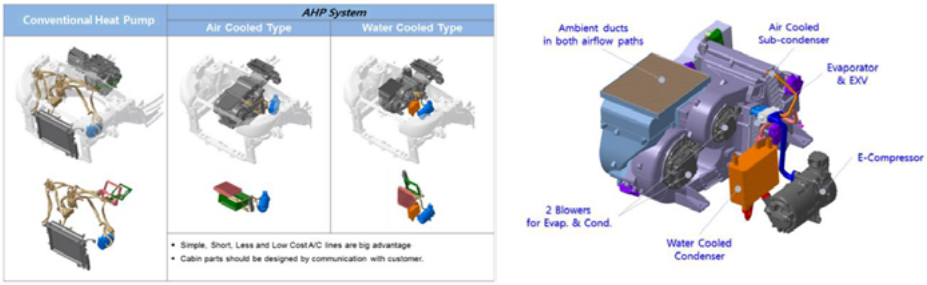

Fig. 3. AHP system construction and vehicle layout

3. Performance evaluation

3.1. Bench rig test

We did bench rig test with previously mentioned water-cooled type AHP prototype sample and evaluated it with conventional heat pump system's performance. The performance-related goals of this research were aimed at the same level of A/C performance and compressor power consumption compared to the conventional EV. The heating performance reached the same as conventional type (Cabin room average temperature 20 °C after 20minutes driving @ ambient -20°C) but the power consumption reduced as details shown in Table 1.

Table 1 Performance target of bench rig test

		Target (@-20°C Ambient)	Conventional system		AHP system
			PTC only	Heat Pump	
Average cabin room temp. (°C)		20	26.2	23.1	**Over 20**
Power consumption (kWh)	PTC heater	-	3.93	1.99	**Improve 20%**
	e-Compressor	-	0	1.07	
	Total	-	3.93	3.06	

Fig.4. shows the comparison of the test results from the bench performance evaluation at ambient temperature 45°C conditions in the cooling mode of the AHP and conventional heat pump systems. The initial

two simulated driving conditions, 50KPH and 100KPH vehicle speed, are judged to have similar cooling performance and COP. The third case, idle simulated conditions, relatively shows 15% higher cooling capacity and 30% better COP.

These evaluating results are the advantages of the system having a dual condensing, secondary air-cooled condenser of the water-cooled condenser with better sub-cool region due to characteristic configuration of AHP. In the other words, the AHP system configuration can have the advantage of being able to introduce the external air directly into the condenser not affecting heat pick-up in vehicle in-front located condenser.

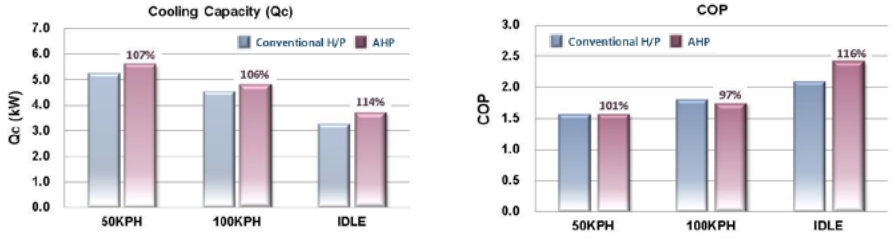

Fig. 4. Comparison of bench rig performance test

With regards to special design and construction of AHP system, this system can have the other advantage of a chance to get more heat recovery from cabin room exhausted waste heat. As is in conventional vehicle air conditioning system, there is some waste heat by extracting air process which can be recovered by recirculation to evaporator inside HVAC in heat pump mode as shown in Fig.7. The case a) conventional system already has partial recirculation logic for better heating performance, such as a certain portion of the air is recirculated to heater (or inside condenser) with fresh air from cabin outside and the remaining is extracted out to ambient. While in case of b) AHP system, some portion of extract air induced to evaporator located in HVAC and makes it possible to recover the waste heat so that refrigerant cycle works in low ambient temperature.

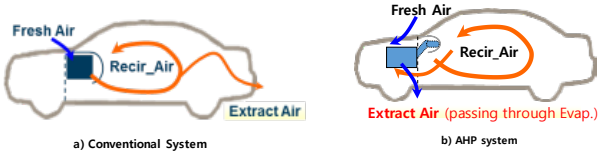

Fig. 5. Outdoor discharge air waste heat recovery in heating mode

Fig.6. shows the bench performance evaluation results of EHR (Exhaust air Heat Recovery) effect on AHP system compared to conventional heat pump system. Although conventional system has heat recovery from electric driving power system, EHR concept has better performance up to 32% and same level of COP. This effect would be more increased in low ambient temperature condition with increasing refrigerant flowrate in system.

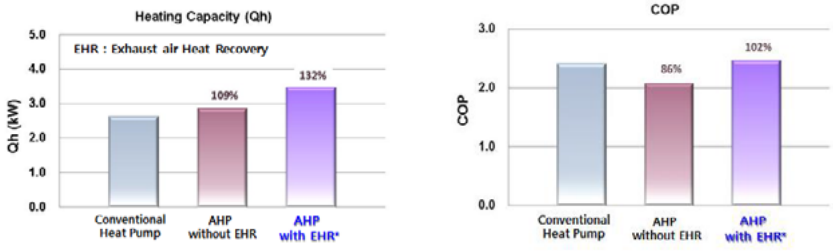

Fig. 6. Effect of EHR in bench rig heating performance test

3.2. Vehicle performance test in climate chamber

In previous section, we got the results of better performance level of AHP system in bench rig test to evaluate the effect of power consumption in real vehicle application. AHP concept sample was equipped to EV product and tested in climate chamber. Table 2. shows detailed test condition of cabin heating and cooling including performance target.

Table 2. Test condition and performance target of vehicle chamber test

	Test condition	Driving mode / Check time	Target performance ; (Cabin interior temperature)
Max cool-down	Ambient temperature : 45℃	50 KPH / 5 min.	Under 38 ℃
	Relative humidity : 40%	50 KPH / 30 min	25 ℃
	Sun load : 1,000 W/m^2	100 KPH / 60 min	22 ℃
	Vehicle full soaking	IDLE / 90min	29 ℃
Max heat-up	Ambient temperature : -20℃	50 KPH / 20 min.	Over 20 ℃
	No sun load	IDLE / 25 min	-
	Vehicle full soaking	100 KPH / 40 min	29 ℃

Fig.7. shows the results of the actual vehicle max cool-down test evaluation. In the case of AHP each temperature is satisfied with the target performance in the entire driving mode, 0.3℃ ~ 0.7℃ difference compared to the conventional system, and especially in the IDLE mode it has a dominant performance of more than 4℃. This can be seen as the advantages of the dual condensing system with water-cooled and auxiliary air-cooled condenser. Also we can consider IDLE performance is much better with less heat pick-up effect which is AHP system characteristics of no front-end located condenser. Despite this better A/C performance, its power consumption was confirmed to be 97% compared to conventional system.

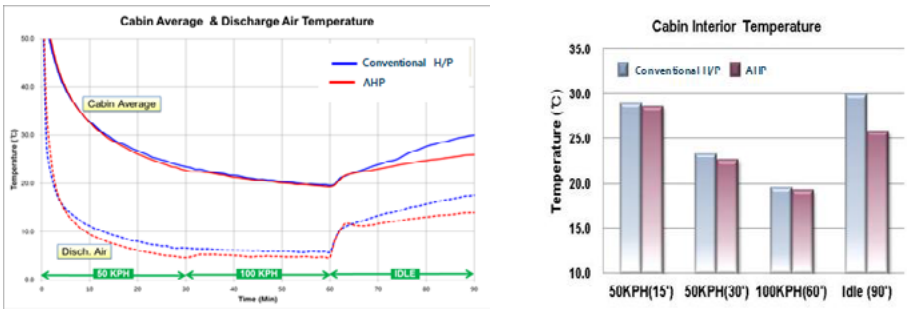

Fig. 7. Comparison of climate chamber vehicle cool-down test

As discussed, it is very serious issue that EV cabin heating requirement makes driving range decreased. For this reason, AHP system development is focused on heat pump efficiency and how to control the electric heater in initial driving mode. With EHR concept and optimized control logic of electric PTC heater operation, AHP system can get more efficiency with same cabin heating performance as shown in Fig. 8. The heating performance of AHP system meets target of average cabin temperature in driving modes and shows somewhat better discharge temperature compared to conventional H/P. In addition, the total power consumption of AHP is 2.39kWh for all the vehicle test modes which is 15% reduction from conventional H/P system power consumption of 2.8kWh. Those results can be achieved with EHR system's characteristic concept for more heat recovery that cause more refrigerant flow in low ambient temperature condition. And another contributor can be electric heater operation control that optimized usage portion in initial mode right-after vehicle start with soaking status. Fig 9. shows power consumption of e-compressor and electric heater (high voltage PTC heater) of different operation logics with regards to test time flow and driving modes.

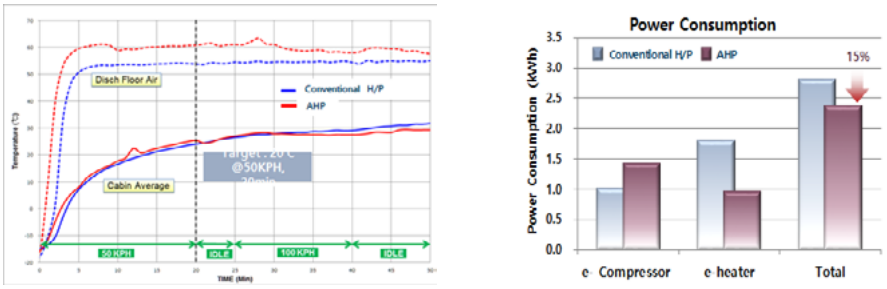

Fig. 8. Comparison of climate chamber vehicle heat-up test

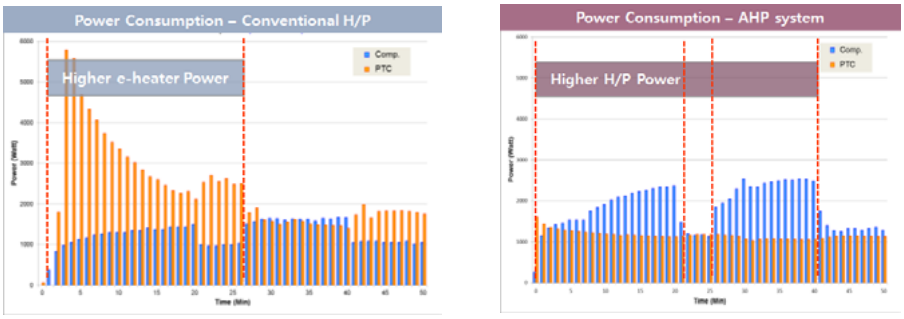

Fig. 9. Comparison of power consumption in vehicle heat-up test

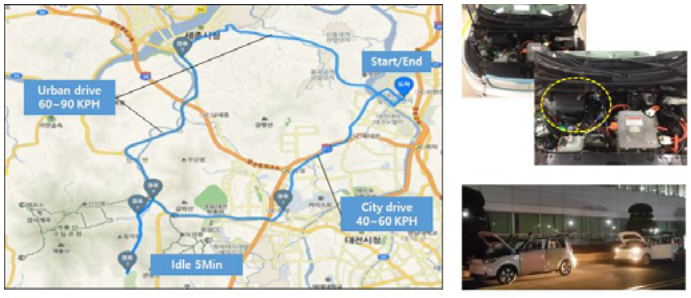
3.3. Vehicle fleet test for driving range evaluation

The main target of this study is EV driving range extension effect with more efficient air conditioning system. With this purpose, we did vehicle fleet test with 3 type of air conditioning system; PTC heater only system, conventional heat pump system and AHP system. The fleet test was conducted at the same time with auto temperature setting for 3 different vehicles with each air condition system and driving range was evaluated with vehicle battery SOC measurement and power consumption calculation. Fig. 10 shows the fleet test course, ambient condition of early winter season and test vehicle status.



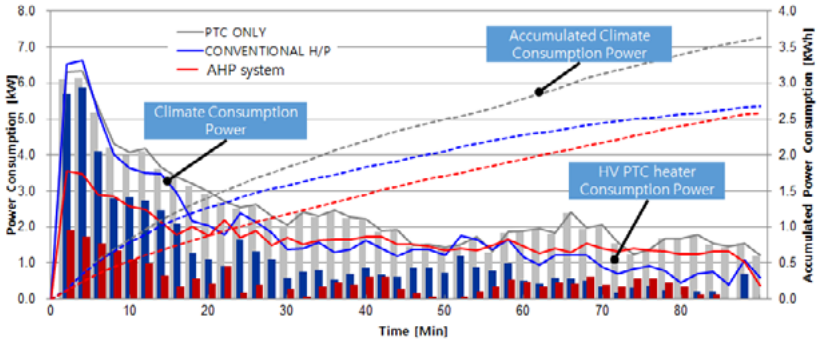


Fig. 10. Vehicle fleet test course and condition

We conducted vehicle power consumption and driving range calculation with real time battery SOC and air conditioning power measurement as shown in Fig. 11. The AHP system has 30.5% less power consumption and 27% driving range extension compared to PTC heater only system. When compared to conventional heat pump system, driving range extension effect is not much higher but this effect may become better in lower ambient condition test. Of course, cabin heating performance is at the same level in all type of vehicles but AHP system shows best performance.

Model	Accumulated Power Consumption			
	Comp.(kWh)	PTC (kWh)	Blower(kWh)	Total (kWh)
PTC ONLY	-	3.65	0.07	3.72
Conventional H/P	0.96	1.68	0.07	2.71 (-27.2%)
AHP system	1.67	0.75	0.17	2.59 (-30.5%)

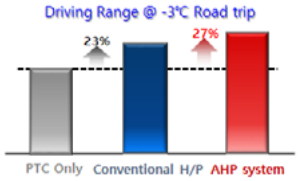

Fig. 11. Power consumption and driving range extension in vehicle fleet test

We may get more improvement in driving range extension after engine room thermal insulation, optimizing cabin room temperature control logic and fast-activated refrigerant cycle through EXV control improvement.

4. Conclusion

A new concept air conditioning system for electric vehicles is evaluated with air controlled heat pump system. In the bench rig, climate chamber vehicle and real road vehicle performance test, AHP system has better efficiency in cool-down and heat-up performance which can be a positive effect on driving range extension. Followings are the detailed conclusions.

- Through the bench rig and vehicle climate chamber test, AHP system cooling performance is better than the current heat pump system, particularly in idle performance.
- The heating performance in bench rig and vehicle test are almost same and efficiency is 3~15% higher, especially in lower ambient temperature condition. This higher efficiency of AHP system affect positively on driving range with the extension of 15~27% compared to electric heater only system.
- The improvement with more efficient component control logic and vehicle package study will be followed for future application in electric vehicle industry.

Next stop: the mass market! Heat pumps on the verge of large-scale deployment in Europe

Thomas Nowak[a]

[a]Secretary General, European Heat Pump Association AISBL, Rue d'Arlon 63-67, 1040 Brussels, Belgium

Abstract

Heat pump sales have been growing since 2013, and the last four years even showed double-digit growth. By the end of 2018, 11.8 million heat pumps were operating in Europe. Jointly they used 128 TWh of renewable energy to provide heating and reduced final energy demand by 164 TWh. Heating related CO_2 emissions declined by 33 Mt/year. The technology is now everywhere – from whitegoods via industrial processes to residential and commercial heating and cooling systems as well as in district energy systems. In applications with an energy label, heat pump-based systems score highest on energy efficiency. In some implementations, like dryers and heating, the top category can only be achieved with heat pump-based systems. Heat pumps have achieved prominent recognition not only in policy but also with scientists and researchers, many of them pointing at the importance of this technology for a decarbonised heating and cooling sector. Heat pumps are covered in the renewables, energy efficiency and building efficiency legislation. Their contribution will become even more visible, once the different planning and reporting mechanisms put in place. But is this enough? Europe has between 115 and 120 million buildings in different categories. With heating heat pumps operating in approx. 5% of the building stock, fossil fuels still provide the majority of heat. To change this, the status quo needs to be reversed – instead of 75% of gas and oil using devices, we should see the deployment of 75% of heat pumps. That means between 86 and 90 million heat pumps, none of which has yet been installed. Consequently, the current annual sales of slightly above 1 million heating heat pumps must triple, ideally overnight. The paper will explore the underlying logic, look at the market developments over the last 10 years and present policy instruments that could help to make the much-needed growth a reality
.

Keywords: heat pump;, market development; sustainable energy system; decarbonisation; Europe; Green Deal; statistics; policy

1. Status quo

The need to address climate change in a meaningful way is picking up speed. While the United Nations Climate Change Conference meets for the 25th time [1], local, national and international legislators declare "climate emergencies" [2] and the general population, led by iconic figures like Greta Thunberg ask for science based action[3], the single measure indicating in increase in global mean temperature seems unaffected.

Global primary energy demand has increased by 2,9% in 2018 and CO_2 emissions have increased by 2 %, the fastest increase since 2010 and 2007 respectively.[4] It is safe to say: "we are not on track".

2. Legislation for decarbonisation: Clean energy for all Europeans

From a European perspective, tackling climate change means decarbonising heating and cooling. This sector is responsible for approx. 50% of final energy demand and 27% of CO_2 emissions. The sector cannot be handled as lightly as it has been handled, if Europe is to become the first decarbonised continent, as recently re-iterated by the new president of the European Commission, Ursula von der Leyen at the COP25 conference.[5]

Corresponding author: Thomas Nowak. Tel.: +49 17663201140 ; fax: +32 24001018.

A first climate and energy package rolled out between 2007 and 2014 consisting of legislations and directives on

- renewable energy,
- energy efficiency,
- energy performance of buildings,
- minimum performance standards of buildings and related labelling,
- re-design of the electricity grid,
- emissions trading and the related scheme.

In addition, heat pump technologies are subject to product-based energy efficiency and labelling directives, the regulation on fluorinated gases and a number of legal provisions on the national level including those defining the requirements for support schemes and subsidies as well as those on vocational training, skills and university level education.

The European Parliament and the Council have recently passed the "Clean energy for all Europeans"-package in order to update and shape Europe's energy and climate policy until 2030 and to deliver the EU's obligations under the Paris agreement.[6]

This package acknowledges the importance of involving the individual citizen in the endeavour to make Europe carbon neutral. Thus several articles inside the eight legislative acts address the participation of this stakeholder group. The Member States now have up to two years to implement the directives into national law. The package also contributes towards the proposed Long Term Strategy (LTS) which covers the necessary measures until 2050.[7]

The clean energy package is a mix of revised and new legislation:

1. The recast renewable energy directive [8]
2. The amended energy efficiency directive [9]
3. The amended energy performance of buildings directive [10]
4. A directive and a regulation on the design of the electricity market [11]
5. A newly introduced regulation on the governance of the energy union and climate action [12]
6. A regulation on risk preparedness in the electricity sector [13]
7. A regulation establishing a European Union agency for the cooperation of energy regulators (ACER) [14]

The first four pieces of legislation listed here will directly affect the decarbonisation of heating and cooling in general, as well as the building sector [15]. Consequently, a high ambition in these areas will affect the market development of heat pumping technologies, as they are not only mentioned as technologies to use renewable energy but do contribute to energy demand reduction and are listed as one of the "high efficiency alternatives" to be considered in new construction and renovation of the building stock.[16]

The existing pieces of legislation affect the development of heat pump demand on different levels of the energy system in parallel and are expected to mutually reinforce each other (see figure 1).

1. **System level**: the focus on **energy efficiency** and the promotion of the use of **renewable energy sources** will result in a parallel reduction of energy demand and an increase in the share of renewable energy to cover it. Both directives apply to all sectors: electricity, transport and heating/cooling.
   The directives set **new targets** for the reduction of final energy demand (against a forecast value) of 32,5% and a share of 32% of renewable energy to cover that said total final energy demand. Both are to be achieved by 2030. For the first time, the renewable heating directive is giving 'cooling' more prominent recognition, allowing also renewable cooling to be counted in the renewable energy statistics. However a definition is yet to be found.

   Impact: As heat pumping technologies are contributing to the renewables and energy efficiency targets, they can expect to receive increasing political recognition and support. The importance of energy efficiency including in cooling will give additional attention to heat pumps offering a heat-recovery / cooling-recovery function to the market.
2. **Sector level:** The **energy efficiency** directive (EED) sets energy saving obligations (art. 7). Under this requirement, measures to reduce the energy demand of existing buildings can be counted (Annex V).

Impact: As the technology development has made heat pumps much more suitable to be deployed in the building stock and as their installation exceeds the status quo of building renovation, resulting savings can be counted. This fact should increase the technologies recognition as a tool to achieve the energy efficiency target of 2030.

3. **Sector level:** The **renewable energy** directive [17] sets forth a specific growth trajectory in art. 23 for the use of renewable energy in heating and cooling. Member States are encouraged to take measures to increase this share by 1,3 percentage points per year. Article 24 obliges Member States to ensure also an increased share of renewable energy in district heating and cooling grids.

   Impact: Comparing the target to the growth of renewable energy over the past 10 years shows that this sector target will have a tremendous impact if executed on the Member State level. The current growth rate needs to be nearly tripled on an annual basis which requires a broader effort in the national implementation. As the potential of heat pumps is currently underused, support and incentives for this technology will help policy makers to achieve even more ambitious targets. Large industrial heat pumps, as a relatively new segment are now manufactured in capacities of up to 35MW being able to provide temperature levels up to 160°C. Both – smaller residential and larger industrial heat pumps can be expected to move to the centre of attention as a key solution to quickly integrate significant amounts of renewable energy to the system.

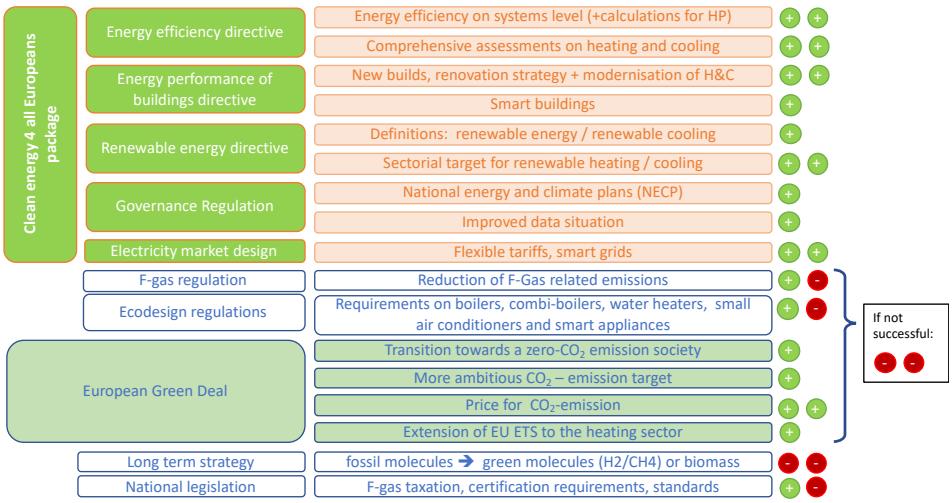

Fig. 1. Qualitative assessment of the impact of European energy and climate-based legislation on heat pump technology.

4. **Sub-system level**: the **energy performance of buildings** directive (EPBD) focussed first on new buildings. The introduced minimum efficiency targets for this building category were making near-zero energy buildings (NZEB) the standard for private (2021) and public (2019) buildings. With the introduction of the first directive in 2010 the requirement to reduce the energy demand of a building and to consider highly efficient heating and cooling solutions was established. In 2018, the amendment to the directive obliges Member States in art. 2a. to develop long-term renovation strategies that move the whole building stock – residential and non-residential, independent of ownership – to nearly zero-energy buildings.[18] These strategies were previously mentioned in art. 4 of EED and have now been moved to the EPBD to ensure a more coherent legislation.[19] Further reference is made to the provision of advisory tools (art. 20), financing solutions (art. 2a (3)), in particular for low income households and the recognition of indoor air quality, fire safety and possible impact from seismic activity.
   It is surprising, that no reference is made to adapt buildings to the possible impacts from climate change, namely the need for cooling, resistance against storms or heavy rainfall / floods.

With reference to buildings becoming active nodes in an increasingly smart electric grid (see the electricity market design directive), EPBD also requires the European Commission to develop a smart readiness indicator (art. 8 (10) and Annex I A) that should rate the ability of the building to adapt to the grid while fulfilling the needs of the occupant. This can be seen as a bridge to the electricity market design directive.

Impact: The lower the energy demand for a building the easier it is to deploy heat pumping technologies. In areas where at least some cooling demand exists, the dual functionality to provide heating and cooling makes the installation of a single heat pump also a cost-efficient solution. Where heat demand is moving towards passive house levels, a combination system to provide ventilation, heating/hot water and cooling can efficiently be provided. A concept that is found already in the market and is meant to be optimised by the joint IEA HPT/ECES annex 55/34 (also part of mission innovation #7).[20]

5. **Consumer level:** The consumer is addressed in many areas. The electricity market design directive [11] aims at ensuring affordable and transparent energy prices as well as supply security. It also defines an active consumer as a generator of energy in the market (chapter 3). Among the rights defined for the consumer is the "entitlement to a dynamic electricity price contract" (art. 11) and the right to purchase and sell electricity services independent of their supply contract (art. 13), enabling them to become active customers in the market (art. 15). The precautions taken in these articles will give a value to demand side flexibility and will enable users that can provide such services to benefit economically. In case of heat pumps and storage systems, the heating and electricity sectors will be connected (sector integration) giving the heating sector a European dimension, as it will be able to contribute to grid stability and contribute from this service in a way that helps reduce operating cost for the end user and system cost for society.

   Impact: It is expected, that this new consumer-centric market design will lead to the creation of new business models helpful to overcome the investment burden of heat pumps vs. incumbent fossil technologies and the technical uncertainty of end users, as most likely such models will be offered by service companies and or aggregators.

6. **System level**: The **governance regulation [12]** defines the cooperation between the European Union and the Member States. As Member States are free to decide on their energy policy but have to apply the related regulations and implement the different directives the governance regulation connects the European energy and climate targets to action 'on the ground'. The different planning tools in connection with monitoring and reporting allow for a better management of the energy transition and a timely evaluation of the status of the Member States and the Union in achieving the 2030 targets. The regulation introduces national energy and climate plans (NECP) to govern the 10-year planning cycle. They integrate previously separate reporting obligations on a) renewable energy, b) energy efficiency, and c) greenhouse gas emission reductions. Based on a common template, Member States of delivered draft versions of their plans covering the period from 2021 to 2030. The European Commission has reviewed these draft versions and has sent improvement suggestions which have to be implemented in the final version [21]. Similarly, the community of non-governmental organisations active in Brussels supported the assessment. Much higher ambition seems to be possible.[22]
   Member states must include their long-term renovation strategies into the NECPs and set indicative milestones and estimates on the amount of energy saved and the share of own building stock renovated (within the 3% renovation obligation).
   Beyond the buildings sector, Member States are obliged to establish Long Term Strategies (LTR, art. 15) to plan and execute necessary action to make national societies carbon neutral. The governance documents reference multiple times to the need for a multi-level dialogue between different stakeholders in order to activate civil society and achieve public acceptance. The deadlines for these plans are overlapping and should be aligned in the future.

   Impact: The NECPs and the Long-Term Renovation Strategy will improve knowledge about the energy demand in buildings and will help and encourage Member States to focus more on the need to address the decarbonisation of their societies in general making use in particular of the opportunities in the building stock. The required "evidence-based" estimates will make an improved

data basis for the building sector essential. As this is lacking today, an estimate of the impact of technology deployment is often difficult to achieve or not coherent. Thus, better building and technology statistics will make market assessments and forecast easier, an improvement that should be beneficial to all renewable heating technologies, including heat pumps.
The Long-Term Strategies create the bridge to connect Member State ambition with the Long-Term Strategy of the European Union, which aims at creating a decarbonised continent by mid-century.

In summary, the clean energy for all Europeans package establishes a multi-level framework to decarbonise society in general and the building sector in particular. Heat pump technologies will benefit, as they contribute to the renewable energy, energy efficiency and CO_2 emission reduction targets as well as providing flexibility to the grid, thus supporting its stability. The technology is readily available in volume and recent developments in research and innovation have opened industrial applications and the build environment for its deployment. From a societal perspective, most of the value chain is still local providing employment and paying taxes. Thus the technology can expect further positive recognition in the upcoming industrialisation strategy which should improve demand from end-users. What is the status of development and what needs to be done to accelerate?

3. The need for a fast acceleration of heat pump deployment

The European Heat Pump Market has grown continuously since 2012. By the end of 2018, a total of 11.8 million heat pump units have been installed in the 21 countries covered by the EHPA statistics [26]. This is a plus of 12% or 1.26 million units over 2017.

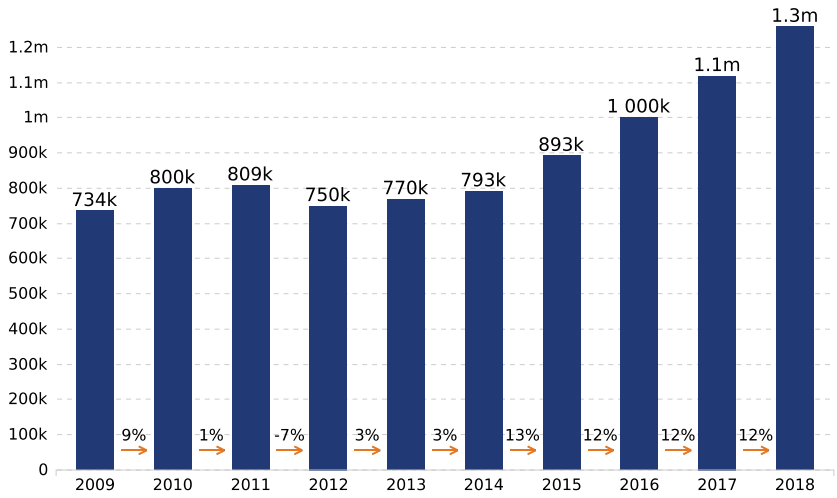

Fig. 2. Sales development of heat pumps in Europe Source: EHPA [26]

The leading markets continue to be France, Italy and Spain. Together they are responsible for more than half of the annual heat pump sales in Europe. Most remarkable – France is now close to completing an uninterrupted 10 year growth path and continues to be the engine for further growth. A recent assessment by AFPAC (Association Française pour la Pompe à Chaleur) has revealed a bullish outlook of +30% in a market that has been growing very strong in the past. Other countries are about to follow. The Netherlands has declared its aim to become "gas free" in residential heating, the UK has announced a ban of oil and gas boilers in new buildings, Ireland has put heat pumps at the centre of its efforts in decarbonizing the building stock. Even those countries that have no specific policy in place see a positive market development.

In 2018, heat pumps with a thermal capacity of 10.6 GW were installed producing approx. 20.7 TWh of useful energy and integrating 12.9 TWh of renewables in heating and cooling while avoiding 3.3 Mt of CO_2-equivalent emissions.

In order to produce the 2018 sales volume and to maintain the installed stock, a total of 68 277 man-years of employment were necessary. Obviously real employment related to the heat pump market is larger, as not all employees work full-time on heat pumps only.

In aggregated terms, the 11.80 million heat pump units sold since 1996 have an installed thermal capacity of 102.2 GW. The stock of heat pumps produces 201.5 TWh of useful energy, 128.5 TWh of which being renewable. Their use saved 164.1 TWh of final and 75.7 TWh of primary energy.

While heat pumps by now are the #1 heating technology in the new build segment of many national markets, they are also making an inroad into the renovation sector. Improved technologies and new business models help their deployment and prepare the technology for continues growth. This will be further fuelled by the implementation of the "Clean energy for all Europeans"-package as described in chapter 2 of this paper.

4. Position of heat pumps in the European heating and cooling market

In principle, heat pump technology can be used in most buildings and in many industrial processes. Precise data on these sectors is however difficult to find.

In 2019 Europe had 223 million dwellings [23]. No official figure exists on the number of buildings, but it can be estimated at around 115 and 120 million units based on the following assumptions:

1. On January 1st 2019 Europe had 513 million inhabitants [24]. With an average household size of 2,3 people, Europeans inhabit 223 million dwellings.
2. The number of single-family buildings is determined at approx. 90 million units, consequently, 207 million inhabitants live in single-family buildings.
3. The remaining 306 million inhabitants require 133 million dwellings.
4. If the typical multi-family building consists of 8 dwellings, 133 million dwellings are distributed across 16 million multi-family buildings
5. A separate statistic states that there are 10 million commercial buildings in Europe.

Europe's building stock would thus consist of 90 million single family buildings, 16 million multifamily buildings and 10 million non-residential buildings – in total approx.116 million units.

The majority of these buildings is today still being heated by fossil sources (see figure 3). A meaningful decarbonisation will require

a) the replacement of the fossil technologies with renewable heating and cooling technologies, and/or
b) the change of energy carrier from fossil to renewable sources, which may include green gases and hydrogen.

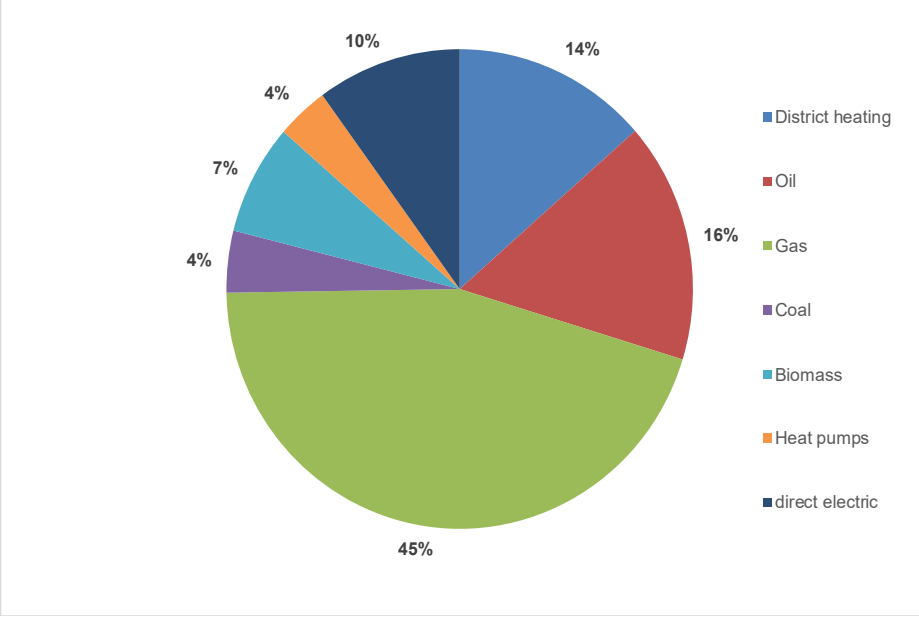

Fig. 3. Decomposition of European building stock by energy source used. Sources: Odysssee [25] and EHPA [26]

In order to evaluate the challenge a quick look the European heater market is essential. Combining data by BRG Ltd (UK) and EHPA results in an estimated market size for heaters of around 7 million units [BRG + EHPA]. This figure can be further dissected into the share of heaters installed in new build and in renovation projects as well as the number of units simply replacing existing heaters.

While this split is not part of available data, it can be deducted from a number of individual pieces of information.

- EUROCONSTRUCT estimates a rate of new construction of around 1,5% per year [29] [30]
- The renovation rate is generally reported as being too low without consistent data being available per member state. A typical figure found in the discussion is a rate around 1% [27] [28, p. 4]
  ➔ based on 116 million buildings, approx. 1,16 million buildings are renovated per year

Thus the 2018 heater market of 7,16 million units can be split into 661 400 heat pump units in new builds, and 478 600 units in renovation project and 1 743 500 other heaters being installed in new and renovation projects. The remaining 4 270 000 units are replacements of existing heaters without significant renovation of the building.

Already today, all new buildings are fit for heat pump deployment (with a very few exemptions) and this will even be truer after 2020, when all new buildings have to comply with near zero energy performance standards. Consequently, a technical market potential of around 1,8 million units in new construction can be estimated. The same argument can be made for renovation projects: All buildings undergoing moderate to deep renovation are fit for heat pump deployment (while there is no definition for deep renovation, see [32, p. 36] for a typology).

No good data exist on heat pump opportunity in the case of like-for-like boiler replacement. It is not known, in how many existing boilers could be replaced with a heat pump (which would be considered a “minor renovation”), but anecdotal evidence shows that this is also successfully happening in many projects in Europe. An “installer rule of thumb” states that a building can be efficiently be heated with a heat pump, if on some of the coldest days in the year, the user is comfortable while the radiators can be touched by hand without burning the skin. In technical terms this means a feed-in temperature to the system of around 55°C.

Assuming around half of the direct heater replacements to be possibly executed with heat pumps results in an additional potential of 2,1 million units. Figure 4 gives an overview of the last 5 years of sales development and an outlook until 2021.

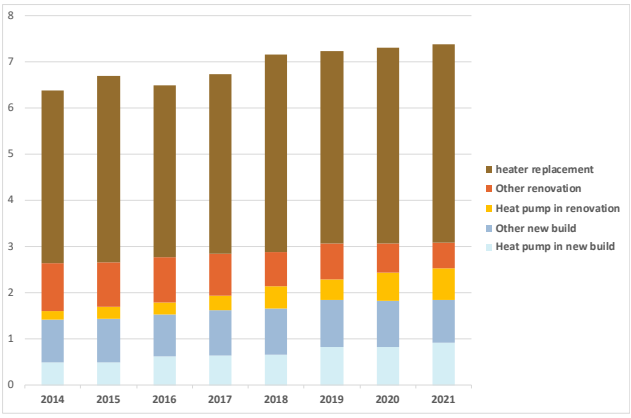

Fig. 4. The split of heat pumps in the European Heater Market (in million units).

However, these numbers are expected to increase as a result of the proposed legislation, as

- more renovated buildings create possibilities for heat pumps and
- technology development makes more heat pumps capable of efficiently providing also temperatures above 65°C.

5. Potential of heat pumps in a decarbonised European heating and cooling market

The impact assessment to the Energy performance of buildings directive estimates a necessary multiplication of today's renovation rate to min. 3% in order to significantly decarbonise the building stock. The in-depth analysis of the data on which the European Commission's long-term strategy is based expects a reduction of buildings energy demand of 48% by 2030 compared to 2015 and based on current policies. The assessment further expects a share of electrical appliances (mainly heat pumps) of 28%. [31, p. 94]

The two scenarios compatible with a 1,5°C mean temperature increase target foresee high shares of electrification in both residential and non-residential buildings. Translating the electrification share into heat pumps would result in an increase of the currently installed heat pump stock by a factor of 5 for residential buildings and about 4 – 4,5 for non-residential buildings. Based on a useful life of 20 – 25 years, all heat pumps expected to be installed in 2050 still have to be build and consequently the necessary production numbers are somewhere between 50 – 60 million units, to be manufactured and installed in the next 30 years. As production would not only have to cover new installations, but also the replacement of older units, it would require an average annual production of more than 2 million units. Compared to today's sales numbers the market would at least have to double, to fulfil this expectation.

Scientific studies looking at feasible pathways to fully decarbonize Europe's energy system similarly conclude that a high share of efficiently electrified heating and cooling is necessary. A technology specific assessment by Lappeenranta university and the energy watch group estimates the share of heat pumps in providing heat to be 44% of final energy demand. Applying this figure to today's building stock would result in 51 million units, very close to the in-depth assessment of the European Union.

Thus, the key question is: **How can the European Union and its Member States support a faster deployment?**

Over the past 10 years, the European Heat Pump market grew by 6,4% per year on average with the last four years seeing a growth of 12%. At the end of 2019, a total installed base for all heat pumps of 13 million will be reached, 12,4 million of which are expected to be heating units, the rest are hot water heat pumps. In the current very positive market environment experts expect growth to continue for the next 5 – 10 years and growth rates around 10% seem entirely feasible. This maybe pessimistic, considering that all measures of the

Clean energy for all Europeans are only currently translated into national law, thus their impact can only be expected to unleash starting in 2021.

However even if only the long-term average growth rate could be maintained, the annual heating heat pump market would arrive at approx. 2 million units around 2030, thus being able to deliver the estimated 50 – 60 million units by 2050.

An even faster growth could be achieved if not only the legal framework would be shaped more heat pump friendly, but if also the fundamental economics would be addressed and changed. The market growth over the previous years was achieved in many Member States of the European Union without significant subsidies and against an often-difficult economic framework. In particular the comparison of the cost of one unit of heat generated from fossil energy with one unit of heat provided by a heat pump shows that reveals an advantage of fossil-based heating. This disadvantage limits further heat pump deployment, as it adds an operations cost disadvantage to the still higher investment cost of heat pump technology.

The price ratio is directly affected by the taxation of the different energy carriers and thus the result of government action. The fact that in absolute terms electricity is taxed (much) higher than gas creates a disadvantage for (efficient) electric heating in the marketplace.

Against the backdrop of the need to reduce CO_2-emissions also from heating a economic disadvantage for heat pumps results from the fact that the negative environmental impacts of using fossil energy for heating are not internalised and thus are not reflected in the price of the energy carrier. Thus, heat pumps, whose main energy source is subject to the precautions of the European emission trading scheme (EU ETS), operate based on internal effects of their environmental impact, while fossil fuel boilers as the main competing technology are not subject to the same conditions. Instead, fossil heating is perceived as cheap while at the same time environmental pollution and health cost are born by society.

The heat pump industry is requesting a correction of both a) relative energy prices and b) cost of CO_2-emissions in order to be able to compete also economically with fossil heaters. It is expected that the European Green Deal, which is shortly to be presented by the European Commission, will address the need for an internalisation of external effects. Prices, taxation and subsidies must reflect the environmental impact of the respective energy carrier and in order to send the right behavioural signal to the end-user.

6. Conclusion

The outlook for heat pumps is positive for three reasons: a strong market foundation, a first legislative acceleration and an expected legislative booster.

1. The continued growth of heat pump technologies over the past decade has led to the technology representing nearly 10% Europe's heating equipment stock. This share was mainly achieved without (sometimes even despite of) government intervention. If the current growth only continued on a business as usual trajectory, heat pumps would be used in more than 1/3 of Europe's buildings by mid-century.

Fortunately, the currently implemented and the proposed legislative framework is recognizing heat pumping technologies more broadly across all sectors and functions and will thus have a re-enforcing effect on market growth, making heat pumps the dominant heating and cooling technology:

2. The clean energy for all package sets the right legislative framework for more energy efficiency and the deployment of renewable energy, leading to overall CO_2 emissions within the timeframe from 2020 to 2030. The unified reporting obligations will provide more detailed data enabling better modelling and more precise governance. The packages transposition to national law should **accelerate the development** of national heat pump markets by 2022, building on an already robust current growth path.
3. The long-term strategy has presented scenarios that make a decarbonised society by 2050 not only possible but also affordable. Its recognition of heat pumps as a robust contribution to a sustainable society will serve as a **booster to market development.** The upcoming European Green Deal is expected to also develop the necessary climate law. It is expected to include a re-assessment of the CO_2-emission reduction target, a discussion on how to apply a price on CO_2-emissions as well as additional legislation to increase ambition level in light of visible climate change.

Without doubt, the transition towards a decarbonised society is possible. In such a future, the typical answer to "what technology heats/cools your building?" or "which technology is used to run an industrial process or a district energy system" is answered simply by "a heat pump"!

Abstract

For the longest time, heat pump technology has been presented based on its technical merits. Good for the environment (renewable heat), energy efficient, low CO2 emissions and sometimes even cost savings. But are these really the keywords that have triggered a change in opinion? The presentation will explain a different approach as charted and deployed by the European Heat Pump Association. Aiming at a positive emotional perception of the technology while trying to achieve a high level of recognition, the association has shaped a communications campaign that re-coded the benefits of heat pump technology in colours: green for renewable energy, orange for energy efficiency, blue for GHG emission reduction, red for security of supply, yellow for smart grids and purple for employment. These were then produced as chocolate candies (m&m) and packed together with a mug that said "I love HP". The backside of the mug listed the term "heat pump" in the 24 official languages of the EU plus Japanese, Mandarin and Russian. A pack of candies and a mug were sent to each member of the relevant committees in the European Parliament and to the European Commission. The paper will explain the underlying reasoning and execution of this communication campaign over the last four years and aims at encouraging new approaches of heat pump lobbying.
.
Keywords: Public affairs; communication; emotional approach; heat pumps; energy transition

1. From facts to fiction: a new narrative for heat pump related communication

Over the past 20 years, heat pump technology has arrived in the marketplace in Europe. Positioning was not equally successful in the different member states. Obstacles that had to be overcome ranged and range from general understanding, terminology, connectivity of information to the knowledge level of the target groups to doubts and outrights rejection of technical details.

Table 1 Heat pump-myth levels to be overcome by communication

General	Conceptual	Technical
What is a heat pump?	Heat pumps are not using renewable energy. They are just an energy efficiency technology.	Which temperature levels can a heat pump provide?
How does a heat pump work?	Heat pumps are not increasing energy efficiency. Certainly not on a primary energy basis!	Can heat pumps efficiently be employed in the build environment?
Why is it called heat pump if it can also cool?	Heat pumps are only a marketing tool to push for higher electricity sales!	Can heat pumps provide the high temperature levels needed in industrial applications?
How can a heat pump work at temperatures below 0°C?	Heat pumps compete with district heating!	Heat pumps cannot provide the high temperatures and capacities needed in district heating.
Electricity is too valuable to be used for heating!	Can a heat pump really provide heating and cooling? Why is it called a heat pump then?	
Will large heat pump deployment not lead to black outs?		
Heat pumps are too expensive. They are not affordable, in particular for low-income households.		

Around the year 2000, heat pumps were a niche technology in the European heating market hardly recognized by policy makers. Even though a 1997 white paper by the European Commission [1] considers contributions from biomass, hydro power, wind energy, solar thermal, photovoltaics, passive solar and geothermal and geothermal heat pumps to be relevant, the authors expected a number of 180 000 units to be installed in the EU-15 countries by 2010. Using energy from ambient air and water resources was not considered renewable. The reality surpassed the study with 800 000 heat pump units installed in 2010, 116 000 of which using geothermal energy.[2]

In this first phase of communication the main focus was on

a. explaining the working principle of the technology
b. application examples – which were mainly showcasing the use of heat pumps in new buildings
c. highlighting the fact that heat pumps could also use air, water and (later) waste-water.
d. Highlighting that heat pumps provide heating and cooling at the same time.

The main target group where the European Commission, members of the European Parliament and representatives of the Council. Convincing them was not easy, as scepticism against the technology was widespread, often based on national perceptions and the respective political orientation. Members of the Green party, particularly those from Germany, rejected heat pumps as a tool to increase electrification of heat and thus to facilitate new nuclear power generation facilities.

A second line of argument was focussing on the difference between primary and final energy. While the energy efficiency and energy services directive [3] suggested a conversion factor of 2,5 (an average efficiency of thermal powerplants of 40%), this value was often questioned as being too low. In combination with the doubt of the true efficiency of heat pumps the technology was deemed less efficient than the direct combustion of fossil energy. Rejection of heat pump technology was based on the argument, that the technology would have to be added to the existing load of the grid and would thus result in switching additional generation capacity, usually dirty, hard and brown coal (pollution from marginal emissions).

A third argument applied on the technical feasibility of heat pumps in providing heat and hot water to the build environment. It was argued, that the supply temperatures of heat pumps were not sufficient to heat buildings efficiently and thus a heat pump was just a direct electric heater in disguise. This argument was originally applied to all heat pumps. Later it was modified by accepting geothermal heat pumps in new buildings and it took until 2009 for policy makers to agree to and decide that all heat pumps are in principle

feasible to heat buildings. Even today, after more than 10 years of fast track technology development and despite many successful examples it is still questioned whether heat pump technology can be deployed in the existing building stock or in industrial processes.

As a latest area of scepticism, it is now argued, that the electric grid is not fit to accommodate a much larger share of heat pumps and their deployment will endanger black-outs.

From 2007 to 2009 communication efforts were entirely based on facts focusing on a change of perspective with regards to these arguments. It was continuously argued that the heat pump technology worked, often using the example of developed markets like Sweden, Norway and Switzerland and in which not only air was successfully used as energy source, but also these markets had a significant share of heat pump deployment in renovation and in multi-family buildings.

Eventually the so-called Renewables Directive [4] acknowledged aerothermal, hydrothermal and geothermal energy in its definitions (article 2), to be used by heat pump technology. Besides officially stating that heat pump technology uses renewable energy sources, it also set down the need for educated installers and prescribed a calculation method for renewable energy generation by heat pumps. The Directive was a huge leap forward, as it established a legal basis and a reference point for policy makers and administrators.

In the following years, communication efforts focussed on the technical details of

- The energy performance of buildings [5],
- Improving energy efficiency of the whole energy system [6]
- Implementing measures of the Ecodesign Directive [7] and the energy label [8] for boilers
- The regulation on the use of fluorinated gases. [9]

The underlying discussions where mainly led by experts and where often backed by scientific justification of the different claims and by studies elaborating on the impact of each measure on the market. From an industry perspective a typical communication would start by highlighting the benefit of the technology towards the aims followed by the different pieces of legislation and the targets put forward.

EHPA established such fact-based communication by connecting claims to its statistics and enhancing sales numbers by calculating the renewables contribution of all heat pumps, the energy savings of their deployment and the related CO_2-reduction.

After the implementation of the Ecodesign requirements on boilers and the energy label the association realised that the communication needed to change – in order to achieve a more widespread impact, decision makers would need to consider heat pump technology as a solution that they needed to recognize in order to shape a favourable legislative framework.

2. A stakeholders heart is through its stomach

While the early years of heat pump related communication focused on the technical facts stressing its contribution potential towards Europe's climate and energy targets, they were not able to overcome a "feeling based" and sometimes deep-rooted scepticism against the technology. Stating the obvious seemed never to be good enough.

Thus, inside the association, new communications approaches were deemed necessary to create a fundamentally positive perception of the technology even with hesitating stakeholders. Likewise, it was clear that a shift was needed from fact based to more emotional communication. As the association did not want to risk its reputation as a reliable source of information, all considerations circled around "saying the same, just different" [9].

A multi-annual campaign was crafted based on this new approach. It used an emotional approach wrapping the factual benefits of heat pump technologies into a layer of emotion and executing this approach from different angles, using the effects of repetition and recognition to create anchor points for positive acknowledgement.

As the campaign consisted of different phases, a cut-off would have been possible between the different phases in case of failure.

Table 2 Facts presented and emotional layer used to change the perception of heat pump technology

Campaign phase	Fact layer	Emotional layer	Main target group
Chocolate and coffee	Renewables Energy efficiency CO_2 emission reduction	Tastiness of chocolate and coffee	Members of the European Parliament and the Commission active in the field of energy / heating.
It's cool to like heat pumps	Supply security Smart grids	Tastiness and comfort of ice-cream	Larger group of stakeholders in the energy transition
Plan(t) for the future	Local employment	Planning for a nice, flowery garden	Cities mayors and energy consultants

The different campaign phases addressed a range of stakeholders starting with members of the European Parliament (MEPs), continuing via a wider audience interested in EU sustainable energy issues (Sustainable Energy Week), concluding with a focus on EU mayors. Representatives of the EU Commission and the Council were also targeted in the action. Our goal was to make heat pumps appealing on the emotional level, to make them easy to like, and their advantages to be remembered.

This approach was executed via

- chocolate and coffee,
- ice cream, and
- flowers.

The main contribution of heat pumps to the EU climate and energy targets were colour coded and repeated in all campaign phases.

These six advantages of heat pump technologies were highlighted and promoted:

- GHG emission reduction (blue as in "blue skies")
- Renewable Energy (green)
- Energy Efficiency (orange)
- Energy Security (red)
- Creation of local jobs (purple)
- Smart grids (yellow)

Starting in 2014 every year a different communication angle was chosen. The message was transported via chocolate candies presented together with the "I love HP"-coffee mug (2014), via ice cream flavours (2015, 2017 and 2018) eventually via tulip bulbs (2017).

2.1. Chocolate candies and "I love HP"-mug

In 2014 we created the basic concept of the campaign and its first phase. The decision on the initial colour coding of heat pump technology benefits was taken. They were applied in white type to chocolate lentils (similar to the well-known M&M brand (Mars Inc)) and packed into a transparent box.

Fig. 1. Benefits of heat pumps presented via chocolate candies

How often have you asked people to discuss something "over a coffee/tea"? Connecting heat pump benefits to the prevailing habit of having a hot drink and some sweets resulted in the creation of a mug that stated "I love HP*" similar to the "I love NY" meme, adding an asterisk (*) explaining that "HP stands for heat pump". On the back of that mug we printed the word heat pump in several European languages to enable an easy recognition for members of the target group from different language background.

Fig. 2. "I love HP"-mug

As support and explanation, we asked our designers to design a postcard that pictured the six candy colours in a very reduced visual design explained each benefit in a few words. The motto of the postcard was "It's easy to like heat pumps". But the postcard not only explained the technologies, but also

a) asked recipients for testimonials on their own experience with heat pumps,
b) offered recipients to request more information,
c) invited them to contact us by email, to follow us on twitter or to participate in our annual Forum

Finally, we packaged 1) a box of candies, 2) the postcard and 3) the mug and sent it to all members of the ITRE and ENVI Committees of the European Parliament. In order to avoid any conflict of interest, the recipients were informed about the value of the package (less than 10 €).[10]

In a second communication round, we sent the postcard as PDF by mail to all MEPs and informed them, that those that would return the mail, would receive a mug and a box of candies in the mail as well.

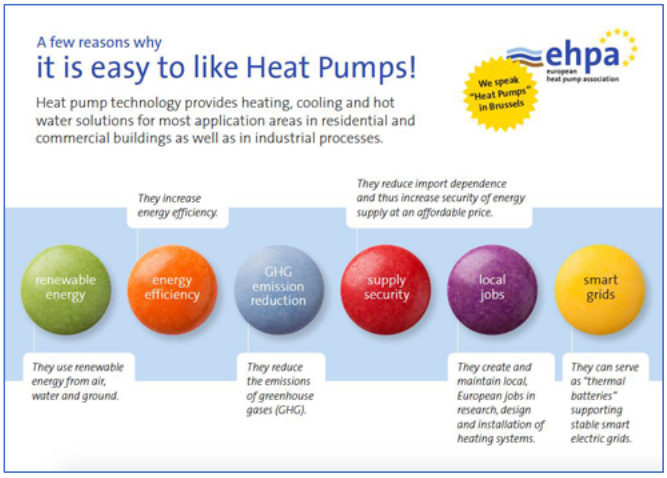

Fig. 3. “It’s easy to like heat pumps”-postcard

Evaluation:

This first campaign phase proved very successful. On the one hand we received very positive feedback in writing, on the other hand MEPs that we visited and talked to throughout the year remembered the mug and the chocolate. Many of them had the mug still on the tables in their offices. Even today can we point to this activity and people recognize us as “the heat pump guys that sent the nice mug and the smarties”.

2.2. Adding cooling: from energy stakeholders to EU policy makers at EUSEW

Based on the successful first phase, it was decided not only to continue to phase II, but also to change the target group. Looking for a different angle, we decided to stress the dual provision of heating and cooling via a heat pump and as it was summer and one of our events took place during the European Sustainable Energy Week (EUSEW) [11], **ice cream** was chosen as the transport medium of the message.

Looking at the first phase of the campaign, we decided to stick with the explanatory format and asked our designers to design a postcard that would picture six ice cream scoops in different colours, again showing each benefit in different colours.

We searched for and found an ice cream company that not only agreed to manufacture the ice cream for us, but also to come with a typical sales booth and to hand out the ice cream. Due to production limitations, we had to adjust the selected colours slightly:

- Vanilla = smart grids
- Pistachio = renewable energy
- Chocolate = GHG emissions
- Red fruit sorbet = energy security
- Lemon sorbet = energy efficiency
- Blueberry = local jobs

Fig. 4. Explanatory postcard: "It's tasty to like heat pumps"

Participants were then invited to use these titles when ordering an ice cream. This created a lot of laughter, when ie. the Director of the General Directorate for energy (DG ENER ordered) "one scoop of renewables and one scoop of smart grid".

Fig. 5. The ice cream booth at EUSEW 2017

In the second and third year, we slightly modified the text on the postcard. Cooling had entered the political agenda and we thought it to be a smart idea to enhance the focus of the campaign from "heating" to "cooling", continuously highlighting the fact that heat pumps provide heating and cooling at the same time.

Evaluation

This idea is still remembered in Brussels lobby circles. The impact was of such a nature, that the organizers of EUSEW asked us to repeat the activity in the years 2017, 2018 and 2019 as it was reported to them as a great success by participants and session organizers. From 2017 onwards, the booth was set up prominently in the lunch area of the Residence Palace (one of the two central event locations of EUSEW) and we handed out more than 600 scoops of ice-cream in each year, with even more people recognizing the activity.

2.3. Flower Campaign: Plan(t) now for the future!" – targeting EU Mayors

At the end of 2015 we started the preparation for the 3rd phase of the campaign. As we had identified cities as important actors of the energy transition, we did some brainstorming on what measure would resonate with city majors. We agreed, that a main characteristic of a city government is long term perspective, in particular for spatial planning and that this resonated well with planting. But how could we connect this idea to our colour scheme? We considered different plants and vegetables but either the execution was too complicated, too costly or the plant would not be available in the colours that we wanted. In fact, this proofed to be the most stringent restriction. And then we turned to tulips and came up with the idea to package 6 tulip bulbs in a nicely designed box and to send them to Mayors of EU capital cities as well as cities that have been using green solutions in transport, energy, etc.

While preparing the third phase of the campaign took longer than expected, we received very positive feedback for the ice cream idea and were invited back to the Sustainable Energy Week to offer the ice cream both to a wider audience in a more prominent location.

Fig. 6. The box with 6 tulip bulbs

In order to finalise the visuals, we asked our graphic designers to illustrate and to explain the campaign with a postcard using the headline "Plan(t) now for the future!". On the backside of the postcard we invited mayors to contact us if they required more information on what heat pumps could contribute to sustainable cities and to send us pictures of the tulips as soon as they bloomed.

Evaluation

In fall 2017, we sent batch of 50 boxes of tulips to the majors of the capitals of Europe and some additional cities that we had been pointed to as particularly active and ambitious in the attempt to green their cities. Not only did we receive 4 invitations to have meetings with the energy departments (London, Madrid, Riga, Budapest), but after 6 months we also received photos of blooming tulips. One package was given to Park Won Soon, Mayor of Seoul and then also president of ICLEI, who later sent his appreciation to the idea by mail.

The idea of the campaign was multiplied by some of our national heat pump associations who translated the postcard and sent the tulips to cities in their own country.

3. Impact of the campaign on the association and its lobbying strategy

The European Heat Pump Association considers the campaign a full success. It increased the recognition of heat pump technology and of the association with the designated stakeholders. It was perceived as innovative and fun, opening a communication channel to also talk about the details of technology.

While each phase could have stood by itself, the connection via the colour coding and their slight modification each year have resulted in very positive recognition and continuity reducing the effort needed to execute.

From a cost perspective, the investment in the campaign was comparatively small, costing less than 10 000 € over the first four years but the material is still used at various occasions helping us to illustrate the benefits of heat pumps in a creative and colourful way in the ongoing discussions with different stakeholders.

The overall result is even better than expected:

- Several Members of the European Parliament (MEPs) confirmed that they have been using the "I Love Heat Pump" mugs and we receive this feedback even today, after 5 years. Just recently, a member of the Commission stated, that the Mug had been "stolen" from him and he would appreciate a new one.
- The idea of the mug is so well received, that now a Chinese, German, Finnish and Slovak versions exist; done by the national heat pump associations respectively. For the next version on the EU level, we will add the term heat pump also in Kyrilic as well as Chinese and Japanese Kangxi. The ice cream campaign at EUSEW is now a classic and participants enjoy ice cream while getting to know the benefits of heat pumps, also understanding that heat pumps provide heating and cooling. For the next edition, an extension to two days is planned.
- The flower campaign has been picked up by 3 National Heat Pump Associations (Austrian, Finnish and Slovak) which approached their target groups with the same concept and motto. In addition, we managed to book 4 meetings with 4 mayors and their energy experts who wanted to discuss further about heat pump applications in cities.
- EHPA is recognized as an association that does not only do lobbying but does it with a fresh approach. This has resonated very well with existing members but has also attracted new members.
- The campaigns have helped the secretariat of the association to establish itself as a creative, forward thinking group of people using innovative yet very cost-efficient approaches to promote the interest of its members.

In 2019 the association was awarded the European associations award in gold in the category "Best associations communications campaign". [12]

The campaign has added a new dimension to heat pump lobbying. Using an emotion-based communication approach it combines technical advantages of the technology with human attributes creating a positive technology perception on a personal level. Attributes like "tasty" and "cozy" (see chocolate, coffee, flowers) were connected to heat pump technology making it easier to remember its benefits (see our selected motto in the postcard "it's easy to like heat pumps"). The importance of planning for the future in the context of creating a decarbonized society was stressed via the flower campaign.

The campaign proved that emotional-based communication does not contradict fact-based communication. Instead it strengthens the argument by using a human dimension to transmit complicated facts.

As a result, the association uses the new approach to deliver its messages to its target groups. We have moved to employing more advanced techniques to raise further awareness of the technology and it's multiple benefits.

Most recently we have deployed the "party heat pump", a device making the cooling and heating dimension of carnot-cycle technology directly tangible. Using the cold part to cool drinks and the hot part to heat sausages (vegetarian and meat based) allowed the discussion on the functioning principle in a comfortable and relaxed atmosphere.

Acknowledgements

The five years of work on this campaign were a real team effort. We would like to express many thanks to Pieter-Jan Cluyse, who helped to bring the original idea to life in a conference room in Stockholm, our design agency Ebmeyer and Ebmeyer from Munich (http://www.2-se.de), who brought our ideas to life and delivered

clear and direct communication tools, the team at EHPA under guidance of Eirini Litina who executed the campaigns with a meticulous eye for detail as well as the rest of the EHPA team and the different communications interns that helped us spread the word. Last, we would like to thank the board of the association for giving us the freedom to experiment with new formats and develop ideas like the ones presented here.

Abstract

In this study, the relationship between the enthalpy characteristics and the refrigeration characteristics of five typical refrigerated display cases in a grocery store were clarified by experiments. Based on the results, we devised a method to calculate the energy saving amount considering the interaction between the load of space conditioning and the load of refrigerated display case. Lower the store temperature by space-conditioning has the effect of reducing the total power consumption of refrigeration and space-conditioning, but it has been found that the store temperature needs to be lowered to 22 ℃ or below. Under the same store temperature and humidity conditions, the energy saving effect is greater at a low outside air temperature than at a high outside air temperature. It is important to control the space conditioning and shift the load of display cases to the load of space conditioning in early summer and early autumn.

Keywords: Grocery store, Space conditioning, Refrigerated display case, Energy saving

1. Introduction

From changes in Japan's final energy consumption, the overall increase rate from 1973 to 2013 was 1.2 times, but the increase in business divisions wahot.4 times, so that energy saving is required [1]. Manufacturers are actively developing energy-saving equipment for space-conditioning and lighting, which are typical energy-consuming equipment for business use. On the other hand, refrigeration equipment with a high energy consumption density is exposed to cost competition in the food store industry, so that energy-saving equipment is slow to spread. Therefore, it is important to save energy by devising operation and design.

From the advantage of easy to get products, many open display cases are installed in food stores. The open display case maintains the internal temperature with the air curtain, but from a part of the air curtain cold air in the refrigerator leaks from the display case and the surrounding air enters the display case. Leaked cold air stays in the lower part of the store, affects the air enthalpy in the store and worsens comfort. At the same time, air enthalpy entering display case affects the display case refrigeration load. For these reasons, the load of the open type display case interacts with the space conditioning load, making it difficult to consider energy saving.

There have been many reports on energy conservation in food stores [2]. Narumi created a prediction formula from the store's actual measurement data and calculated the energy saving effect when the display case type was changed or when the store's environmental temperature was changed [3]. Nakayama has reported the energy-saving effect of stores when the operation of space conditioning with high COP is increased by measuring food stores [4]. CFD analysis is effective to examine the effects of space conditioning and ventilation on store energy savings in detail [5], on the other hand the CFD analysis's cost is high, it is also important to develop the method that can be easily calculated.

In this report, the relationship between enthalpy characteristics and refrigeration characteristics of five typical refrigerated display cases in a grocery store was clarified through experiments. Based on the results, an

E-mail address: Fujita.Miwako@chuden.co.jp.

energy saving calculation method was devised that takes into account the interaction between the space conditioning load and the refrigeration load. Using the devised method, the summer energy calculation was performed on a store model with a total floor of 2127m^2.

2. Outline of space conditioning and refrigeration energy calculation

Since display case power consumption is greatly affected by environmental enthalpy, it is important to adjust the enthalpy in the store by space conditioning and ventilation. Combining with space-conditioning load calculation and display case load calculation (refrigeration load regression formula), we calculated annual space-conditioning and display case power consumption at food stores. Figure 1 shows the calculation flow.

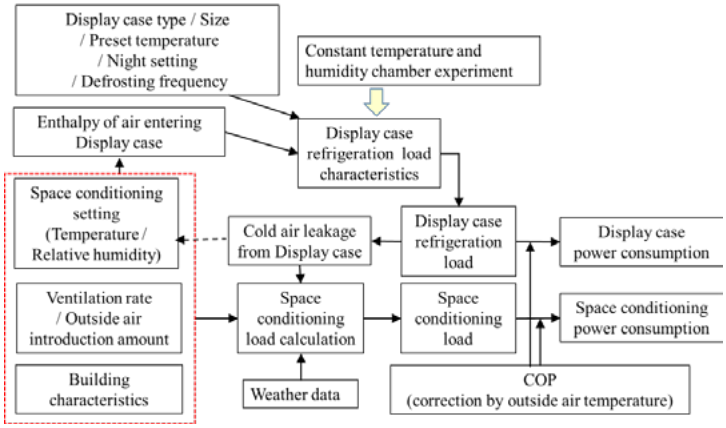

Fig.1. Calculation method of power consumption required for space conditioning and refrigeration

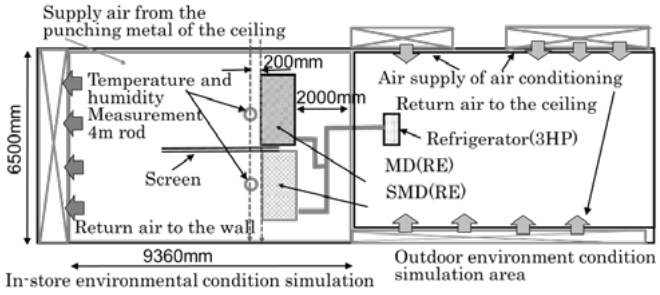
3. Energy consumption calculation for refrigeration

3.1. Energy consumption calculation for refrigeration

The display case refrigeration load characteristics were measured at constant temperature and humidity in the laboratory. There are two types of refrigerated temperature zones (multi-deck (MD (RE)) and semi-multi-deck (SMD (RE))) and three types of freezing temperature zones (multi-deck (MD (FR)) and flat tub (TUB (FR)) and glass door attachment (RI (FR))). Table 1 shows the outline of display case specifications, and Table 2 shows the specifications of refrigeration machines.

Table 1 Specification of the display cases refrigeration systems



TYPE※1	MD(RE)	SMD(RE)	MD(FR)	TUB(FR)	RI(FR)

Table 2 Specification of refrigerator (Outdoor Environment: Temperature: 32 ºC Relative Humidity: 40%)

Items	refrigeration machine (3 HP)	efrigeration machine (8 HP
Working refrigerant	R410a	R410a
Evaporating Temperature (ºC)	-10	-40
Freezing capacity (kW)	7.77	6.70
Power consumption (kW)	3.5	6.5

MD (RE) and SMD (RE) were combined with a refrigeration machine (3HP), MD (FR) was combined with a refrigeration machine (8HP), and TUB (FR) and RI (FR) were combined with a refrigeration machine (3HP). The experimental equipment layout is shown in Figure 2, and the measurement items are shown in Table 3. For display case in the refrigerated temperature zone, the refrigeration load (total heat) was obtained from the sensible heat of the circulating air and the amount of drain discharged. For the freezing temperature zone display case, the refrigeration load was determined from the refrigerant enthalpy difference before and after the evaporator and the refrigerant flow rate.

Table 3 Measurement item and implementation method

Items	Measuring Location and method
Power consumption	Each device (refrigerator, case blower fan, Case lighting, heater)
Environmental measurement	Measurement 4m rod (8 points in temperature + 6 points in temperature and humidity)
Temperature and humidity Wind speed	Air curtain air supply and inlet (2 to 4 points for each display case air supply and inlet)
Refrigerant flow rate	Refrigerant piping for each display case
Weight of drain water	Continuous measurement of drain water of each display case

The experimental photograph of the multi-deck type is shown in Figure 3. Figure 4 shows the relationship between the display case refrigeration load at the time of stability and the enthalpy of the air entering the display case, obtained from experiments. If the enthalpy that enters the display case calculated from the enthalpy of the store air is input to these relational expressions, the refrigeration load of the display case can be calculated.

In order to correspond to the calculation for 24 hours, in addition to the steady load characteristics, the defrost time changed by the in-store air enthalpy, the load characteristics after defrost, and the load characteristics when installing the night cover in display case were also obtained from the experiment.

3.2. Calculation of power consumption for display case (refrigerator)

Various parameters are required to calculate the power consumption from the refrigeration load. In this study, (1) COP change due to evaporation temperature determined from display case preset temperature, (2) COP outside air temperature correction, and (3) refrigeration capacity decrease correction due to pipe length were formulated from manufacturer catalog values. In addition, a correction was made to increase the evaporation temperature when the display case load is small.

In order to confirm the validity of the calculation, the calculated value of the refrigerator power consumption was compared with the actual measurement value using the refrigeration load calculation and the refrigerator power consumption calculation method described above. The enthalpy of the store air which is used for the calculation, are the measured values on August 10, 2017. Table 4 shows the calculation conditions, and Figure 5 shows the calculation results. It was almost reproduced the load drop and the power consumption at night due to defrost.

4. Energy consumption calculation for space conditioning

4.1. Outline of space conditioning load calculation

The space conditioning load is calculated by the building structure, ventilation, internal heat generation, indoor air temperature and humidity in the building as same. However, the space-conditioning of grocery stores is affected by the cold air leaking from the display case, so that the store temperature is not uniform. Although the horizontal temperature distribution does not become uniform depending on the arrangement of display case and the position of the entrance, we devised a calculation method that gives only the upper and lower temperature distribution with the horizontal temperature distribution being uniform.

First, the temperature and humidity near the ceiling were given, and the vertical temperature distribution was calculated. The building space conditioning load is calculated using the calculated vertical temperature distribution. Next, the intrusion enthalpy into the display case is calculated, and the refrigeration load is calculated using the enthalpy. The load obtained by subtracting the display case internal load (lighting and fan) from the refrigeration load becomes leakage cold, which reduces the building space conditioning load. The amount of heat obtained by subtracting the display case leakage cold air from the building space conditioning load is the net space conditioning load. A schematic diagram of the relationship between the vertical temperature distribution and the thermal load is shown in Figure 6. When the net space-conditioning load is negative, the temperature and humidity near the ceiling given first are lowered so that the net space-

conditioning load becomes zero. In this report, the food retail store shown in Table 5 was used as a model, and the load was calculated using a general-purpose load calculation program (BEST).

Table 5 Prerequisites for calculating space conditioning load

Items	Prerequisites	
Software	BEST program (Thermal load calculation function)	
Weather data	Extended AMEDAS (2010 edition) standard year Nagoya	
Sales floor area	2172m^2	
Floor height	5.6m（Ceiling height 4.0m）

	Inner wall glass	4.27 W/m^2・K
	Inner wall	3.31 W/m^2・K
	Ceiling	0.73 W/m^2・K
Ventilation	Ventilation frequency 1 time / hour Gap Wind 0.1 times / hour	

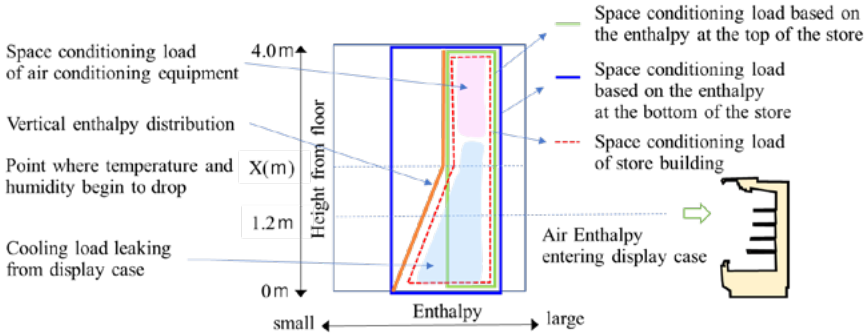

Fig. 6. Relationship between vertical temperature and humidity distribution, leakage heat from display case and space conditioning load

4.2. Determination method of vertical temperature and humidity distribution

The vertical temperature and humidity distribution were measured at the 24 points of the store in the November, where there was no space conditioning load. It is a grocery store with a sales floor area of 2172m^2 and a ceiling height of 4.0m. A floor plan view of the sore is shown in Figure 7. MD (RE) is installed on the wall of the store, and TUB (FR) and RI (FR) are installed. The average value of the measurement results is shown in Figure 8. Using the measurement results, it was assumed that the temperature and humidity would drop from FL + 2.0 m with a ceiling height of 4.0 m, and the space conditioning load calculation described above was performed. The building space conditioning load was 79 kW, and the cooling heat from display case was 70 kW, confirming that the two values were roughly balanced. In the subsequent calculations, it was assumed that temperature and humidity gradients occurred from FL + 2.0 m regardless of the season. The temperature / humidity gradient was calculated from the relationship between FL + 3.9m and FL + 1.2m obtained from annual measurement data.

4.3. Calculation method of space-conditioning power consumption

The calculation of power consumption required for space-conditioning was performed using a space-conditioning COP (outside air temperature correction only), assuming that no unprocessed load was generated and that all space-conditioning loads were processed by the space conditioner. It does not take into account the partial load characteristics resulting from the decrease in space conditioning load factor or the margin for space conditioning equipment. The rated COP is assumed to be 3.5 for cooling and 4.0 for heating.

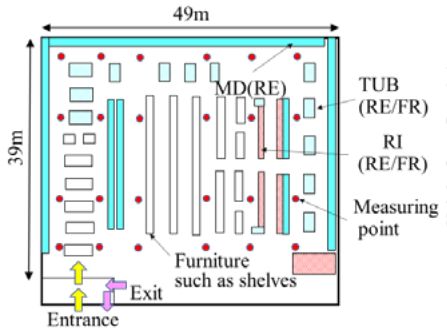

Fig. 7. Store floor plan and measurement points

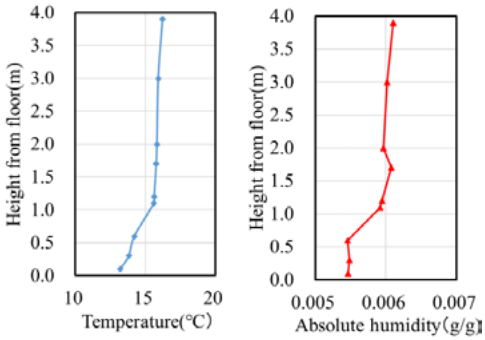

Fig. 8. Vertical distribution of average temperature and average absolute humidity

5. Calculation of power consumption for air conditioning and refrigeration energy

5.1. The validity evaluation of the calculation

The validity of the proposed energy calculation method was evaluated. For space conditioning and refrigeration energy, the results calculated using the standard weather data model (August 4) were compared with the measured data (August 10, 2017). As shown in Figures 9 and 10, the values and changes of space conditioning and refrigeration power consumption are well reproduced. Using this method, the energy saving effect by changing the space conditioning operation in summer was calculated.

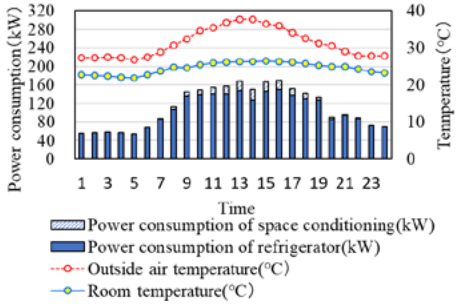

Fig. 9. Actual measurement (August 10, 2017)

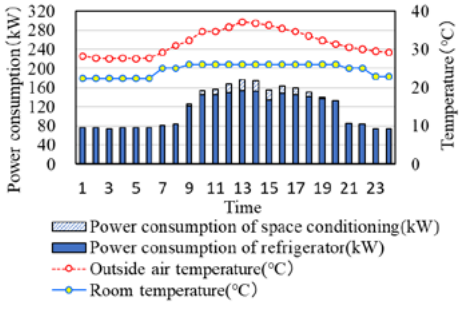

Fig. 10. Calculation (meteorological data August 4 Nagoya, Japan)

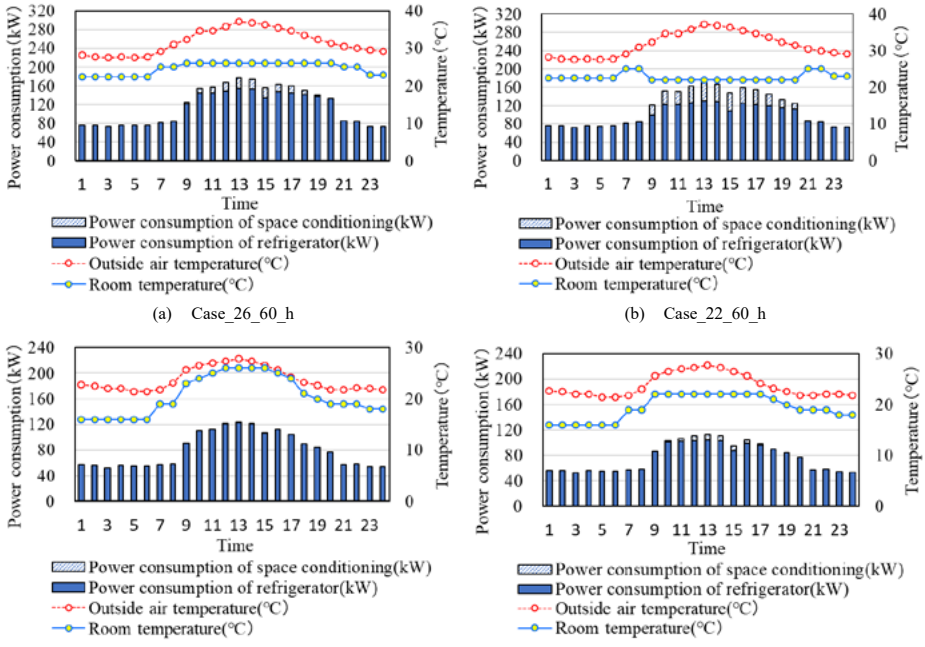
5.2. Calculation model and calculation cases

The space conditioning load calculation conditions are shown in Table 5 described above. Table 6 shows the display case conditions in the store. As shown in Table 7, there were 8 types of calculation cases. The weather model was a hot summer day (hot day: August 4) and a slightly cool day (cool day: September 25) in Nagoya, Japan. The space condition near each ceiling was set to 26 °C 60% to 20 °C 60%.

Table 6 Store display case conditions



Items	Conditions
MD(RE)	3～9℃ setting:108m / -3～0℃ setting:50m
TUB(FR)	-3～0℃ setting:11m / -20℃ setting:14m
TUB(RE)	7℃ setting:43m
RI(FR)	-20℃ setting:33m
Night setting	Setting to cover at night / Increase set temperature by 4 ° C
Defrosting times	Refrigerated display case: 4 times / day Freezing zone display case: 2 times / day

5.3. Calculation results

Figure 11 shows the time changes for case_26_60 and case_22_60. Even on a hot day in summer, at 26 ° C near the ceiling, the display case leakage cold and the building space conditioning load balance, and there is almost no true space conditioning load. Under any conditions, increasing the space conditioning load decreases the total power consumption of refrigeration and space conditioning. The shape of the energy consumption curve, which is the sum of refrigeration and space conditioning, shows almost no change in any condition, indicating that the display case load has moved to the space conditioning. Japan's electricity charges are greatly affected by the annual peak power. For this reason, it is important to shift the display case load to the space conditioning load to suppress the peak of power consumption. Moreover, if the load shared by space conditioning increases, operation control for peak suppression can be performed by space conditioning instead of display case. This increases the ease of control.

Table 7 Calculation case

Case name	Temperature and humidity near the ceiling	Weather conditions (Extended AMEDAS)
Case_26_60_h	26℃ 60%	(2010 edition) standard year Nagoya August 4, 2006 Lowest Temperature : 27.6℃ Highest temperature : 37.2℃

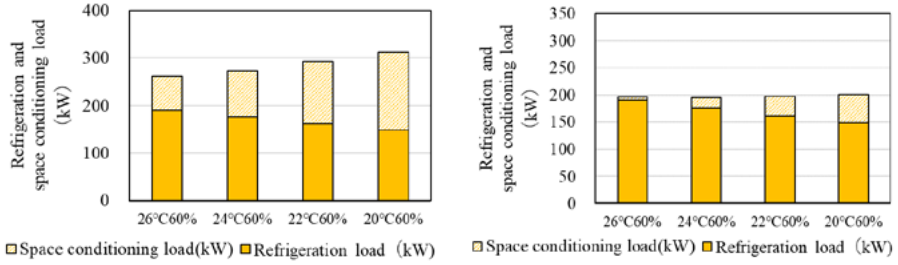
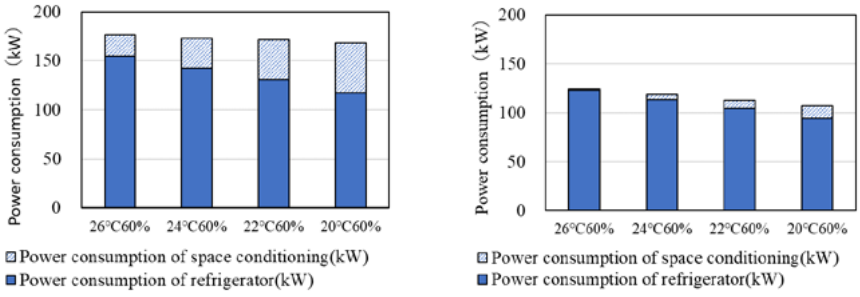
Case_26_60_c	26℃ 60%	(2010 edition) standard year Nagoya September 25, 2006 Lowest Temperature : 21.4℃ Highest temperature : 27.8℃
Case_24_60_c	24℃ 60%	
Case_22_60_c	22℃ 60%	
Case_20_60_c	20℃ 60%	



(a) Case_26_60_h (b) Case_22_60_h

(c) Case_26_60_c (d) Case_22_60_c

Fig. 11. 24-hour transition of power consumption for space conditioning and refrigeration



Take the time of 13:00 in each calculation case and compare in detail (Figures 12 and 13). As the temperature near the ceiling decreases, the rate at which the display case load shifts to the space conditioning load increases, and the energy consumption is suppressed by the difference between the display case and the

COP of the space conditioning. Energy savings due to the shift to display case load space conditioning are smaller in hot day where the temperature is high than in cool day where the temperature is low. The reason is that the COP of the space conditioner is more susceptible to the outside air temperature than the COP of the refrigerator, and the space conditioning load for controlling the store temperature and humidity is increased. Compare the amount of power saved each day in each case based on case_26_60 (Figure 14). Compared to hot day, the total power consumption of space conditioning and refrigeration in cool day decreases as the outside air temperature decreases, but the amount of energy saving increases compared to hot day. In grocery stores, the thermal environment has deteriorated due to cold air leakage from display case, so it is difficult to reduce significantly the space conditioning temperature in the store when the outside air temperature is high. However, if the outside air temperature decreases, the amount of clothes increases, so it is easier to reduce the store temperature than in midsummer. In order to save energy in the summer, it is important to control the space conditioning and shift the display case load to the space conditioning load in early summer and early autumn.

Fig. 13. Relationship between temperature and humidity near the ceiling, refrigerated power consumption and space conditioning power consumption

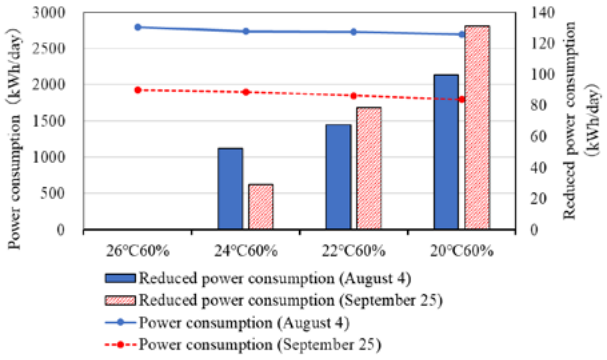

Fig. 14. Comparison of power saving of daily power consumption of refrigeration and space conditioning for each temperature and humidity near the ceiling

6. Conclusions

In this report, we proposed a method to give ingress air enthalpy to display case considering the vertical temperature and humidity distribution in the store. We changed the temperature and humidity in the store, and calculated the energy consumption in summer using a real store as a model. We investigated how changes in store temperature and humidity affect the relationship between space conditioning and display case load, and obtained the following knowledge. In the future, we proceed with consideration for the heating conditions.

1) If the temperature and humidity in the store are lowered by space conditioning, the total power consumption of refrigeration and space conditioning will be reduced.
2) It was found that the temperature inside the store decreased due to the cold leaked from the display case, and the space conditioner hardly operated under the condition of 26 °C near the ceiling. In order to save energy by operating space conditioning, it is necessary to greatly reduce the temperature to 22 °C or 20 °C.
3) Under the same store temperature and humidity conditions, the energy saving effect is greater at a low outside air temperature than at a high outside air temperature. Further, when the outside air temperature is low, it is easy to set the store temperature low, and energy saving can be expected. For this reason, it is important to use space conditioning well during the intermediate period such as early summer and early autumn.

b University of Geneva, Boulevard Carl-Vogt 66 – 1205 Genève, Switzerland

Abstract

The most commonly used performance indicator (PI) of heat pump (HP) systems is the COP. But is it a good PI? If so, does it have a minimum threshold? This article covers the potentials and constraints of different PIs for HP systems implemented in non-renovated residential buildings from an environmental, economic and social acceptability point of view, based on real case studies situated in Geneva, Switzerland. After describing the Geneva context and listing the most common PIs, we first compare a traditional gas boiler to an air to water HP system for space heating and domestic hot water of single-family building (SFB). We then follow by a similar comparison for multifamily buildings (MFB). For this particular building demand, a hybrid system is also analyzed (HP combined with gas for the peak loads) and specific PIs are included. Finally, the most pertinent PIs for air to water HP systems are identified and the minimum COP value of 2.5 is recommended to insure the reliability of the system in the 3 mentioned fields in the swiss context.

Keywords: COP; Air to water heat pump; performance indicators; residential buildings; hybrid systems.

1. Introduction

Renewable energy development is one of the main energy policy priorities nowadays. In the past, main efforts were put into renewable electricity, but the adoption of carbon emissions reduction targets as shifted the focus into renewable heat. In Switzerland, carbon emissions originate mainly from transport (32% of overall emissions), buildings (26%) and industry (22%). The country adopted the target of 20% carbon emissions reduction by 2020 compared to 1990 (40% in buildings, 15% in industry, 10% in transport,10% in other sectors) and it has currently announced a new ambitious climate policy target: 50% reduction of carbon emissions in 2030 compared to 1990 [1].

At a federal level, a variety of policy instruments (carbon tax and subsidy) were implemented to achieve carbon emissions reduction and promote renewable heat solutions. Nevertheless, they are now officially recognized as not sufficient to achieve the desired goals. Note that Switzerland's share of renewables in heat supply is about 16% (including 11% of wood-based systems, 5% of other renewables). Most of the heat (75%) is supplied by imported fossil fuels (40% heating oil, 33% natural gas, 2% coal). At the canton level, some actions were put into place. For example, in Geneva canton, the local public utility *Services Industriels de Genève (SIG)* has an energy efficiency program portfolio – *éco21* – that supports renewable heat uptake by final consumers from both single family and multifamily housing sectors [2].

The distinction between these two sectors (single-family buildings – SFB – and multifamily buildings – MFB) is important because in Switzerland, 55% of the existing building stock is composed of MFB, against 45% for SFB [3]. While MFB have the largest potential of CO_2 emissions reduction, SFB are easiest to tackle. For SFB, Geneva canton and *éco21* offer subsidies that cover about 20% of initial investment costs (including equipment and installation services). For MFB, this type of support is not suitable due to the peculiarities of Swiss housing legislation. Contrary to SFB, the majority of inhabitants of MFB are tenants. Tenants are responsible for payment of the energy bills, while it is the responsibility of the owners to invest in heating system. Investment costs cannot be transmitted to tenants via heating bills. Currently for existing buildings the

investment costs of the renewable heat systems such as heat pumps are from three to five times higher compared to the conventional solutions (fossil fuel-based). The owners therefore have no incentive to opt for renewables. [1].

Technically, the replacement of fossil heat by a renewable heat solution – more precisely a HP system – is also harder to tackle in MFB than in SFB. This is reflected in the market share of HPs in the residential sector that grew from nearly zero in the 1990s to about 50% today, but only 10% corresponds to MFB (CSD, 2017). For SFB, the HP market is mature, standard hydraulic schemes guaranteeing a good system performance are used, the whole process can be handled by one professional service. For MFB this process is more complex [1,4]:

- multiple households, with diluted decision power and related problems of governance;
- buildings often located in highly dense urban areas, with limited access to renewable heat sources other than air;
- if not threated carefully, noise emissions can easily become a barrier;
- higher shares of DHW in overall heat demand and related high temperature, which can affect the HP performance;
- absence of standard hydraulic schemes and system regulation guaranteeing a good system performance;
- multiple professional services (energy concept development; noise, static and building physics assessment; planning and implementation of heating, electricity and sanitary works; administrative procedures).

The aim of this work is to study performance indicators and their importance in the transition from fossil heat to renewable heat, more precisely Gas to HP heat. In order to do so, economic, environmental and social indicators are defined. Their values are then presented for different heat solutions (a gas boiler, HP system and HP+Gas system) and for both SFB and MFB. The indicators importance is discussed, solutions to improve economic, environmental and social barriers are presented. The positive and/or negative impact of these solutions on the remaining fields is also discussed. Finally minimum system performance value for the Swiss context is proposed, for both SFB and MFB.

Nomenclature

CHF	Swiss francs (0.91 €; 1.01 US$)
COP	Coefficient of performance
DHW	Domestic hot water
HP	Heat-pump
MFB	Multi-family building
PI	Performance indicator
SFB	Single family building
SIG	Industrial Services of Geneva

2. Methodology

We perform the analysis for three types of buildings: single-family, average and large multifamily. The reasoning for the respective distinction is based on two major motives:

- Contrary to the case of SFB, integration of HP heating systems in MFB is currently still more complicated than in SFB;
- The average-size MFBs do not have access to liberalized electricity market and therefore face relatively high electricity tariffs nowadays, compared to large MFBs.

2.1. Economic PI

To evaluate the performance of various heating solutions from economic perspective, we studied the available estimates of initial investment, operation and maintenance costs per unit of installed thermal capacity (CHF/kW, Fig. 1) [1]. These estimates are based on data from heating supply contracting projects provided by

Swiss ESCOs (24 air-to-water heat pumps), combined with heating modeling tools developed by Services Industriels de Genève (SIG).[1] We adjusted the available estimates, based on the available field data.

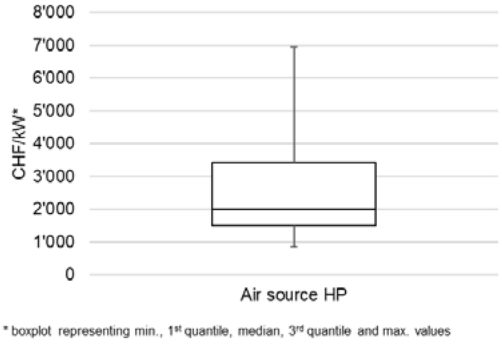

Fig. 1. Initial investment costs of heap pumps per unit of installed thermal capacity.

We calculate the levelized heating costs for an assumed lifetime of 20 years, based on the current average natural gas and electricity tariffs; and the average values of current initial investment costs, as well as average maintenance costs (Table 1). We performed the calculations with the carbon tax rate of 96 CHF/ tCO_2, and the current subsidy level of 70 and 28 CHF/tCO_2 for SFB and MFB respectively. We assumed a natural gas boiler efficiency of 85%. An annual air to water HP system performance (here on called COP) of 2.5, 3 and 3.5 for SFB [5], 2, 2.5 and 3 for MFB (for sensitivity analysis purposes).

For the HP + Gas system, we assumed the HP system would cover 80% of the heat demand and Gas the remaining 20%.

Table 1 Assumptions used in calculations of levelized heating costs of natural gas and heat-pump solutions

Item	Single-family building		Average multifamily building		Large multifamily building	
	Natural gas	Air-Water HP	Natural gas	Air-Water HP	Natural gas	Air-Water HP
Heat demand [kWh/year]	26’400		226’667		500’000	
Heated surface [m^2]	198		1700		3750	
Initial investment [CHF/kW]	600	2200	600	2200	600	2200
Maintenance [CHF/kW/year]	55	25	27	27	28	28
Energy tariff incl. carbon tax [CHF/kWh]	0.090	0.212	0.080	0.205	0.075	0.160

2.2. Social PI

In Switzerland (62%), even more so in Geneva (84%), most inhabitants of residentials buildings are not owners but tenants [6]. These buildings are heated by a centralized heating system that then distributes both SH and DHW to the apartments. The owner is obliged to provide a functioning heating system, and the tenants pay charges that cover the costs of energy consumption, maintenance and CO_2 tax.

In this context: i) owners have no financial benefit when investing in a renewable solution (higher investment costs and no benefits from the reduction of energy consumption); ii) tenants have no interest in investing in a property that they don’t own, even though they could eventually benefit from a reduction of energy consumption and CO_2 tax.

[1] Swiss ESCO datasets and SIG modelling tools are not publicly available.

Given this paradigm, the solution studied in this work is to define the tenant charges as being equivalent to the fossil system's, with a maximum increase of 10% if the fossil system is replaced by a HP solution. This way, the tenant has at maximum a rise of 10% of its charges while the owner can pay back his investments.

2.3. Environmental PI

In the case of HP systems, induced CO_2 emissions are calculated on the basis of a recent study concerning the carbon content of the Swiss electricity consumption mix [7], which uses hourly available data concerning the production of the various European countries, per type of production, as well as hourly data on imports/exports between the countries.

In a follow-up paper, the same authors analyze the induced CO_2 emissions of HP systems, for covering the heat demand of a sample of 6 different multifamily buildings [8]. Therefore, the authors combine the hourly dynamic of: i) the electricity used by the HPs; ii) the CO_2 content of the Swiss electricity mix. As a result, they derive the hourly CO_2 content of the electricity used by HP systems. For air-source HPs, the annual average of this mix finally amounts to 150 g CO/kWh_{el} (lower CO_2 mix), or 303 g CO_2/kWh_{el} (upper CO_2 mix).

The discrepancy between latter 2 values arises from a specific controversy concerning the carbon content of electricity generation from blast furnace gas units in Germany, which represent only a small share of the generation capacity of the total market, but play an important role in compensating for capacity shortages at the European level in the winter period.

In the case of gas boilers, emissions are related to natural gas consumption, by way of a constant emission factor of 228 g CO_2/kWh_{th} given by the Swiss Coordination Conference of Building Services [9].

3. Results and Discussion

3.1. Economic

The costs of heating supply for the SFB are presented in Fig. 2. These values result from the hypothesis described in section 2.1 and are shown for the 2 studied technological solutions and 3 different system performances.

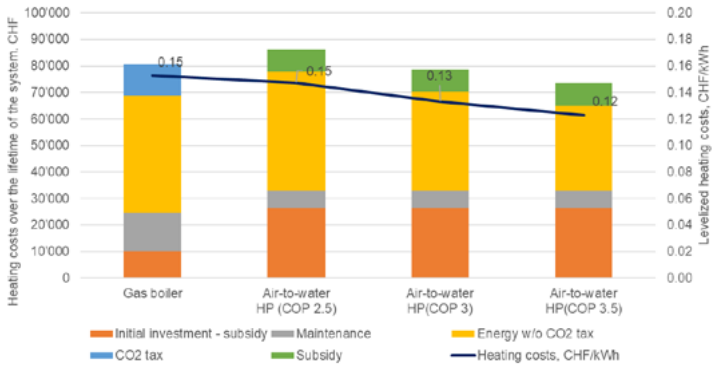

Fig. 2. Heating costs by technological solution and system performance for a single-family house (heat demand 25 MWh/year, 200 m^2 of heated surface), with CO_2 tax rate 96 CHF/t CO_2, w/o a subsidy; the assumed tariffs are 0.09 CHF/kWh for natural gas, 0.2118 CHF/kWh for electricity used for heat pumps.

The results are very positive for the air-to-water HP compared to gas boiler in the SFH. Of all solutions, Gas is the more expensive over the lifetime. It is probably explained by the well-known technology and standardized air-to-water HP systems available in the market for heating powers under 30 kW. There is no need for further engineering costs and material adaptation when installing these HP solutions.

We can consider that the subsidy granted in Geneva covers the risks of a hypothetical gap performance, which is not ideal if we aim for better performances.

From an economic point of view, this subsidy (about 20% of the initial investment) is no longer useful to cover the lifetime costs but still essential to reduce the initial investment.

The costs of heating supply for both average and large MFB are presented in Fig. 3 and Fig. 4 respectively. These values result from the hypothesis described in section 2.1 and are shown for the 3 studied technological solutions and 3 different system performances.

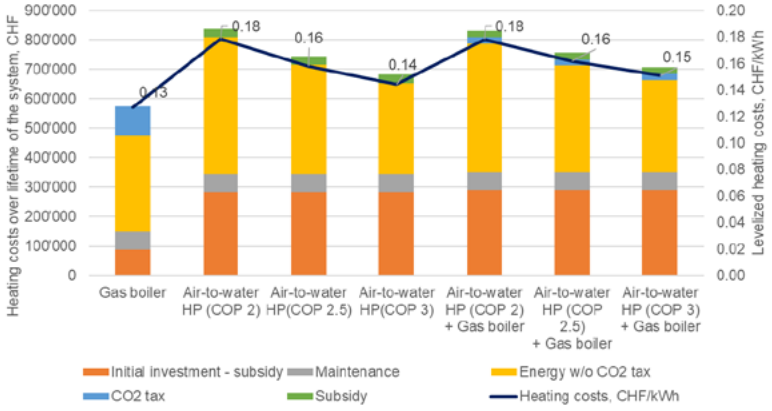

Fig. 3. Heating costs by technological solution and system performance for an average multifamily building (heat demand 225 MWh/year, 1700 m² of heated surface), with CO_2 tax rate 96 CHF/t CO_2, w/o a subsidy; the assumed tariffs are 0.08 CHF/kWh for natural gas, 0.205 CHF/kWh for electricity used for heat pumps.

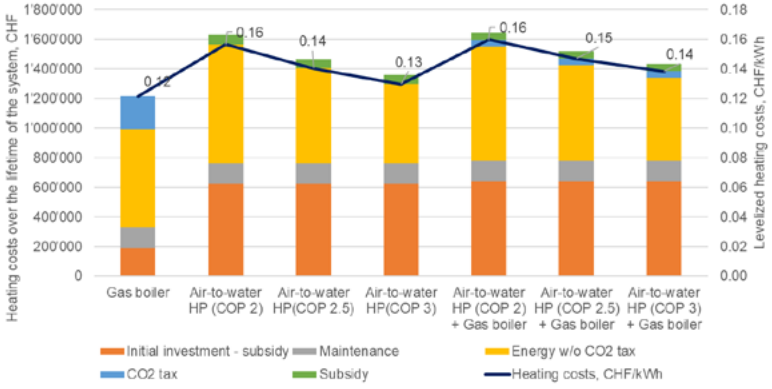

Fig. 4. Heating costs by technological solution and system performance for a large multifamily building (heat demand 500 MWh/year, 3750 m² of heated surface), with CO_2 tax rate 96 CHF/t CO_2, w/o a subsidy; the assumed tariffs are 0.075 CHF/kWh for natural gas, 0.16 CHF/kWh for electricity used for heat pumps.

For an average building, the heating costs over the lifetime of the gas system are 575 kCHF, of the HP system it's between 655 and 810 kCHF and of the HP+Gas system between 685 and 810 kCHF, depending on system performance. For a large MFB these values are: Gas 1'215; HP between 1'300 and 1'565; HP+Gas between 1'385 and 1'595 kCHF.

As seen by the figures, the big discrepancy between the Gas boiler and HP systems is mainly due to the current level of initial investment: HP heating solutions have a 3 times higher initial investment costs than the gas boiler solution. The gap between these solutions is shortened by the CO_2 tax, subsidy and increase of system performance: for example, in the average MFB, a HP system with a COP of 3 is only 80 kCH more expensive than a gas boiler solution, whereas a COP of 2 system would be 230 kCHF.

From all heating solutions, the gas boiler is the cheapest, both in terms of initial investment as well as levelized costs. This is true for both building sizes and despite of the system performance and CO_2 tax. With

this discrepancy, current CO_2 tax and subsidies are not enough to make HP heating solutions economically attractive.

When comparing both figures, large MFB have lower levelized costs than average MFB. This is explained by a liberalized market price to electricity consumers above 100 MWh/yr in Switzerland (0.16 CHF/kWh instead of 0.21 CHF/kWh). This electricity tariff for bigger consumers leads to a HP solution that is more attractive for large MFB than average MFB.

3.2. Social

The costs of heating supply for SFB are presented in Figure 5, including the tenants charge and owner investments. These values result from the hypothesis described in sections 2.1 and 2.2.

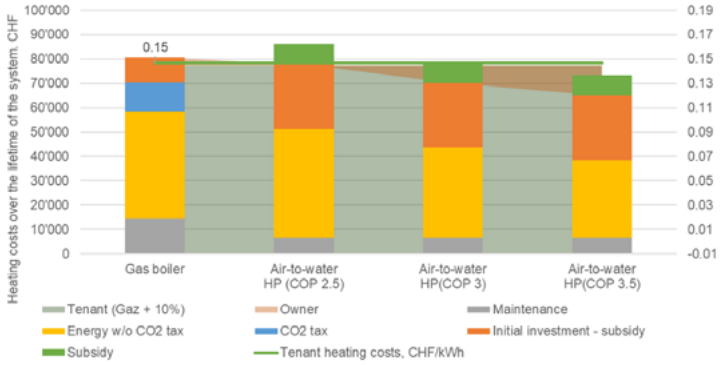

Fig. 5. Heating costs by technological solution and system performance for a single-family house (heat demand 25 MWh/year, 200 m^2 of heated surface), with CO_2 tax rate 96 CHF/t CO_2, w/o a subsidy; the assumed tenant charges are the equivalent to the gas boiler system (energy consumption, maintenance and CO_2 tax), with a maximum increase of 10%.

With the replacement of a gas system by a HP system, and tenant charges equal to the Gas solution +10%, the owner can, in all performances, pay back his investment and the HP system performance becomes crucial to the owner: the better the performance, the more he will be able to benefit from his initial investment.

One could argue that, with current subsidy and a CO_2 tax payed by the tenant, the 10% increase in tenant charges is not needed because the owner can still payback his investment with an average system performance.

Note that, in SFB if the tenant is planning to live in the same house in the very long term, he may assume some (or all) of the investment for a HP system. This unusual situation may occur when there is a good relationship between the owner and the tenant in place, for example when the house is owned by a family member.

The costs of heating supply for both an average and large multifamily building are presented in Fig. 6 and Fig. 7 respectively, including the tenants charge and owner investments. These values result from the hypothesis described in sections 2.1 and 2.2.

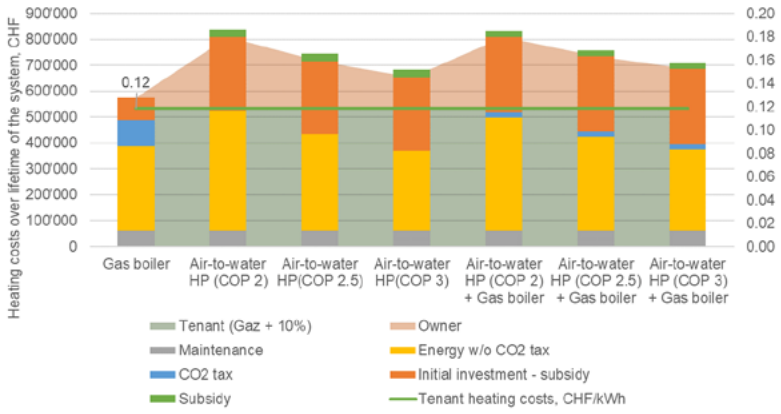

Fig. 6. Heating costs by technological solution and system performance for an average multifamily building (heat demand 225 MWh/year, 1700 m² of heated surface), with CO_2 tax rate 96 CHF/t CO_2, w/o a subsidy; the assumed tenant charges are the equivalent to the gas boiler system (energy consumption, maintenance and CO_2 tax), with a maximum increase of 10%.

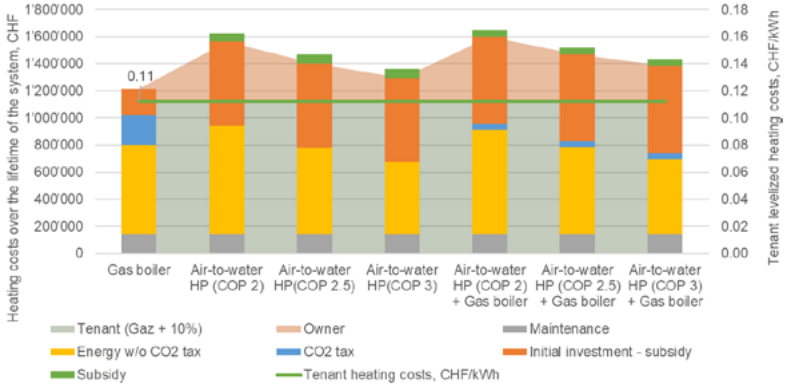

Fig. 7. Heating costs by technological solution and system performance for a large multifamily building (heat demand 500 MWh/year, 3750 m2 of heated surface), with CO2 tax rate 96 CHF/t CO2, w/o a subsidy; the assumed tenant charges are the equivalent to the gas boiler system (energy consumption, maintenance and CO_2 tax), with a maximum increase of 10%.

As seen in the figures, the tenant charges remain acceptable – 0.12 CHF/kWh for average and 0.11 CHF/kWh for large MFB. The 10% increase leading to a small increase of 0.01 CHF/kWh in the levelized costs of the Gas system.

With the replacement of a gas system by a HP system, and tenant charges equal to the Gas solution +10%, the owner can pay back part but not all of his initial investment. In this case, the HP system performance becomes crucial to the owner: the better the performance, the more he will be able to payback his initial investment.

All in all, to promote the replacement of a gas system by a HP system, the best system performance should be achieved and one or more of the following policy instruments could be used:

- increase in the CO2 tax, to increase the levelized heating costs of natural gas solution. In this case, it is important that the carbon tax is paid by the owner, and not the tenants who pay energy bills and have no voice in the choice of the heating systems. In addition, in the context of uncertain future energy prices, it is questionable whether building owners make their choice of a heating systems based on levelized costs only. In fact, operational costs including the carbon tax are paid on an annual basis. Investment costs are paid upfront from own savings or a loan and are recovered during

the years of heating system operation. Alternatively, a contracting mechanism should be introduced to resolve landlord-tenant dilemma and mitigate potential negative effects of long payback time on owner decisions.

- an increase of subsidies, to reduce the levelized costs of heat pump solutions. However, it is important to consider increased public expenditure or potential distributional effects related to increased financing of the energy programs, as well as the risks of increased investment costs due to induced market distortions.
- legal obligations put on building owners with regard to the maximum level of emissions or energy consumption (e.g., max. tCO2/m2/year, max. kWh/m2/year). This policy measure can put a significant burden on building owners, and should be carefully thought to avoid unnecessary market distortions. Namely, it is important not to subscribe a concrete technology into the legal obligations, to incentivize innovation and market competition on different levels (e.g., between technological solutions, contractors).

In practice, a combination of different policy instruments, constantly adapting according to the market developments, may be more efficient. The proposed policy measures require adjustments in current legislation.

3.3. Environmental

The CO_2 emissions of the studied solutions, for a SFB, are presented in Fig. 8. Note that this figure displays the upper CO_2 mix of 300g/kWh$_{el}$ described in section 2.3 - the least favorable scenario for HP systems. The CO_2 emissions for both upper and lower CO_2 mixes are shown in Table 2.

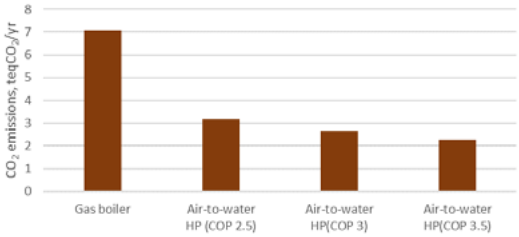

Fig. 8. CO_2 emissions (300 g CO_2/kWhel; 228 g CO_2/kWh$_{th}$) by technological solution and system performance for a single-family building.

Table 2 SFB CO2 emissions of all studied solutions for both upper (300g/kWhel) and lower (150g/kWhel) CO2 mixes in teqCO2/yr.

	upper CO_2 mix (300g/kWh$_{el}$)	**lower CO_2 mix (150g/kWh$_{el}$)**
	SFB, teqCO_2/yr	**SFB, teqCO_2/yr**
Gas boiler	7.1	7.1
Air-to-water HP (COP 2.5)	3.2	1.6
Air-to-water HP (COP 3)	2.6	1.3
Air-to-water HP (COP 3.5)	2.3	1.1

As seen by the figure, a HP system reduces CO_2 emissions by a factor of 3 in SFH, by a factor of 5 if we consider the lower CO_2 mix of 150g/kWh$_{el}$. In addition, more and more individual houses combine heat pumps with photovoltaic solar panels, which tends to lower CO2 emissions due to the grid electricity consumption.

The improvement in HP system performances can lead up to 30% savings. Note that, since the CO_2 emissions of these systems are already quite low, these savings are also low in absolute values (from 0.9 to 0.2 teqCO_2/yr.).

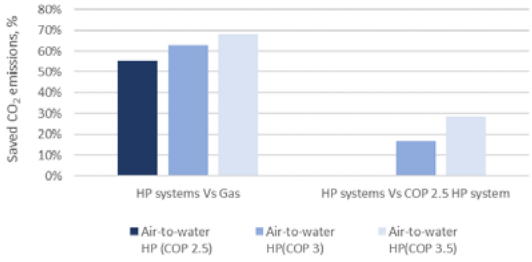

Fig. 9. Saved CO_2 emissions (300 g CO_2/kWh$_{el}$; 228 g CO_2/kWh$_{th}$) for a single-family building when comparing: i) HP solution to Gas solution; ii) HP system performance to lowest COP of 2.5.

The CO_2 emissions of the studied solutions, for both an average and large MFB, are presented in Fig. 10. Note that this figure displays the upper CO_2 mix of 300g/kWh$_{el}$ described in section 2.3 - the least favorable scenario for HP system. The CO_2 emissions for both upper and lower CO_2 mixes are shown in Table 3.

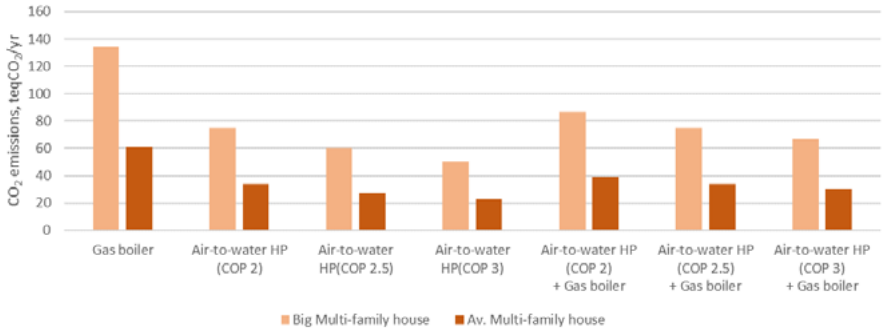

Fig. 10. CO_2 emissions (300 g CO_2/kWhel; 228 g CO_2/kWh$_{th}$) by technological solution and system performance for both average and large multifamily building.

Table 3 CO_2 emissions of both MFBs and all studied solutions, for both upper (300g/kWh$_{el}$) and lower (150g/kWh$_{el}$) CO_2 mixes.

	Upper CO_2 mix (300g/kWh$_{el}$)		**Lower CO_2 mix (150g/kWh$_{el}$)**	
	Large MFB [teqCO_2/yr.]	**Average MFB [teqCO_2/yr.]**	**Large MFB [teqCO_2/yr.]**	**Average MFB [teqCO_2/yr.]**
Gas boiler	134	61	134	61
Air-to-water HP (COP 2)	75	34	38	17
Air-to-water HP (COP 2.5)	60	27	30	14
Air-to-water HP (COP 3)	50	23	25	11
Air-to-water HP (COP 2) + Gas boiler	87	39	57	26
Air-to-water HP (COP 2.5) + Gas boiler	75	34	51	23
Air-to-water HP (COP 3) + Gas boiler	67	30	47	21

The solution with highest CO_2 emissions is the Gas system, followed by the HP + Gas system and lastly the HP system. The HP systems (both HP and HP+Gas) have around half of the CO_2 emissions of the gas system, around a quarter if we consider the lower CO_2 mix.

The CO_2 emissions of the HP+Gas system with COP of 3 are approximately the same as the HP system with a COP of 2.

Fig. 11 shows, in percentage and for the upper CO_2 mix of 300g/kWh_{el}, the saved CO_2 emissions when comparing: i) HP and HP+Gas solutions to Gas solution; ii) HP and HP+Gas performances to the lowest performance (COP of 2); iii) HP solution to HP+Gas solution. These values are valid for both average and large MFB.

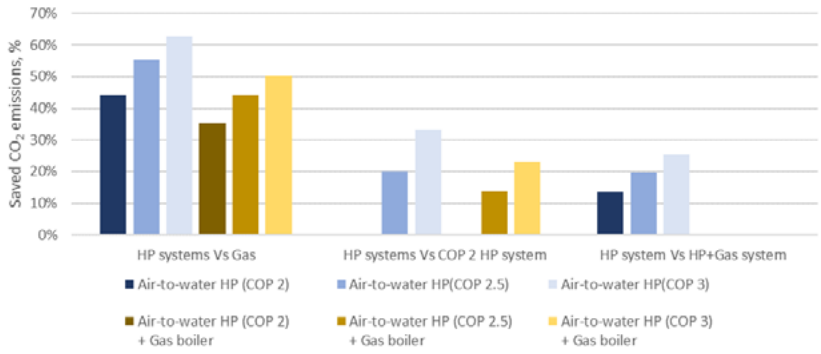

Fig. 11. Saved CO_2 emissions (300 g CO_2/kWhel; 228 g CO_2/kWh_{th}) for both average and large multifamily building when comparing: i) HP and HP+Gas solutions to Gas solution; ii) HP system performance to lowest COP of 2; iii) HP solution to HP+Gas solution.

As seen in the figure, when a Gas system is replaced by a HP+gas system around 45% of CO_2 emissions are saved, and if replaced by a HP system, the savings are around 55% (depending on the system performance). For the lower CO_2 mix, these values would be around 60% and 75 % respectively.

Within systems with HPs, the improvement in system performance can lead up to 33% savings in HP systems and up to 23% in HP+Gas systems. Note that, since the CO_2 emissions of these systems are already quite low, these savings are also low in absolute values (for a large MFB, 25 teqCO_2/yr. for a HP system, 20 teqCO_2/yr. for a HP+Gas system).

When comparing HP+Gas system to HP systems, the latter saves 14 to 25% of CO2 emissions (12 to 17 teqCO_2/yr. for a large MFB).

3.4. Overall

According to previous results, in SFB in Switzerland the replacement of gas boilers by HP systems is both environmentally, economically and socially reliable for the lowest studied system performance of 2.5. Economically, the subsidy (which helps with the high initial investment) and the absence of CO_2 tax helps the owner payback is investment in the lifetime of the equipment; the better the performance of the system, the more he will be able to save in energy costs. Environmentally, the replacement of gas by HP is positive but the increase from a COP of 2.5 to 3.5 is less impactful. Nevertheless, the benefits from better performances in peak electricity consumption should not be forgotten. Socially, with current subsidy and a CO_2 tax payed by the tenant, the 10% increase in tenant charges is not needed. Lastly, the aim of having better system performances and less CO_2 emissions is pursued, not for environmental or social reasons but because it is economically beneficial.

Regarding MFB in Switzerland, the replacement of gas boilers by HP systems is only economically and socially reliable for system performances above 2.5, particularly for average MFB. Economically, in order to payback the investment, the highest performance should be achieved and other tools should be applied (increase in subsidy and/or increase of CO_2 tax and/or obligation to have a share of renewable heat/limited CO_2 emissions). Socially, an increase of the CO_2 tax should be avoided because it would mean higher tenant charges (unless the CO_2 tax would be partially or entirely payed by the building owner), increase of subsidy and/or obligation to have a share of renewable heat and/or contracting solution could be implemented. Environmentally, similar to SFH, the replacement of gas by HP is positive but the increase from a COP of 2 to 3 is less impactful. Nevertheless, the benefits from better performances in peak electricity consumption should not be forgotten.

In other words, in MFB, system performance is critical for Social and Economic reliability but not for Environmental.

The difference between SFB and MFB results could be explained by the fact that available air-to-water HP on the market are optimized in terms of regulation for SFB. Due to lack of high-power HPs in the market, scaling up small HPs for MFB implies a more complex regulation to control all the low power HPs which in turn increases the risks of system underperformance. Standardized hydraulic schemes guaranteeing the HP system performance do not exist yet for MFB. Optimal regulation is not yet defined (production during day time – higher air temperatures – would lead to better performances and avoid running the system at nighttime when noise levels are limited).

Lastly, if policy measures are implemented (CO2 tax, subsidies, renewable heat share/limited CO2 emissions obligation), feedback mechanisms about those policies should be implemented in order to guarantee that those measures are achieving their goal.

4. Conclusion

This article covers a comparative analysis of the potentials and constraints of different performance indicators for HP systems implemented in non-renovated residential buildings from an environmental, economic and social acceptability point of view, for both single-family and multifamily buildings in, Switzerland.

In SFB, the replacement of gas boilers by HP systems is both environmentally, economically and socially reliable for the lowest studied system performance of 2.5.

Regarding MFB in Switzerland, the replacement of gas boilers by HP systems is only economically and socially reliable for system performances above 2.5, especially for average MFB. Economically, in order to payback the investment, the highest performance should be achieved and other tools should be applied (increase in subsidy and/or increase of CO_2 tax and/or obligation to have a share of renewable heat/limited CO_2 emissions). Socially, an increase of the CO_2 tax should be avoided because it would mean higher tenant charges (unless the CO_2 tax would be partially or entirely payed by the building owner), increase of subsidy and/or obligation to have a share of renewable heat and/or contracting solution could be implemented. Environmentally, similar to SFH, the replacement of gas by HP is positive but the increase from a COP of 2 to 3 is less impactful. Nevertheless, the benefits from better performances in peak electricity consumption should not be forgotten.

In conclusion, system performance is critical for Social and Economic reliability but not for Environmental and, for Switzerland, a system performance above 2.5 is highly recommended.

Heat pump and thermal energy storage integration in non-continuous processes – an application to the food industry

Edward J. Lucas[a], Jan A. Stampfli[a], Lorenz P. Rast[a], Raphael Agner[a], Beat Wellig[a*]

[a]Lucerne University of Applied Sciences and Arts, Technikumstrasse 21, 6004 Luzern, Switzerland

Abstract

Industrial sectors routinely represent a considerable share of a countries total energy demand. An increasing emphasis is on heat recovery across the sector and reducing greenhouse gases (GHG). Heat pump (HP) integration offers the potential to realize energy efficiency and GHG reduction, but is often challenging as a significant portion of energy demand is allocated to non-continuous processes. Consequently, heat recovery measures involving thermal energy storage integration are frequently the only option to recover heat indirectly. Additionally, careful consideration of available condensation and evaporation duties using the grand composite curve, and HP operational parameters such as evaporation and condensation temperatures, are required to perform HP integration within the system. A practical procedure for combined heat pump and thermal energy storage (HPTES) integration into non-continuous processes is presented. HPTES parameter selection is addressed using a graphical approach based on pinch analysis. The approach is demonstrated through application to a candy production plant, which produces in three daily shifts of similar duration and procedure. Up to 74.1% utility reduction can be achieved through HPTES integration, with internal rate of return of 11%.

Keywords: pinch analysis; heat pump; thermal energy storage; integration; COP curves; non-continuous processes

1. Introduction

Industrial sectors across the globe consume a considerable share of total energy demand (EU avg. 24.6%, 2017) [1], and represent a substantial share of total greenhouse gas (GHG) emissions. A large portion of this demand is in the form of thermal energy. Increasingly in industry, emphasis is placed on reducing total energy consumption in order to realize energy and cost savings, and on the consequential reduction of GHGs in accordance with stringent climate-change targets.

Process integration is an established method of accomplishing energy optimization, whereby pinch analysis (PA) is used to determine cost-optimal energy targets for process heat recovery and process hot and cold utility demands [2]. This systematic analysis differentiates processes into two thermodynamically separate sub-systems, separated in temperature by a pinch point. Typically, only heating is required above the pinch point and cooling below, allowing a direct calculation of the maximum potential for increasing process energy efficiency.

After exploiting the potential for energy efficiency through direct heat exchange, further savings may be available via indirect heat recovery using thermal energy storage (TES), and heat pump (HP) integration [3]. The latter requires processes still contain considerable amounts of low-grade excess heat and heating demands at suitable temperature levels. Appropriate methods are needed to assess whether HP integration in industrial processes is thermodynamically and economically feasible. Methodologies based on PA have been developed for HP integration using composite curves (CCs) [4], and later grand composite curves (GCCs) [5], which display the deficit heat above the pinch and heat surplus below the pinch [6][7]. While these methodologies were originally constrained to the analysis of continuous process only, later developments of the time slice model (TSM) [8] allowed non-continuous processes to be included in the analysis. Recently, approaches based

on the TSM for complete heat pump and thermal energy storage (HPTES) integration using graphical techniques and mathematical programming have been developed [9].

Multiple challenges face HP integration in industry which has prevented widespread adoption of the technology however [10]. Non-continuous processes present particular difficulties when selecting a heat pump with appropriate operational characteristics such as evaporation and condensation temperatures, as well as evaporator and condenser duties for optimal placement across the pinch point [11]. Furthermore, limited expertise and experience represent barriers to entry for the technology and directly affect adoption of the HP technology in industry because of the uncertainty and subsequent financial risks. This is despite such systems being shown to be economically viable, e.g. waste heat recovery from batch reactor systems [12], and a small but growing number of non-continuous process HP integration case studies [13]. Consequently, HP integration has often been relegated to the integration of continuous processes only, restricting the possible contributions of heat pump technology to the reduction in energy consumption across the industrial sector.

This paper aims to reduce these barriers to entry by providing experience and expertise in the form of a case study, helping to support the application of heat pump technology in industry. A procedure based on an optimization approach [9] has been employed to integrate a heat pump into a non-continuous process in the Swiss food and beverage industry.

2. Heat pump integration procedure

An overview of the procedure and a concise description is presented here. For brevity, only the most pertinent parts of the procedure are explained to allow readers to understand how the case study data are treated and the results are produced. Only the graphical method of the full hybrid approach has been used here for heat pump integration. A detailed description of the complete hybrid approach including mathematical optimization can be found in Stampfli et al. [9].

2.1. Overview of procedure and initial steps

The procedure for integrating a heat pump thermal energy storage (HPTES) system proceeds in 6 steps (Fig. 1). The first step considers the extraction of process data using process control systems, process schematics, and direct measurements where necessary, in order to characterize the process requirements (Step 1). Process scheduling, heating and cooling demands and the economic framework are all required. These

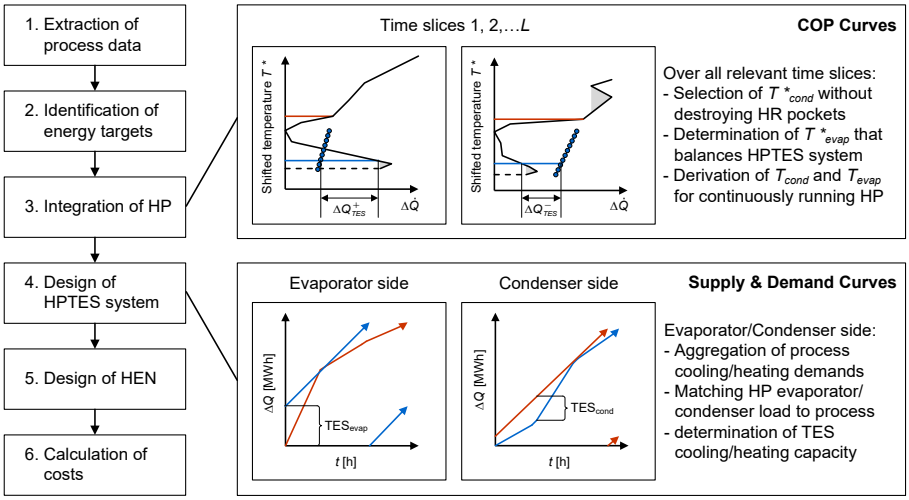

Fig. 1. Procedure for HPTES integration into non-continuous processes

factors form the basis for determination of the energy and cost targets for the process (Step 2) using pinch analysis. Process scheduling directly informs the identification of energy targets through use of the TSM [8].

The process is split into a series of time slices (TSs), according to where the process can be taken as continuous, i.e. periods of time where no streams are beginning or ending in operation, and the available process streams are continuous for the duration of the TS. A change in process heating or cooling requirements dictates the end of the current TS and the beginning of the next. A heat cascade is then calculated for each TS, allowing determination of TS energy targets as well as a pinch temperature during the pinch analysis. When an overall ΔT_{min} is selected, a GCC for each TS is produced. The GCC shows the amount of surplus heat below the pinch [6][7], and can be used for HP integration (Step 3). The required condenser and evaporator temperature and maximum duties for each TS are calculated using the GCC and COP curves, as well as the amount of thermal energy that must be covered by the storage system to complete the energy balance across all TSs. This information is used to size the smaller condenser and evaporator duties of the continuously running heat pump that will be integrated using supply and demand curves (Step 4). These curves also allow the calculation of the required storage capacities. Once sizing is completed, a heat exchanger network (HEN) for the system that functions across all TSs can be designed (Step 5). As a final step (Step 6), the costs of the HPTES system are estimated. This includes investment and yearly operational costs, and an estimation of the yearly energy and cost savings.

2.2. Heat pump integration using COP curves

The GCCs are used to identify feasible and constant HP evaporation and condensation temperatures despite the varying operational demands of the process. Heat recovery loops (HRLs) incorporating thermal energy storage (TES) are used to cover these variations in the process heating and cooling demands. The storages are often, but not limited to, stratified tanks containing two layers of thermal storage media at near-constant temperature. As the HRL contain HEXs themselves, heat pump evaporation or condenser temperature is shifted from the process stream temperature by several instances of ΔT_{min} (Eq. 1).

$$\Delta T = \underbrace{\frac{1}{2}\Delta T_{min} + \frac{1}{2}\Delta T_{min}}_{\text{process stream} \leftrightarrow \text{HRL}} + \underbrace{\frac{1}{2}\Delta T_{min} + \frac{1}{4}\Delta T_{min}}_{\text{HRL} \leftrightarrow \text{HP}} = \frac{7}{4}\Delta T_{min} \tag{1}$$

Between the process streams and the HRL normal heat transfer coefficients are assumed, and therefore two standard temperature contributions of 1/2 ΔT_{min} are applied [6][7]. For feasible heat transfer between the HRL and the HP, given the high film heat transfer coefficients that occur during phase change of the refrigerant, the temperature contributions are reduced to 1/2 ΔT_{min} and 1/4 ΔT_{min}. The resulting temperature differences between process streams and HP is thus a total of 7/4 ΔT_{min}.

Evaporation and condensation temperatures T^*_{evap} and T^*_{cond} determined from the GCC are already shifted with respect to the process streams by 1/2 ΔT_{min}. The shift from these temperatures to the real temperatures of the evaporator T_{evap} and condenser T_{cond} are thus 5/4 ΔT_{min}:

$$T_{evap} = T^*_{evap} - \frac{5}{4}\Delta T_{min} \tag{2}$$

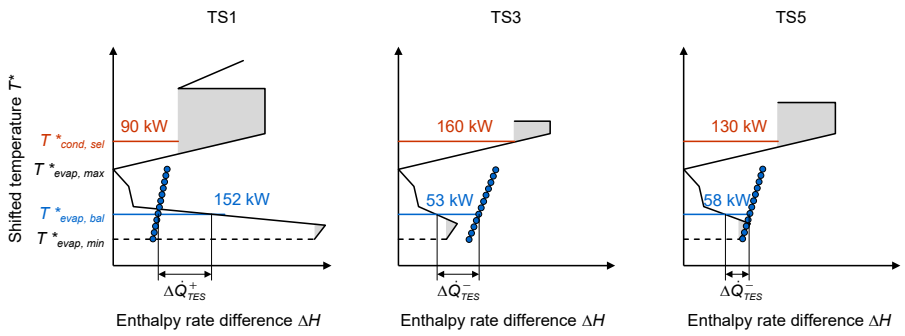

Fig. 2. GCCs of time slices (ΔT_{min} = 5 K) showing COP curves, taken from case study (transitional period)

$$T_{cond} = T^*_{cond} + \frac{5}{4}\Delta T_{min} \tag{3}$$

The heat pump operating evaporation temperature is found graphically using the COP curves (Fig. 2, blue dots). These curves describe the absorbed heat flow of the HP as a function of the evaporation temperatures and chosen condensation temperature. A condensation temperature $T^*_{cond,sel}$ is first selected that ensures the heat flow emitted by the HP is maximized (in order to maximize heat recovery) without destroying self-sufficient pockets, and that is as close to the pinch temperature as possible to reduce the temperature lift of the HP and maintain efficiency. An evaporation temperature is then searched between the bounds of $T^*_{evap,\max}$ and $T^*_{evap,min}$. An estimation of the amount of heat absorbed is made for each evaporation temperature and plotted on the GCC (blue dots), creating the COP curves. The calculation assumes the HP operates in a reduced-efficiency Carnot cycle with a second-law efficiency of 0.5 (Eq. 4). Usual values for second-law efficiency are around 0.55 [15]. Absorbed heat (evaporation duty) is calculated from the COP_{HP} (Eq. 5).

$$\mathrm{COP_{HP}} = \eta_{2nd\ law,HP}\,\mathrm{COP_{Carnot}}\ ;\quad \mathrm{COP_{Carnot}} = \frac{T_{cond}}{T_{cond} - T_{evap}} \tag{4}$$

$$\dot{Q}_{evap} = \dot{Q}_{cond}\,\frac{\mathrm{COP_{HP}} - 1}{\mathrm{COP_{HP}}} \tag{5}$$

Provided the COP curve and GCC intersect, the process cooling demand is exactly equal to the absorbed heat flow by the evaporator. For evaporation temperatures where the absorbed heat is less than the TS cooling demand at this temperature (Fig. 2, TS1), surplus from the process $\Delta\dot{Q}^{+}_{TES}$ must be stored in TES. For evaporation temperatures where absorbed heat exceeds the TS cooling demand at this temperature (Fig. 2, TS3&5), heat deficit $\Delta\dot{Q}^{-}_{TES}$ has to be provided by storage. The evaporation temperature which satisfies the energy balance of the storage across all time slices $T^*_{evap,bal}$ is located where the sum of all heat surpluses and deficits across all TSs ($l = 1 \ldots L$) is equal to zero, given by:

$$\sum_{l=1}^{L} \Delta Q^{+}_{TES,l}\left(T^*_{evap,bal}\right)\cdot\Delta t_l + \sum_{l=1}^{L} \Delta Q^{-}_{TES,l}\left(T^*_{evap,bal}\right)\cdot\Delta t_l = 0 \tag{6}$$

Where Δt_l represents the TS duration. Once these discontinuous heat flows to and from the TES are known, the TES and HP can be sized using supply & demand curves.

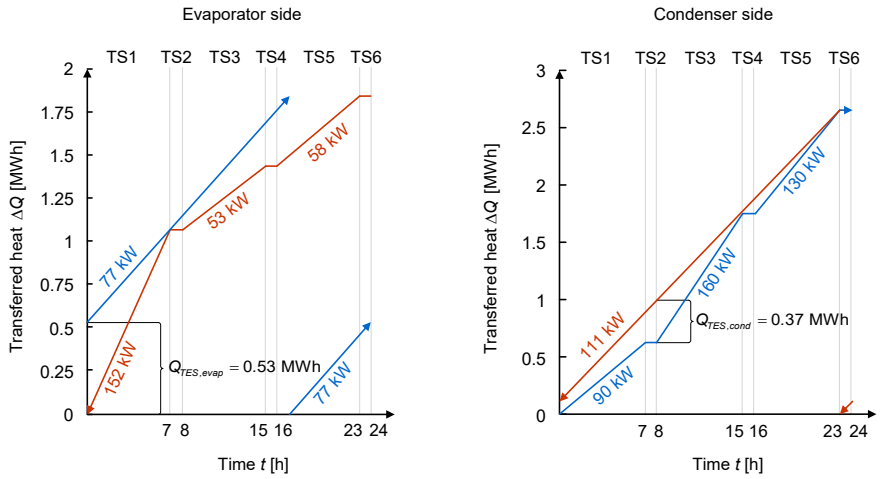

Fig. 3. Supply & demand curves for sizing of HPTES system; values taken from case study

2.3. HPTES sizing using supply & demand curves

Supply & demand curves [14] were developed for the sizing of utility systems of non-continuous processes and are used to size the heat pump for continuous operation, as well as size the necessary capacities of the TESs. For the HRL, two such plots exist, one for the evaporator (Fig. 3, left) and one for the condenser (Fig.3, right). Values are taken directly from the case study data. The diagrams plot the relative flows of heat provided by the HP and demanded by the process across all time slices, which allows calculation of the heat load supplied to or demanded from the TES in order to energetically balance the system.

For the cold HPTES evaporator side, the process TS cooling demands (152 kW, 53 kW, 58 kW) are drawn in red and the HP cooling supply (77 kW) in blue. The maximum discrepancy between the demanded cooling load and the supplied cooling load equals the required TES cooling capacity (0.53 MWh). For the hot HPTES condenser side, process TS heating demands (90 kW, 160 kW, 130 kW) are drawn in blue and the HP heating supply (111 kW) in red. Here, the maximum discrepancy corresponds to the required TES heating capacity (0.37 MWh). It should be noted that during time slices 2, 4, and 6, while no heating or cooling demands are made by the process of the HPTES system, the HP is still in operation. This causes an increase in the heating capacity (hot side) and cooling capacity (cold side) available after these time slices, and hence an increase to the overall required storage capacities on either side of the system.

Without storage, the HP would have to be capable of meeting the process demands directly and would have to be sized according to the maximum demands from the process (evaporator side, 152 kW, condenser side, 160 kW). With TES, the heat pump can run continuously and hence provide the required heat load over a longer duration, reducing the required heat load of the HP.

2.4. Heat pump and storage calculations

Storage volume is calculated from the required mass inventories, which are found using the capacities given by the supply & demand curves (0.53 MWh, 0.36 MWh) and the specific heat capacity of the storage media. The inventories must meet the amount of mass needing be transferred during each TS to cover the heating and cooling demand of the streams. A brief summary of pertinent equations is given for the case of the cold HRL i.e. heat transfer to the storage from the hot process streams. For the hot HRL and condenser equations, see [9]. The required mass of storage media in the HRL to cover the heat transfer demands is given by:

$$m_{C,HRL} = \frac{Q_{TES,evap}}{c_{p,HRL}\left(T_{C,h} - T_{C,c}\right)} \tag{7}$$

Where, $c_{p,HRL}$ is the specific heat capacity of the media, $Q_{TES,evap}$ the required cooling capacity, and $T_{C,h}$ and $T_{C,c}$ the hot and cold temperature levels of the cold storage.

HP electrical power P_{el} can then be calculated by completing the energy balance between the emitted heat of the condenser $\dot{Q}_{cond}$, the absorbed heat of the evaporator $\dot{Q}_{evap}$, and the input power P_i, assuming a drive efficiency η_{drive} (Eq. 8). An assumption is made that when considering heat pumps of significant size, open type compressors are often used. For open type compressors, where frictional losses to heat are lost to the environment, drive efficiency is assumed to be around 0.9. For closed type compressors, assuming almost all electrical power going into the system is transferred to the refrigerant, this value can be taken as approximately unity ($\eta_{drive} \approx 1$).

$$\dot{Q}_{cond} = \dot{Q}_{evap} + P_i \approx \dot{Q}_{evap} + P_{el}\eta_{drive} \tag{8}$$

3. Case Study

3.1. Introduction

The case study chosen for analysis is based on a site that manufactures confectionary for the Swiss and European food and beverage markets. To demonstrate more clearly the procedure, the case study data have been simplified, focusing primarily on the parts of the production processes that have substantial heating and cooling demands. The seasonal dependency of certain process streams has been retained, splitting the analysis into three operating cases: Summer (S), Transition Period (TP), and Winter (W). Additionally, the scheduling of the daily production shifts has been modified. The main areas of consideration are:

- Bonbon (BB) Candy Production
- Soft Fruit Candy (SFC) Production
- Hard Fruit Candy (HFC) Production
- Utility Systems

The site produces three types of candy daily, in three consecutive shifts. Although the exact process requirements of each candy variety vary, their manufacture involves the common stages of syrup preparation, mixing, and boiling, as well as casting, drying, and final treatment of the candies. The heating and cooling requirements of these stages are provided for by the on-site utility systems, which consist of hot, warm and cool water circuits. The hot water circuit is heated using stream purchased from off-site, and provides heating to the candy production, the warm water circuit, as well as the domestic hot water and building air handling.

3.2. Process description and requirements

In order to proceed with the pinch analysis, the process requirements must be extracted. While the stream data have been adapted for this paper, they originate from stream measurements conducted directly on-site. Process diagrams, monitoring systems and online measurements were consulted to characterize the thermal energy demands of the process. The adapted process requirements are found in Table 1. Where stream identifiers (IDs) have been duplicated between streams, this reflects a sharing of the process equipment between seasons or shifts.

Table 1 Process requirements (AY All Year, S Summer, TP Transition Period, W Winter)

Process Stream	**Stream ID**	**Process period**	**Inlet T. (°C)**	**Outlet T. (°C)**	**CP (kW/K)**	**$\dot{Q}$ (kW)**	**α (W/m^{2}K)**
Exhaust Air	H2	AY	55	25	2.43	73	100
Drying Air	C3	S	20	64	2.27	100	50
	C3	TP	12	41	1.92	56	50
	C3	W	5	64	1.27	75	50
BB Vapor 1 bar(a)	H1	AY	99.7	99.6	1200	120	5000
BB Hot Water	C1	AY	95	110	6.0	90	1000
BB Warm Water	C2	S	50	70	20.0	400	1000
	C2	TP	50	70	10.5	210	1000
	C2	W	50	70	13.0	260	1000
BB Cooling Water	H4	S	35	25	28.0	280	1000
	H4	TP	35	25	8.0	80	1000
	H4	W	35	25	6.5	65	1000
BB Cooling	H3	AY	35	25	18.0	180	1000
SFC Vapor 0.5 bar(a)	H1	AY	81.4	81.3	500	50	5000
SFC Warm Water	C2	S	50	70	20.0	400	1000
	C2	TP	50	70	10.5	210	1000
	C2	W	50	70	13.0	260	1000
SFC Cooling Water	H4	S	35	25	17.5	175	1000
	H4	TP	35	25	5.0	50	1000
	H4	W	35	25	3.0	30	1000
HFC Vapor 0.75 bar(a)	H1	AY	91.8	91.7	800	80	5000
HFC Warm Water	C2	S	50	70	20.0	400	1000
	C2	TP	50	70	10.5	210	1000
	C2	W	50	70	13.0	260	1000
HFC Cooling Water	H4	S	35	25	21.0	210	1000
	H4	TP	35	25	6.0	60	1000
	H4	W	35	25	3.5	35	1000

During candy production of any variety, vapor is produced during the boiling and cooking of the gelatin mixtures and according to the temperatures of the cook, the produced vapors vary in pressure (0.5, 0.75, and 1.0 bar absolute). BB production demands the hottest boiling temperatures, and therefore produces the highest vapor pressures. During modelling, all vapor streams are handled as simplified phase changes, having a small temperature difference and a large heat capacity flowrate (CP). After cooking, the candies are formed using cornstarch casts. Before casting can commence the casts must be air-dried, which produces a stream of humid air (Table 1, "Exhaust air"). This humid air is cooled in order to dehumidify it. During dehumidification partial condensation occurs and causes the stream coefficient of heat transfer to increase, as reflected in the table (100 W/m^2K).

Drying air is also required for candy drying, which takes place immediately after casting. The candies are moved to a drying room where a mixture of fresh air and re-circulated room air is cooled and dehumidified via an adsorption process to maintain the room at a specific temperature and humidity. The fresh air used in this drying process must itself first be cooled and dehumidified, before being sent to the drying room. The candies are left in this room for up to 72 hours at a time, meaning this room is in use throughout the day. Dehumidification processes for building air handling also operate, however only during the summer period.
In the final hour of each shift, after the cooking and processing equipment are no longer required, CIP water is used to clean and purge the entire system before the next shift. This cleaning produces wastewater, which is currently used for regenerative heating of the CIP water in a newly constructed heat recovery system. Therefore, the CIP and wastewater were not considered during the integration analysis.

Throughout candy production, warm water and cooling water are both used to provide general heating and cooling, and their requirements vary between seasonal periods. In summer, the dehumidification process for building air is active, and significantly increases both heating and cooling demands compared to winter and the transitional period. In addition to this, warm water demands are higher in winter than the transitional period as a result of lower ambient temperatures. Depending on the variety of candy produced, the cooling water requirements also differ due to differences in the production methods. For BB production an additional hot water stream is used during an intensive cooking phase not required during SFC and HFC production.

3.3. Process scheduling

Process scheduling is displayed as a Gantt chart (Fig. 4), which shows the daily production shifts of the plant. Candy production takes place in three shifts, each approximately eight hours in length. This includes an hour for cleaning after production equipment is out of use. The streams associated with heating and cooling during production are assumed continuous over the shift duration, although this is a simplification. Many batches of candies are produced within their 8-hour shift. According to the TSM, the process is divided into six identified Time Slices (TS), although only time slices 1, 3 and 5 are used as the basis for the HP integration. Time slices 2, 4, and 6 were omitted during HP integration as once the wastewater streams were discounted, the exhaust air and drying air streams did not provide enough remaining heat integration for inclusion in the HPTES system according to the pinch analysis.

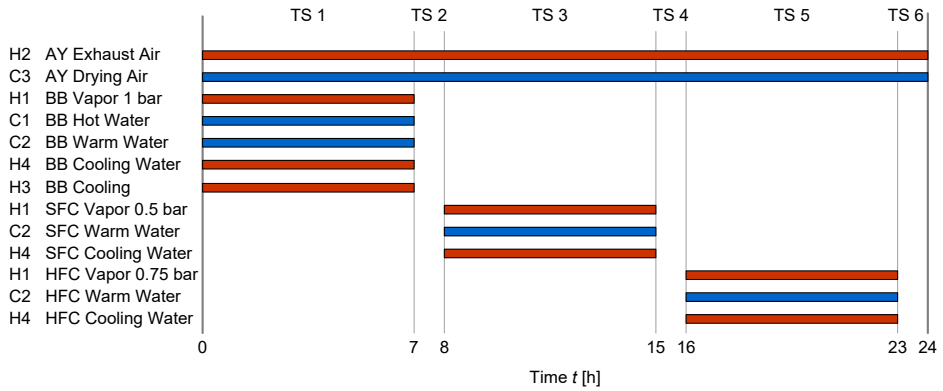

Fig. 4. Gantt-Chart of the daily operating schedule for all seasonal periods

The site is assumed to be in continuous operation 6,000 hours annually. This excludes process downtime such as weekends, in order to simplify the energy targeting analysis [16]. The process hours per individual variety of candy are 438 hours of production and 62 hours of cleaning during summer and winter. During the transitional period, these increase to 875 hours of production and 125 hours of cleaning per candy variety.

3.4. Results

Heat pump and storage sizing

The heat pump was initially sized using generated time slice GCCs of TS1, TS3, and TS5, displayed in section 2 (Fig. 2). A ΔT_{min} of 5 K was selected for all TSs, to avoid the possibility of causing untenably impractical design solutions which require extensive control systems in order to operate successfully. The shown GCCs correspond to the surplus and deficit heat available during the transitional period, which was chosen as a basis for sizing as it is the longest period of seasonal operation. A condensation temperature was selected ($T^*_{cond,sel}$ = 67.75°C, $T_{cond,sel}$ = 74.0°C) that allowed the majority of the required heating demands of all TSs (90 kW, 160 kW, 130 kW) to be satisfied, while remaining as close as possible to the pinch temperature (52.5°C). The COP curves for these time slices were then constructed to locate the initial evaporation temperature. For TS1 there is a relatively large amount of available heat below the pinch point (Fig. 2, TS1), as compared to the later time slices. The heating demands of the process increase from 90 kW in TS1 to 130 kW TS5, peaking at 160 kW during TS3 (Fig. 2, TS3&5). An evaporation temperature was searched (T^*_{evap} = 27.6°C, T_{evap} = 21.35°C) which satisfied the energy balance, resulting in needing TES cooling capacity to cover the cooling demand (152 kW) during TS1, and TES heating capacity to cover the demand for the later time slices (53 kW, 58 kW). These values were then used to construct the supply and demand curves, enabling final sizing of the heat pump condenser (Fig. 3, right, 110 kW) evaporator (Fig. 3, left, 77 kW) as well as the required capacities of the cold and hot side thermal storages (Fig.3, 0.53 MWh, 0.36 MWh). Expressed in cubic meters of water storage, the required storages are 91.3 m^3 (hot side) and 60.0 m^3 (cold side).

The same approach is used to size the storages and the heat pump for winter and summer operation. However the resulting storage capacities were found to be impractically large requiring in excess of 200 m^3 of storage, as high energy demands of summer dehumidification processes come online. This amount of storage is only required during summer, and would remain unused during the other seasonal periods which require significantly less energy due to the absence of taxing dehumidification processes. Therefore, it was decided that in order for the system to remain practically viable, the system was sized according to the period of longest duration (transitional period). This still allows significant savings to be realized during summer and winter although does not completely exploit the savings potential inherent therein. Sizing according to the transitional period only provides some additional economic benefit, as storage and heat pump investment costs are relatively reduced and as the system is designed around one continuous operational point, system complexity and control issues are minimized. As a consequence, the full capacity of the storage is in constant use which helps to reduce thermocline degradation.

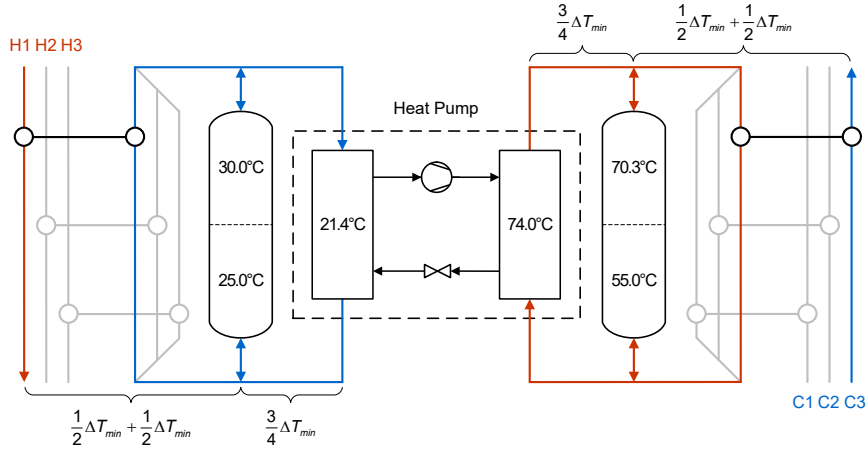

Fig. 5. Conceptual design of the HPTES superstructure

Design of HPTES system

The conceptual design of the HPTES system is given (Fig. 5) showing the heat pump evaporation and condenser temperatures and the temperatures of the storage layers. A summary of the HPTES specifications appear in Table 3.

Table 3 Heat pump and TES specifications

Pinch T. (°C)	Evaporation /Condenser temperature (°C)	Heat pump COP (-)	Condenser load (kW)	TES Hot storage layer temperatures (°C)	TES Cold storage layer temperatures (°C)	TES Hot storage Volume (m^3)	TES Cold storage Volume (m^3)
52.5	21.4/74.0	3.3	111	55.0/70.3	25.0/30.0	60.0	91.3

Design of HEN

The HEN design for the integration of the heat pump and TES system into the process is given (Fig. 6). Integrated streams appear on the right side of the diagram, including the streams HPTES Hot and Cold which represent the intermediate loops of the HPTES system. The design shows the overall HEN with maximum HEX areas, rather than any TS specific HEN where utilized HEX areas may be less than the maximum. HEX areas are displayed beneath their icons. The temperature ranges of the streams are displayed as target and supply temperatures, which begin and end at the pinch (T_p = 52.5°C). The drying air (C3) temperatures are given for each seasonal period (W/TP/S). Utility HEXs have been demarked using arrowed HEXs. The cold utility HEXs have been greyed out, as these are pre-existing heat exchangers which are not considered in the cost calculations. The exhaust air (H2) is a so-called "soft" stream which can provide heating during TSs where this heat can be utilized. If not, the heat is expelled directly to the environment (dotted grey cooler). When calculating energy and cost savings, the cold utility use of this stream is ignored.

Energy savings of the HPTES integration

The hot and cold utility savings after HPTES integration are tabulated (Table. 6). The utility demands of the process per seasonal period have been summed and are presented alongside the required electrical input to the HP. After HPTES integration, there is a large HU (65.3%) and CU (74.1%) utility reduction, equaling an overall utility reduction of 68.8%. This includes the savings from direct heat recovery measures.

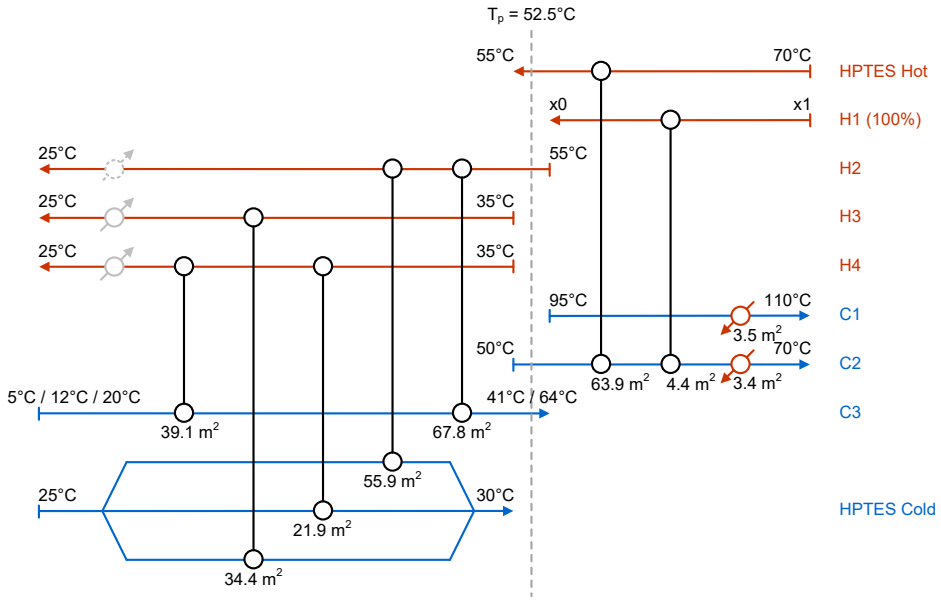

Fig. 6. Conceptual HEN design for candy production (maximum HEX areas)

Table 6 Seasonal energy savings

	Current state		**With HR and HPTES**		
Seasonal Period	Hot Utility (MWh)	Cold Utility (MWh)	Electrical input (MWh)	HU savings (MWh)	CU savings (MWh)
Summer	651.4	429.1	51.2	283.1	177.9
Transitional Period	651.0	494.5	102.4	568.8	486.2
Winter	436.3	205.1	51.2	284.3	171.9
Total	1,738.7	1,128.7	204.8	1,136.2	836.0

Financial analysis

The economics of the HPTES system have been analyzed using prices of hot utility (80 CHF/MWh), cold utility (25 CHF/MWh) and electricity (100 CHF/MWh) provided by the industrial partner. A detailing of the finances are found in Table 7. The system requires an investment of CHF 564,000 (including transport, installation, and VAT) which can be paid back within 6.2 years with annual savings of CHF 91,000. The electricity costs of the installation are CHF 21,000. The calculated return on investment for the HPTES and heat recovery system is approximately 11%.

Table 7 Payback and return on investment calculation of heat recovery measures and heat pump integration. Prices include VAT (8%).

Equipment		**Investment cost**
HEXs of heat recovery measures (incl. HRL)	CHF	202,000
Heat pump	CHF	147,000
TES	CHF	215,000
Total investment	**CHF**	**564,000**
Life time		15 years
Interest rate		3%
Annuity	**CHF**	**47,000**
Total savings of heat recovery measures per year	CHF/y	47,000
Total savings of HPTES system per year	CHF/y	44,000
Total savings	**CHF/y**	**91,000**
Operational costs of HPTES system per year	CHF/y	21,000
Total operational costs	CHF/y	**21,000**
Payback		6.2 years
Net income during payback period	CHF/y	23,000
Net income after payback period	CHF/y	70,000
Return on investment		11%

4. Conclusions

A practical procedure for heat pump integration into a non-continuous candy manufacturing process in Switzerland has been presented. The work allows for integration of a continuously running heat pump and thermal energy storage system that can meet daily variations in process demands. The combined heat pump (condenser 111 kW, evaporator 77 kW) and thermal energy storage system achieves an average utility reduction of 68.8% (65.3% cold utility, 74.1% hot utility) and can be paid back within a reasonable economic time frame of 6.2 years., with an internal rate of return of 11% per year. Whilst not a strictly optimal integration, the procedure has provided a practical, workable, and profitable solution for the case study, that is readily understood by the intended end users in industry. As future work it is recommended to apply a complete thermo-economic optimization, using the extended hybrid method which includes mathematical optimization of the HPTES parameters, in order to locate any potential designs which could further increase energy and cost savings without compromising practicability and controllability.

Abstract

The Coefficient of Performance (COP) of a heat pump and the Energy Efficiency Ratio (EER) of a chiller are strongly dependent on the internal temperature lift, which corresponds to the difference between the condensation and evaporation temperatures. In modern and efficient building heating and cooling systems, low temperature lifts can be achieved. Turbo compressors have high efficiencies at low pressure ratios during full and part-load operation, thus suiting low temperature lift building heating/cooling applications well. This paper presents the results of experimental investigations on a prototype low temperature lift heat pump/chiller with a heating capacity of 500 kW. The heat pump/chiller is equipped with four novel oil-free turbo compressors built with patented, self-acting gas bearings. High efficiency values during full and part-load operation were measured. Second-law efficiencies for building heating applications of up to 62% were determined. Further increases in efficiency during part-load operation are possible by implementing inlet guide vanes or by shifting the design point of the compressor to lower capacities.

Keywords: turbo compressor; oil-free; low temperature lift; water/water heat pump

1. Introduction

1.1. Background

The development of highly efficient processes and products to significantly reduce CO2 emissions and reach stringent climate targets is one of the biggest challenges of this century. The heating and cooling of buildings requires large amounts of energy, reaching up to 73% of regional energy demands [1]. Experts agree that there is still substantial potential to increase the efficiency of heat pump and chiller systems. The efficiency of heat pumps or chillers is specified by the Coefficient of Performance (COP) or the Energy Efficiency Ratio (EER) and is strongly dependent on the internal temperature lift, which corresponds to the difference between the condensation and evaporation temperatures. The required internal temperature lift depends on the heat source and sink of the system. For modern and efficient building heating systems low temperature lifts between 15 K and 30 K are often sufficient: For efficient building cooling systems even lower temperature lifts between 10 K and 20 K are possible. However, heat pumps and chillers only achieve high second-law efficiencies at low temperature lifts if they are specially designed for the corresponding operating conditions. With the development of low temperature lift heat pumps and chillers, the potential of low temperature lift applications can be exploited.

Moreover, moderate to poor part-load efficiencies often diminish the annual efficiency of building heating and cooling systems, which is a frequent issue as maximum capacity is required only rarely during the year. Turbo compressors have high efficiencies at low pressure ratios during both full and part-load operation, thus suiting low temperature lift building heating and cooling applications well. Resultantly, annual efficiencies of heat pumps and chillers that employ turbo compressors can be significantly higher as compared to systems that employ other compressor types.

1.2. Temperature lifts of building heating and cooling

A short summary of temperature lifts in building heating and cooling applications is presented below. For further details, a comprehensive overview can be found in Gasser et al. [2].

Heating applications

The internal temperature lift of a heat pump used for building heating depends substantially on the heat source and the heat delivery system. In most applications, the temperature lift is typically around 15 K to 75 K (Fig. 1, left). For an efficiently heated low-energy building, desirable temperature lifts range from 15 K to 30 K. This would entail, for example, geothermal heat probes or ground water as the heat source and a modern low-temperature heat distribution and delivery system such as an underfloor heating system. The COP_{ideal} of an ideal heat pump (i.e. Carnot heat pump between the evaporation and condensation temperatures) as a function of the temperature lift for a constant evaporation temperature of 10°C is shown (Fig. 1, right). For a temperature lift of 20 K, a COP_{ideal} of 15.2 is possible. If a system with a second-law efficiency of 60% were implemented, a COP of 9.1 would result.

Cooling applications

The temperature lift of a chiller used for building cooling depends substantially on the space cooling and re-cooling system. In most applications, the temperature lift is typically around 10 K to 55 K (Fig. 2, left). For an efficiently cooled low-energy building located in central Europe, desirable temperature lifts range from 10 K to 30 K. This would entail, for example, space cooling using chilled ceilings, concrete core activation or highly efficient fan coil units and an efficient hybrid/adiabatic re-cooling system. The EER_{ideal} of an ideal chiller (i.e. Carnot chiller between the evaporation and condensation temperatures) as a function of the temperature lift for a constant evaporation temperature of 14°C is shown (Fig. 2, right). For a temperature lift of 12 K, an EER_{ideal} of 24 is possible. If a system with a second-law efficiency of 60% were implemented, an EER of 14.4 would result.

1.3. State-of-the-Art and recent research

The use of turbo compressors in compression heat pumps and chillers originates in 1922 when the first centrifugal refrigeration compressor was presented [3]. Today, turbo compressors are mainly widespread in larger heat pumps and chillers with up to several megawatts of heating/cooling capacity. Prestigious manufacturers include Carrier, Danfoss Turbocor, Friotherm and Mitsubishi Heavy Industries.

The smallest available compressors from these manufacturers are about 200 kW nominal cooling capacity. Most compressors above 200 kW nominal cooling capacity were found not to utilize gas bearings, requiring oil lubrication. As an exception, Danfoss Turbocor uses magnetic bearings and is thus the only manufacturer providing oil-free compressors within this capacity range. For heat pumps/chillers with lower capacities, the use of turbo compressors is rather rare. The manufacturers Celeroton and Fischer offer oil-free refrigerant turbo compressors in the range of 20 kW nominal cooling/heating capacity and utilize gas bearings. Accordingly, there is a market gap in capacity of available turbo compressors.

In recent years, various turbo compressors for heat pump and chiller systems have been introduced across several IEA Heat Pump Conferences. Generally, the presented turbo compressors can be split amongst two groups, those with nominal heating capacities in the range of 20 kW, and those with nominal heating capacities greater than 500 kW, with exception to that presented by Kim et al. (ca. 130 kW heating capacity) [4].

For nominal heating capacities in the range of 20 kW, it is noticeable that the rotational speeds are relatively high with 160-280 krpm [2], [5], [6]. For this application and these rotational speeds, Arpagaus et al. already presented self-acting gas bearings which remove the need for oil lubrication [6]. At heating capacities above 130 kW the rotational speeds are often significantly lower with 11-24 krpm [4], [7]. Accordingly, ball and rolling bearings [4], [8], and seldomly, magnetic bearings [9], are used.

Only Gasser et al. indicates the resulting second-law efficiency (determined with the operating condensation and evaporation temperatures) when operating the turbo compressor in a heat pump, which was found to be at maximum 64% [2].

The presented turbo compressors for small heating capacities are intended for use in heat pumps for building heating [2], [6]. For higher heating capacities, the turbo compressors are often used to generate hot water in the range of 75-95°C [9], [10], [11].

From a research perspective, much of the work conducted regarding turbo compressors follows the same trends as the market, tending not to focus on the 20 to 200 kW capacity range.

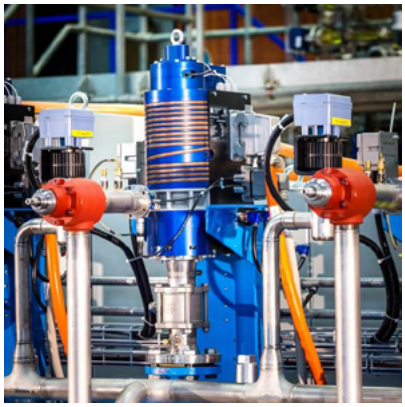

Fig. 3. Novel oil-free, gas-bearing turbo compressor by Teqtoniq GmbH installed in a heat pump/chiller

1.4. Objectives

The goal of this paper is to demonstrate the efficiency of a heat pump/chiller equipped with a novel oil-free, gas-bearing centrifugal turbo compressor. The overall project aim is the development of a marketable and highly efficient centrifugal turbo compressor for heat pumps and chillers with a cooling capacity of 20-100 kW per compressor.

2. Novel oil-free, gas-bearing turbo compressor

The novel, oil-free and gas-bearing centrifugal turbo compressor presented is a development of the Swiss company Teqtoniq GmbH in collaboration with the Lucerne University of Applied Sciences and Arts. The compressor has been developed for use in heat pump and chiller systems with temperature lifts up to 40 K. The cooling capacity of a single compressor can be increased from about 20 kW to 100 kW. Patented self-acting gas bearings are used to support the shaft and impellers at rotational speeds of up to 60 krpm. The gas bearings eliminate the need for oil lubrication, allowing the compressor to operate completely oil-free. Due to the similar gas properties, the compressor can be used with the refrigerants R1234ze, R513a and R134a. In this paper, only the refrigerant R1234ze is considered. The technical data of the compressor are summarized in Table 1.

Table 1 Technical Data of the novel oil-free, gas-bearing turbo compressor by Teqtoniq GmbH

Type	**centrifugal, two-stage**
Electrical power	max. 28 kW
Rotational speed	variable, max. 60 krpm
Refrigerant	R1234ze
Nominal cooling capacity	100 kW
Pressure ratio	max. 4.0
Mass flow rate	max. 0.8 kg/s

3. Experimental setup

3.1. Test rig

The test rig located at the Lucerne University of Applied Sciences and Arts allows the experimental investigation of various thermal systems. Such systems include chillers and heat pumps (up to a cooling capacity of 600 kW) as well as heat exchangers or thermal energy storages.

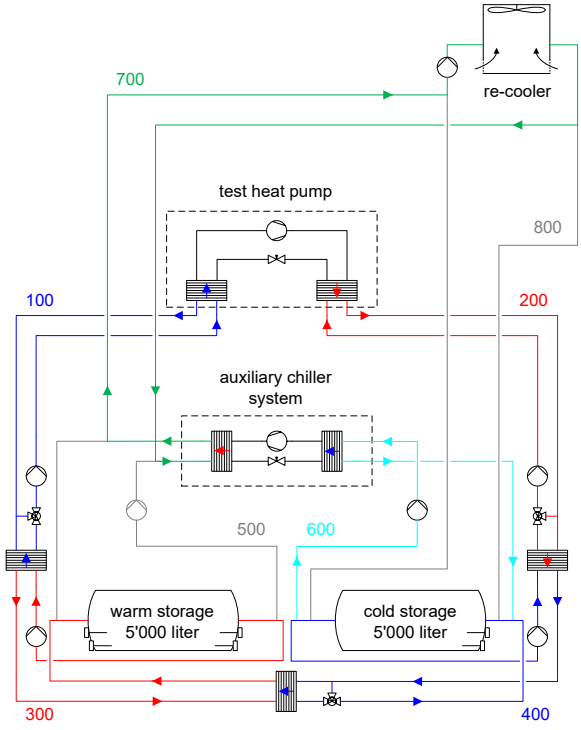

Fig. 4. Simplified schematic view of the test rig at the Lucerne University of Applied Sciences and Arts; application “testing a water/water heat pump/chiller”; cooling of the infrastructure via auxiliary chiller system

With this infrastructure, it is possible to provide heating and cooling within a temperature range of -20°C to +80°C. The core are two separate warm and cold storage tanks, each with capacities of 5,000 litres and filled with an aqueous glycol mixture. Depending on the application, the storage tanks can be conditioned using an auxiliary chiller system, a re-cooler, or electric heating rods. The heat is distributed in various circuits, which are equipped with variable-speed pumps and flowmeters for flow control. The temperatures of some individual circuits are controlled via 3-way mixing valves. With this test rig it is possible to experimentally investigate heat pumps and chillers according to the test standard EN14511. The requirements for control and measurement accuracy can be easily met. Fig. 4 shows a simplified schematic view of the test rig for the application "testing a water/water heat pump/chiller".

When testing a water/water chiller, in circuit 100 the water temperature and mass flow into the evaporator of the test heat pump are adjusted to the specified nominal values. This allows the simulation of a real heat source. In circuit 200, the water temperature and mass flow into the condenser of the test heat pump are adjusted, thereby simulating the heat sink. The two circuits 100 and 200 are connected with the two “inner” circuits 300 and 400 via three heat exchangers. This allows the heat generated at the condenser of the test heat pump to be partially fed to the evaporator of the test heat pump, resulting in maximum heat recovery. The excess heat generated by the larger condenser heat flow in the test heat pump is stored in the cold storage tank, which heats up as a result. When a maximum target temperature is reached, the cold storage tank is cooled to a minimum target temperature via circuit 600 with the auxiliary chiller system. The condenser waste heat from the auxiliary chiller system is released to the ambient air via circuit 700 with the aid of a re-cooler. The task of the warm storage tank is to compensate for temperature fluctuations that occur in circuits 200 and 400. This ensures a constant temperature at the inlet to the heat exchanger, which separates circuits 100 and 300.

Right: Measurement scheme for the heat pump/chiller; PI: pressure indicator, TI: temperature indicator, FI: mass flow rate indicator, JI: electrical power indicator

3.2. Heat pump/chiller prototype

The tested heat pump/chiller prototype (Fig. 5, left) is equipped with four novel oil-free turbo compressors with self-acting gas bearings. Each turbo compressor has a nominal cooling capacity of approximately 100 kW, resulting in an overall nominal cooling capacity of 400 kW or 500 kW heating capacity, respectively. The capacity of the heat pump can be regulated by the rotational speed of the turbo compressors and by switching compressors on and off. The measurement scheme for the heat pump is also given (Fig. 5, right).

3.3. Test conditions

Heat pump application

The seasonal performance of a heat pump for building heating is determined in compliance with the EN14825 standard [12]. Depending on the heat source and sink, the standard specifies operating points with different part-load ratios for the heat pump. The experimentally determined COP values at the respective operating points can then be used to calculate the expected seasonal performance factor associated with climatic conditions of a location. This paper presents a water/water heat pump designed for low temperature lifts. Hence, only low-lift operating conditions of the EN14825 standard are tested. The operating conditions for a heat pump that works with a heat source such as ground water (10°C) and provides heating water with low temperatures (max 35°C) for an efficient new building therefore apply (Table 2). The water flow rates of heat source and sink in evaporator and condenser are determined by adjusting them such that the water inlet and outlet temperatures match the specified temperatures (10/7°C, 30/35°C) for full load operation (see Table 2). For every other operating point, the determined flow rates are kept constant, resulting in a decreasing temperature differential between inlet and outlet as part-load is reduced.

Chiller application

The seasonal performance of a chiller for building cooling is stated frequently using an index called the European Seasonal Energy Efficiency Ratio (ESEER), which is based on the EN14511 standard. This index represents an average annual efficiency of chillers for building cooling purposes in Europe. To achieve this, EER values at full load and in different part-load operating points are combined using different weighting coefficients. The operating points differ depending on the heat source and heat sink used. The water flow rates of heat source and sink in evaporator and condenser are determined as before (see Table 3). For every other operating point, the determined flow rates are kept constant.

Table 2 Test conditions for the test heat pump in heating applications in compliance with the EN14825 [12] standard

Part-load	Water temperatures evaporator in/out [°C]	Water temperatures condenser in/out [°C]
100%	10 / 7	30 / 35
88%	10 / -	- / 34
54%	10 / -	- / 30
35%	10 / -	- / 27
15%	10 / -	- / 24

Table 3 Test conditions for the test chiller in cooling application in compliance with EN14511 [13] and Eurovent [14] standards

Part-load	Water temperatures evaporator in/out [°C]	Water temperatures condenser in/out [°C]
100%	12 / 7	30 / 35
75%	- / 7	26 / -
50%	- / 7	22 / -
25%	- / 7	18 / -

4. Results and discussion

Heat pump application

For heat pump application measurements, the heat pump presented in Section 3.2 was operated with only three turbo compressors. This is because one turbo compressor was demounted for inspection at the time of the measurements. The nominal heat output at 100% load ratio is accordingly related to three turbo compressors and corresponds to approximately 370 kW heat output. The operating points listed in Table 2 are measured based on the EN14511 standard. The results are shown in Fig. 6. The characteristic values COP and second-law efficiency are determined according the following equations:

$$\mathrm{COP_{HP}} = \frac{\dot{Q}_{cond}}{P_{el}} \; ; \; \mathrm{COP_{Carnot}} = \frac{T_{cond}}{T_{cond} - T_{evap}} \tag{1}$$

$$\eta_{2nd\ law,HP} = \frac{\mathrm{COP_{HP}}}{\mathrm{COP_{Carnot}}} \tag{2}$$

It can be seen that the COP increases from 6.12 to 8.48 by lowering the internal temperature lift from 31 K to 16 K (Fig. 6). The second-law efficiency (related to the evaporation and condensation temperature, i.e. internal behavior of the heat pump) decreases from 0.62 to 0.46. This behavior can be attributed to the design point of the turbo compressor, which lies at higher refrigerant volume flows and pressure ratios. This effect is further intensified by the inlet guide vanes, which are not in operation with the current prototype.

The efficiency of a turbo compressor at lower volume flows than at the design point can be increased by the correct use of inlet guide vanes. It can be seen in the right-hand plot of Fig. 6 that the second-law efficiency is the lowest at the operating point with the lowest heating output, by a considerable margin. This behavior can be explained again with reference to the design point of the turbo compressor. The required heating capacity is too small for the turbo compressor at the given temperature lift, resulting in a lower efficiency. If the nominal heat output of the heat pump had been determined with four compressors, the required heat output for one compressor in this operating point at 15% part-load ratio would have been significantly higher, and the resultant second-law efficiency would have been similarly elevated.

In summary, given a second-law efficiency within the range of 46-62% the heat pump with three novel turbo compressors shows remarkable efficiency values despite its prototype status. With optimization measures such as the tuned operation of the already installed inlet guide vanes, the efficiency of the system could be further improved. Additional increases in efficiency are possible by shifting the design point of the turbo compressor to smaller refrigerant volume flows and temperature lifts. Especially in view of the fact that the part-load operating points have a higher share of operation during the year, therefore having a larger impact on the annual efficiency.

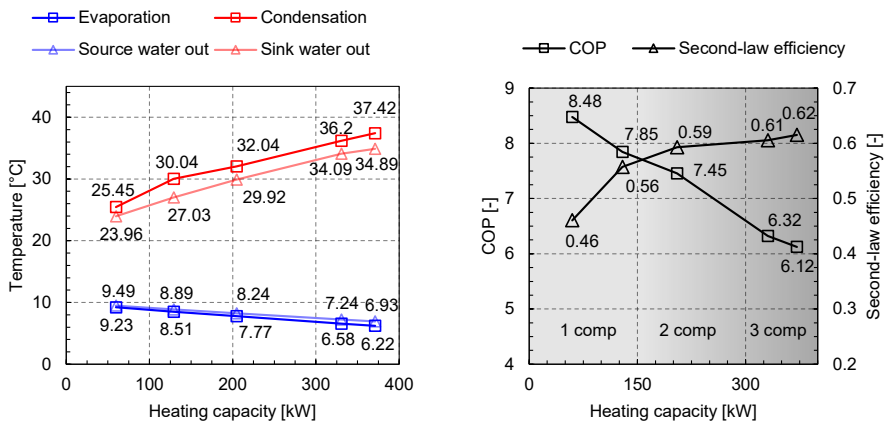

Fig. 6. Left: Water outlet temperatures of evaporator and condenser and corresponding evaporation and condensation temperature depending on the heating capacity at the operating conditions mentioned in Table 2
Right: Corresponding COP and second-law efficiency

Chiller application

The chiller presented in Section 3.2 was operated using all four turbo compressors for the chiller application measurements. The nominal cooling capacity of the system corresponds to approximately 400 kW. The chiller operating points listed in Table 3 are measured based on the EN14511 standard. The measurement scheme of the test heat pump stays the same and can be seen in Fig. 5. The results are shown in Fig. 7. The characteristic values EER and second-law efficiency are determined according to equations (3) and (4):

$$\mathrm{EER_{Ch}} = \frac{\dot{Q}_{evap}}{P_{el}} \; ; \; \mathrm{EER_{Carnot}} = \frac{T_{evap}}{T_{cond} - T_{evap}} \tag{3}$$

$$\eta_{2nd\ law,Ch} = \frac{\mathrm{EER_{Ch}}}{\mathrm{EER_{Carnot}}} \tag{4}$$

In general, similar behavior in the performance of the turbo compressor between the two applications was observed. Noticeably, the second-law efficiency has significantly increased constancy across all operating points. Here, too, the chiller with four novel turbo compressors shows remarkable efficiency values despite its prototype status. Similarly, achieving heightened efficiencies for chiller applications can be accomplished by adjusting the design point of the turbo compressor.

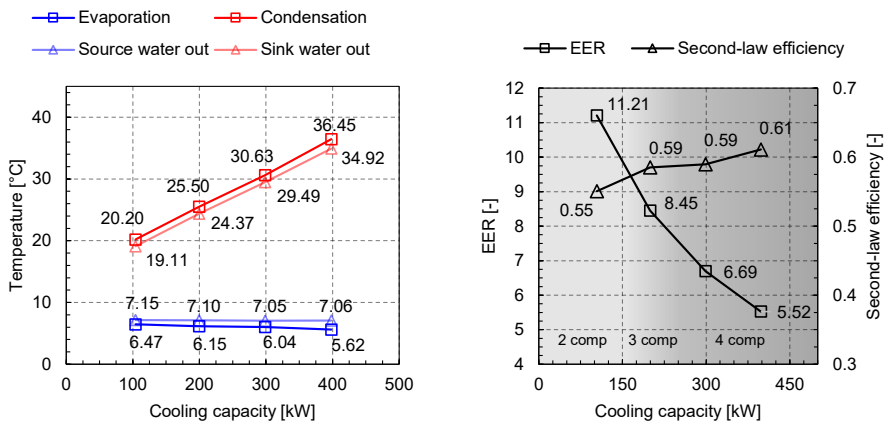

Fig. 7. Left: Water outlet temperatures of evaporator and condenser and corresponding evaporation and condensation temperature depending on the heating capacity at the operating conditions mentioned in Table 3
Right: Corresponding EER and second-law efficiency

5. Conclusions

The consistent use of available low temperature lifts in building heating and cooling can save considerable amounts of electricity. A prerequisite is that the implemented heat pump or chiller be specifically designed for these operating conditions, thus enabling high second-law efficiencies.

The heat pump prototype with four novel, oil-free and gas bearing turbo compressors shows efficiency values which are in the top range for comparable products on the market. For typical temperature lifts encountered in modern building heating and cooling systems, second-law efficiencies around 60% can be achieved for both heating and cooling applications. Overall, the prototype performs better for building cooling purposes than building heating, although is generally well suited to both. Results also indicate potential to increase the efficiency further, by ensuring that compressor part-load performance is optimized for the operating conditions most frequently encountered throughout the year. Increases in efficiency values of several percentage points would be expected, and further work is already being conducted in this area.

Finally, in order to achieve highly efficient building heating and cooling, not only must the heat pump or chiller be efficient, the entire system has to be designed to function efficiently. A non-exhaustive list of design concerns includes the hydraulic circuits, the heat exchange on the source and sink side, building dynamics, and controls systems. Considered implementation of all these measures together with efficient low-lift heat pumps and chillers will lead to a significant reduction in both exergy consumption and on-going operating costs for the heating and cooling of buildings.

CO_2 emission savings of heat-pumps in the residential sector. Case study for multifamily buildings in Geneva

Elliot Romano*, Carolina Fraga, Pierre Hollmuller

University of Geneva, 66 Bd Carl Vogt, 1211 Genève, Switzerland

Abstract

The present paper assesses the CO_2 emissions of air-source and groundwater-source HP systems, with and without complementary PV, for a sample of multifamily buildings (new, retrofitted and non-retrofitted) located in Geneva. HP performance is evaluated by way of numerical simulation in hourly time step, and is cross-cut with the hourly grid CO_2 content of the Swiss electricity mix (taking into account both domestic generation and imports from the neighbor countries). Given the seasonal trend of both the building heat demand and the grid CO_2 content, latter turns out to strongly underestimate the CO_2 content of the HP system electricity. Nonetheless, when compared with a gas boiler, both HP systems induce important annual CO_2 savings (air: 61 - 81% depending on the accounting method; groundwater: 75% - 87%). Finally, while PV can substantially contribute to the summer HP demand, the related annual CO_2 savings remain relatively marginal, also due to seasonality of the grid CO_2 content.

Keywords: heat pump (HP); photovoltaic (PV), multifamily building; CO_2 emissions

1.1. General issue

An increasing number of authors are evaluating the environmental impact of massive heat-pump (HP) introduction, but only few consider the temporal dynamic of the carbon content of electricity-generation. As a notable exception, [1] shows that introducing direct heat pump heating along with combined cycle gas plants could generate significant reductions of greenhouse gas emissions, when compared with classic fossil-fuel heating and electric resistance heating. Similarly, [2] analyze the temporal load curves of heat pump water heaters and air-source heat pumps in the context of temporal grid-level emissions data. However, while the previous two studies do consider the carbon content of electricity at hourly scale, latter is based on the production accounting principle, which doesn't take into account the impact of electricity imports and exports on the carbon content of the electricity mix. In a country like Switzerland, which relies on a high share of electricity exchanges with the neighboring countries, such an approach is not satisfactory.

1.2. Local context

While the space-heating (SH) and domestic hot water (DHW) production for the building sector of the Canton of Geneva rely at 93% on fossil sources, the energy policy objective is to reduce this share to 66% by 2035. Given important low temperature resources, in particular in terms of surface and subsurface water, one of the major foreseen contributions for this change consists in massive introduction of centralized HPs, at building level as well as integrated in district heating networks [3].

Even though multifamily buildings (MFB) only constitute 27% of the Geneva building stock, they represent almost half of the heated floor area of the canton, namely 19.3 out of 40.9 million m2 [4]. About half of these MFB, which were built between 1946 and 1980, are nowadays in need of retrofit and possess a strong energy saving potential. In parallel to reducing of the heat demand of the building stock, in particular by way of retrofit, reducing of the CO_2 emissions can also be achieved by replacing fossil fuels by renewable energies, in particular via heat pump (HP) systems. However, in addition to HP performance issues, the CO_2 content of the electricity needed to run such HP systems, as well as the complementarity with local PV production remain a fundamental issue.

1.3. Objective

In this context, [5] performed a numerical simulation study which compares the potentials and constraints of different heat sources exploited by HP systems, with and without complementary PV, implemented in various types of multifamily buildings located in Geneva. As a complement, a recent study evaluates the hourly CO_2 content of the Swiss electricity consumption mix [6], taking into account both domestic production and imports to Switzerland from the neighbor countries.

Objective of the present paper is to cross-cut these 2 studies, for assessing the CO_2 emissions of air-source and groundwater-source HP systems, with and without complementary PV, for a sample of multifamily buildings (new, retrofitted and non-retrofitted), located in Geneva.

1.4. Method and results

The methodological part of the paper is organized as follows: i) Presentation of the building sample and related heat load profiles, which are rescaled to 2017, the reference meteorological year for which hourly CO_2 content of electricity is available; ii) Characterization of the considered heat sources (air and groundwater), HP system layout and simulation algorithm, as well as complementary PV system; iii) Characterization of the hourly CO_2 content of the Swiss electricity consumption mix, which is given for two distinct accounting approaches (lower and upper grid CO_2 content).

The results are discussed as follows: i) HP performance, in terms of daily *COP* and annual *SPF*, for the distinct heat demands; ii) CO_2 emissions of the stand-alone HP systems (without PV) and comparison with the CO_2 emissions of a gas boiler; iii) effect of PV production on the daily and annual consumption/production of electricity, as well as related CO_2 savings.

2. Building sample and heat load

2.1. Building sample

The present study is based on the same multi-family building (MF) sample which was used in [5]: i) 2 new buildings with identical low SH demand, but differentiated DHW demand; ii) 3 retrofitted buildings, of which one with low SH and the other ones with intermediate SH demand but differentiated SH distribution temperature; iii) 1 non retrofitted building. The main characteristics of the building sample (with SH demand corresponding to standard weather data) are summarized in Table 1. Note that 4 of the buildings correspond to real case studies situated in Geneva (*New, RetBest, RetRef, NoRet*), while the 2 other are combinations thereof, in terms of DHW demand (*NewLow*) or of SH distribution temperature (*RetAvg*).

Table 1 Building sample.

Building	Qsh kWh/m²	Qdhw kWh/m²	Qdem kWh/m²	Tsh.0 °C
New	20.8	47.7	68.5	30
New Low	20.8	28.3	49.1	30
Ret Best	37.8	34.6	72.4	40
Ret Avg	69.3	28.3	97.6	40
Ret Ref	69.3	28.3	97.6	50
No Ret	110.0	28.3	138.3	50

Qdhw, Qsh, Qdem: DHW, SH and total annual heat demand (with climatic correction to standard weather).
Tsh.0: SH distribution temperature, at 0° outdoor temperature.

Comparison with a benchmark on the SH demand of the MF building stock of Geneva [4] shows that, except for *NoRet*, all our buildings are in the 1st decile, meaning that they are representative of the best cases in their respective construction periods. *NoRet* is in the 3rd quartile, close to the 4th quartile, meaning that it is representative of a lower than average building envelope.

Similarly, comparison with a benchmark on the DHW demand of the MFB stock of Geneva [7] yields following results: *New* is in the 4th quartile, amongst the highest values; *RetBest* is slightly above the median; all other cases (which by definition have the same DHW demand) are in the 2nd quartile, closer to the 1st quartile than to the median.

2.2. Heat load profiles

For the sake of the present study, the above building demands are rescaled to 2017, the reference meteorological year for which hourly CO_2 content of electricity is available (see further down). To do so we consider that: i) DHW demand is independent of the meteorological year and is therefore the same as for standard weather data; ii) SH demand is multiplied by 1.03, the ratio between 2017 and standard weather degree days.

In agreement with [5], the hourly demand profile is then defined as follows: i) For DHW, the hourly profile is given by the monitored data of a typical multifamily building [8]. It is adjusted by a multiplication factor, so that the integral of the load corresponds to the annual DHW demand of the building under consideration; ii) For SH, the hourly load is given by a linear function of the outdoor temperature, defined by a set point above which SH is off and a nominal heat load at 0°C outdoor temperature (which is adjusted so that the integral of the load corresponds to the annual SH demand of the building under consideration); iii) For SH distribution temperature, it is given by a linear function of the outdoor temperature. The DHW distribution temperature is considered constant, at 55°C. The limits of this methodology, in particular in terms of load curve, was discussed in details in [9]. For the particular case of a HP system on a low-energy building, it was shown that simulation results with the modelled heat demand are very similar to simulation results with the monitored heat demand, at least at aggregated system level.

The resulting heat load profiles of the building sample are presented in Figure 1, in daily values. We observe the relatively constant DHW demand at outdoor temperatures above 18°C, below which the distinct SH demands of the building sample are visible (with linear patterns corresponding to the above construction).

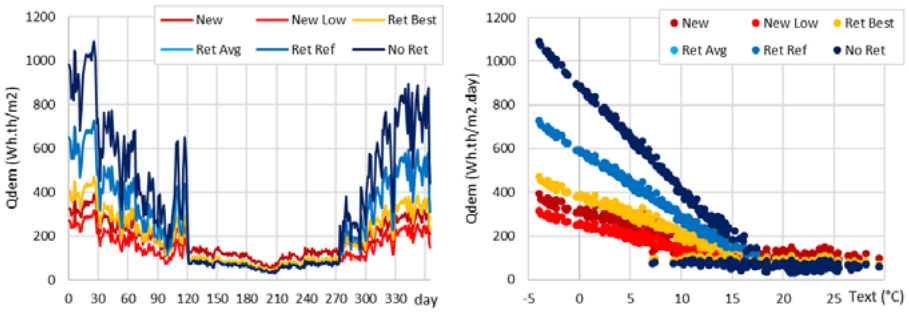

Fig. 1. Heat load of the building sample, profile and relation to outdoor temperature (2017, daily values).

3. HP systems and electrical load

3.1. Heat sources

The above described building sample was previously used for assessing of HP performance for a variety of heat sources [5]: i) ambient air; ii) geothermal boreholes; iii) water from lake of Geneva, pumped from a depth of 35 m; iv) Rhône river, corresponding to the top layer of the lake; v) shallow groundwater; vi) unglazed solar thermal collectors, used as HP heat absorbers in case of insufficient solar irradiation for direct solar production.

As expected, the simulated HP seasonal performance factors (*SPF*) turned out to be strongly related with the heat source temperature: groundwater yielded the highest *SPF* values (4.3 - 4.8, depending on the building heat demand) followed by river (3.9 - 4.5) and lake (3.8 - 4.3). The geothermal borehole performed slightly lower (3.6 - 4.0), while solar and air were at the bottom, with very similar values (solar: 2.9 - 3.5; air: 3.0 - 3.4).

In the present study, we will focus on the two extreme cases: i) air, which is characterized by a strong seasonal and daily variability (hourly values ranging from -5°C to 34°C); ii) groundwater, with a constant temperature of 13°C.

3.2. HP system

The considered system layout (Fig. 2) is similar for the air source HP and the groundwater source HP. Sizing of the components (HP, storage) depends on the maximal hourly heat load of the building under consideration.

Operation of the system obeys following scheme of priorities: i) maintaining the DHW tank above 50°C; ii) covering of the SH demand by way of: a) storage discharge; b) activation of the HP, with surplus production used to charge the heat storage; c) direct electric heating, which is activated only in case of simultaneous SH and DHW without possible storage discharge.

The components are modelled according to energy balance equations, which are integrated in the TRNSYS. simulation software package, taking into account the above defined priority rules [9]. The HP is modelled by an input/output table based on the working temperatures (evaporator input, condenser output), as given by manufacturer data (which, for the air-source HP, includes electricity for de-icing). Each of the storage tanks is modelled by way of a one-node model (disregarding stratification effects, which should be negligible, given the relatively small heat storage capacities), taking into account heat losses to the technical room. Direct electric heating covers the instantaneous difference between demand and production. Auxiliary electricity for circulation pumps is not taken into account. Simulation results were previously validated with monitored values of a solar heat pump system, at component and system level [9]. So as to properly take into account the dynamic of the HP-system, simulation is performed in 6 min time step, with output values stored in hourly time step.

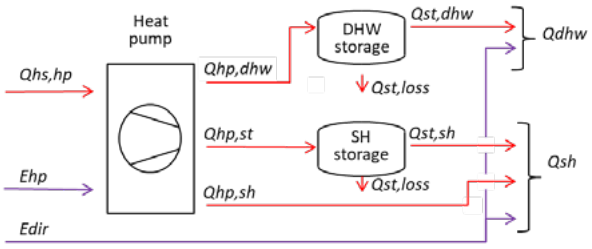

Fig. 2. HP system layout and associated energy flows.

3.3. Reference scenario with gas boiler

As a "business as usual" alternative to the above described HP systems, and for the sake of comparison in terms of CO_2 emission savings, we also consider heat production by way of a centralized gas boiler. In this case the heat production (including storage loses) is considered to match the hourly output of the groundwater HP (plus occasional direct electric heating).

4. PV production

As a complement to the HP system, we study the benefits of adding photovoltaic panels on the available building roof area. In order to do so, we consider following two cases [5]: i) an available roof area of 0.2 m^2 per m^2 heated floor area, corresponding to a "low-rise" multifamily building in Geneva (4 floors, under hypothesis of an 80% ratio between the available roof area, in m^2, and the floor specific heated area, in m^2 per floor); ii) an available roof area of 0.1 m^2 per m^2 heated floor area, which corresponds to a "high-rise" building in Geneva (8 floors).

PV production is based on a 12 % efficiency applied directly to the hourly global horizontal solar irradiation, corresponding to an annual electricity production of 162 kWh per m^2 of PV (2017).

5. CO_2 emissions

5.1. HP systems

In the case of HP systems, induced emissions are calculated on an hourly basis, by way of the 2017 hourly grid CO_2 content of the Swiss electricity consumption mix evaluated by [6]. Latter study takes into account both domestic production and inflows to Switzerland from each of the neighbor countries. To do so, it uses hourly available data concerning the production mix of the various European countries, per type of production, as well as hourly cross-border flows between them. Based on merit-order considerations, it takes into account the impact on the incremental generation mix due to import/export with the neighbor countries.

Finally, the CO_2 content of the resulting electricity mix is calculated by way of the carbon intensity of each production type, as given by the ecoinvent life cycle inventory database [10]. While this method is relatively straightforward for most of the production types (renewables, nuclear, fossils), a specific issue concerns electricity generation from blast furnace gas units in Germany. While latter represent only a small share of the generation capacity of the total market, it plays an important role in compensating for capacity shortages at the European level in the winter period and hence significantly contributes to Swiss imports. In this regard, it should be noted that the CO_2 content of electricity from German blast furnaces is controversial, leading to two distinct accounting approaches: i) on the one hand, such gases can be considered as "waste" from the iron and steel industry, in which case the related CO_2 content is attributed to latter sector and not to electricity generation; ii) on the other hand, in respect to specific economic considerations regarding the decision to flare the gases or to produce electricity, it can also be argued that the corresponding emissions should be attributed to the electricity sector [6].

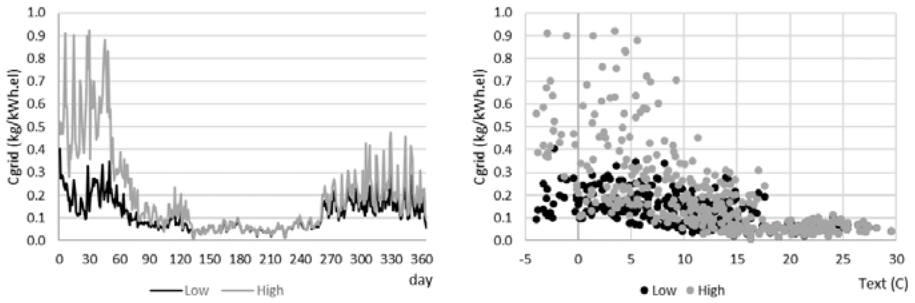

Fig. 3. Grid CO_2 content of the Swiss electricity mix, profile and relation to outdoor temperature (2017, daily values).

Finally, for both of these approaches, the dynamic of the grid CO_2 content (year 2017) is depicted in Figure 3, in daily values. Both approaches reveal a strong seasonal pattern, which results from the seasonality of electricity production and demand in Switzerland and its neighboring countries and the related imports and exports. We further note the fundamental issue of the accounting method for blast furnace gases, with an approximative factor 2 between the resulting annual average (lower grid CO_2: 108 g/kWh$_{el}$, upper grid CO_2: 196 g/kWh$_{el}$).

5.2. PV production and gas boiler

As for the HP systems, avoided emissions related to PV production are calculated on an hourly basis, by way of the above hourly grid CO_2 content. In the case of gas boilers, emissions are directly related to the produced heat, by way of a constant emission factor of 249 g/kWh$_{th}$ given by the Swiss Coordination Conference of Building Services [11].

6. Results and discussion

6.1. Performance and emission indicators

The results will be discussed on the basis of aggregated values of the hourly building heat demand *Qdem* (kWh$_{th}$/m^2), the HP system electricity demand *Esys* (kWh$_{el}$/m^2) and the CO_2 content of grid *Cgrid* (kg/kWh$_{el}$).

Performance of the HP system will be discussed in terms of daily *COP* (kWh$_{th}$/kWh$_{el}$) and annual *SPF*. (kWh$_{th}$/kWh$_{el}$), defined accordingly to their respective daily or annual aggregation level:

$$COP = \frac{\sum Qdem}{\sum Esys} \quad (1)$$

$$SPF = \frac{\sum Qdem}{\sum Esys} \quad (2)$$

Emissions will be discussed in terms of the area related CO_2 content of the heat demand *Cbld* (kg/m^2), the thermal CO_2 content of the heat demand *Cth* (kg/kWh$_{th}$) and the electrical CO_2 content of the HP system electricity *Cel* (kg/kWh$_{el}$). Latter are defined as follows (with daily or annual aggregation level):

$$Cbld = \sum Esys \cdot Cgrid \quad (3)$$

$$Cth = \frac{\sum Esys \cdot Cgrid}{\sum Qdem} \quad (4)$$

$$Cel = \frac{\sum Esys \cdot Cgrid}{\sum Esys} \quad (5)$$

6.2. HP performance

Figure 4 depicts the daily *COP* values of both HP systems. In the case of the air-source HP, when the air temperature is above 10°C the *COP* is mainly in the range of 3 - 4, while it drops for lower temperatures (due to lower resource temperature, as well as related de-icing). In the case of the groundwater-source HP, the *COP* is mainly in the range of 3.5 - 5.5, and is not so sensible to the outdoor temperature.

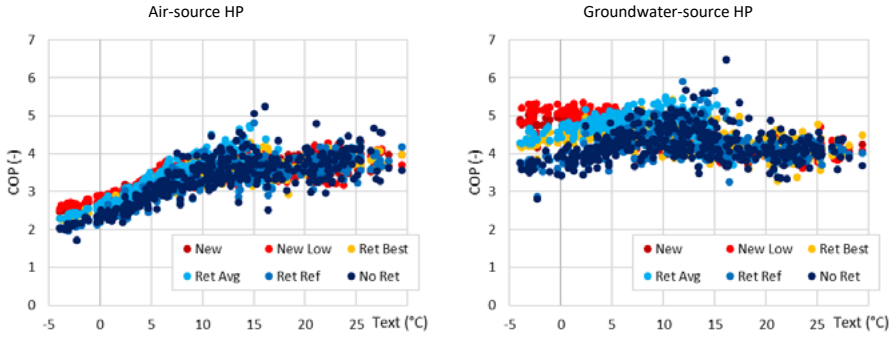

Fig. 4. COP of air and groundwater HP systems (daily values).

The corresponding annual *SPF* values are given in Table 2, with an average of 3.06 for the air-source HP and 4.42 for the groundwater-source HP (not including ancillary electricity for circulation pumps).

Table 2 Annual heat demand and SPF (2017).

Heat demand and SPF		New	New Low	Ret Best	Ret Avg	Ret Ref	No Ret	Average
Qdem	kWh.th/m2	67.12	47.72	69.51	92.23	92.23	129.82	
SPF air	kWh.th/kWh.el	3.24	3.26	3.10	3.11	2.83	2.80	3.06
SPF gw	kWh.th/kWh.el	4.51	4.68	4.46	4.65	4.10	4.12	4.42

air: air-source HP; gw: groundwater-source HP

6.3. CO_2 emissions, without PV

Figure 5 shows the daily values of the system electricity consumption (top) and the area related heat CO_2 content for the lower grid CO_2 content (bottom). While there is a strong correlation between electricity consumption and outdoor temperature, similar to the heat demand (Fig. 1), a much larger dispersion appears for the area related CO_2 content, as induced by the dispersion of the grid CO_2 content (Fig. 3).

The corresponding annual CO_2 emissions are summarized in Table 3, both for the lower and upper grid CO_2 content, as well as for the alternative gas boiler.

While the area related CO_2 content (*Cbld*) obviously depends on the building under consideration, the heat related CO_2 content (*Cth*) turns out relatively constant. In the case of the gas boiler it amounts to 256 g/kWh$_{th}$ (i.e. 3% more than the content of the heat at boiler outlet, see section 5.2, due to storage losses). In comparison, and when considering the lower grid CO_2 mix of electricity, it amounts to an average of 49 g/kWh$_{th}$ for the air-source HP (81% savings as compared to the gas boiler), respectively 33 g/kWh$_{th}$ for the groundwater-source HP (87% savings). When considering the upper grid CO_2 content, it amounts to twice higher values (air: 100 g/kWh$_{th}$ – 61% savings; groundwater: 64 g/kWh$_{th}$ – 75% savings).

Finally, given the seasonal trend of both the heat demand (Fig. 1) and the CO_2 content of the grid (Fig. 3), latter turns out to strongly underestimate the CO_2 content of the HP system electricity (*Cel*). Such is the case both for the lower grid content (grid: 108 g/kWh$_{el}$; air-source HP: 150 g/kWh$_{el}$; groundwater-source HP: 144 g/kWh$_{el}$), as for the upper grid content (grid: 196 g/kWh$_{el}$; air-source HP: 303 g/kWh$_{el}$; groundwater-source HP: 282 g/kWh$_{el}$). While these results confirm the necessity to assess HP emissions by way of hourly values of the grid CO_2 content, the annual derived CO_2 content of the HP system electricity could in principle be used for other annual *SPF* values than the ones considered in this study.

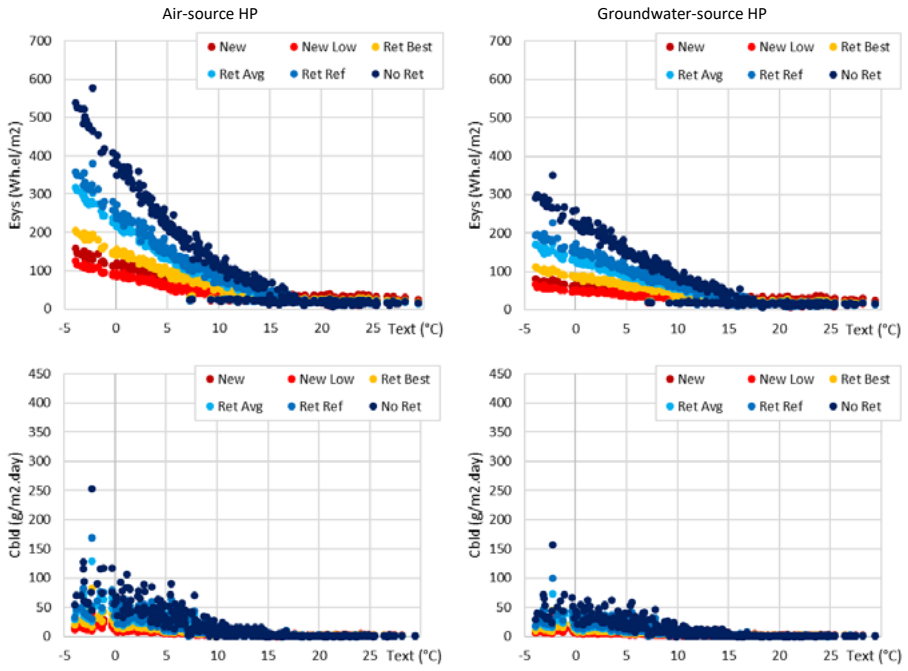

Fig. 5. HP without PV: electricity consumption (top) and area related CO_2 content of the heat demand, for the lower grid CO_2 content (bottom), as a function of outdoor temperature (daily values).

Table 3 Gas boiler and HP (without PV): annual CO2 emissions, for lower and upper grid CO2 content.

Gas boiler			**New**	**New Low**	**Ret Best**	**Ret Avg**	**Ret Ref**	**No Ret**	**Average**
Cbld		kg/m2	17.17	12.25	17.83	23.61	23.72	33.34	
Cth		kg/kWh.th	0.256	0.257	0.256	0.256	0.257	0.257	0.256
HP – lower grid CO_2			New	New Low	Ret Best	Ret Avg	Ret Ref	No Ret	Average

	gw	kg/kWh.el	0.239	0.253	0.273	0.302	0.307	0.319	0.282

air: air-source HP; gw: groundwater-source HP

6.4. Complementary PV

In this section we analyze the performance of combined HP and PV systems. For a PV system of 0.2 m^2 per m^2 heated area (low-rise building, see section 4), Figure 6 depicts the HP-PV system electricity balance (top) and the area related CO_2 emissions of the heat demand, calculated with the lower grid CO_2 content (bottom).

When considering the HP-PV electricity balance (HP consumption – PV production), and when comparing to the case without PV (Fig. 5), we observe the seasonal mismatch between both technologies: for temperatures below 5°C, consumption is very similar to the case without PV; for temperatures above 10°C, PV production reaches much more important values than HP consumption, resulting in PV injection to the grid.

When considering the area related CO_2 emissions, the situation is quite different. As a matter of fact, while PV injection to the grid results in negative CO_2 emissions (savings), the related values remain relatively small, since such happens when the grid CO_2 content is already low (Fig. 3).

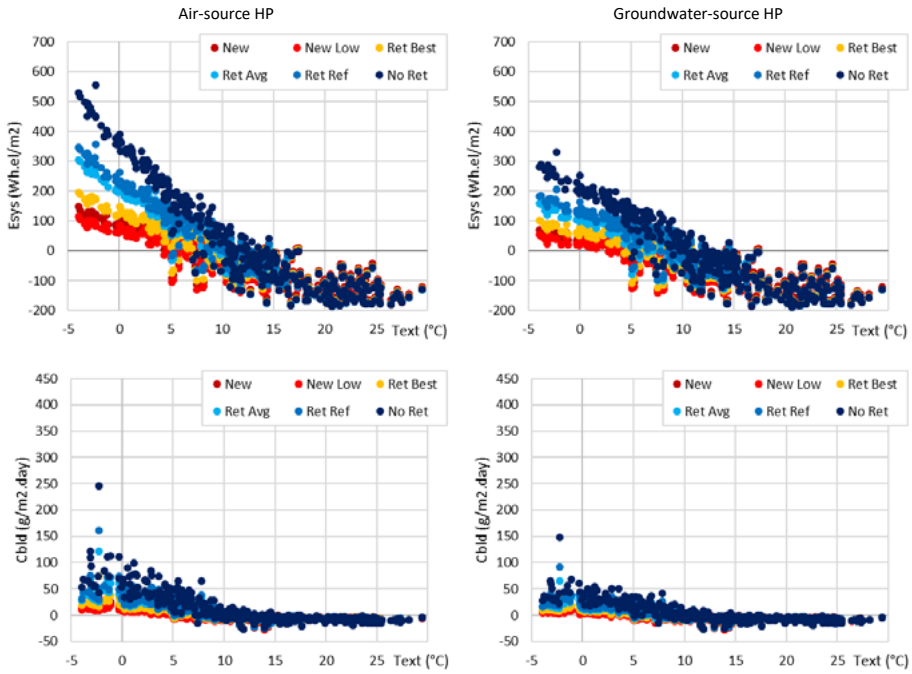

Fig. 6. HP with PV (0.2 m^2 per m^2 heated area): HP-PV electricity balance (top) and area related CO_2 content of the heat demand, for the lower grid CO_2 content (bottom), as a function of outdoor temperature (daily values).

Finally, figure 7 summarizes the annual area related CO_2 content of the 3 production systems (gas boiler, air-source HP, groundwater-source HP) in conjunction or not with PV (0.1 and 0.2 m^2 per m^2 heated area), both for the lower and upper grid CO_2 content of the Swiss electricity consumption mix.

In all cases, the area related CO_2 content is strongly corelated to the building heat demand, with a linear relation between the two. As already pointed out, the CO_2 content of the HP system in all cases smaller than the one of the gas boiler. Finally, while PV can contribute substantially to the summer HP demand, the related annual CO_2 savings remain relatively marginal. Only in the case of buildings with a low heat demand (< 90 kWh/m^2), and in particular for low-rise buildings (0.2 m^2 PV per m^2 heated area), does the annual CO_2 content of the combined HP-PV system lead to CO_2-positive buildings (however not taking into account electricity other than for the HP).

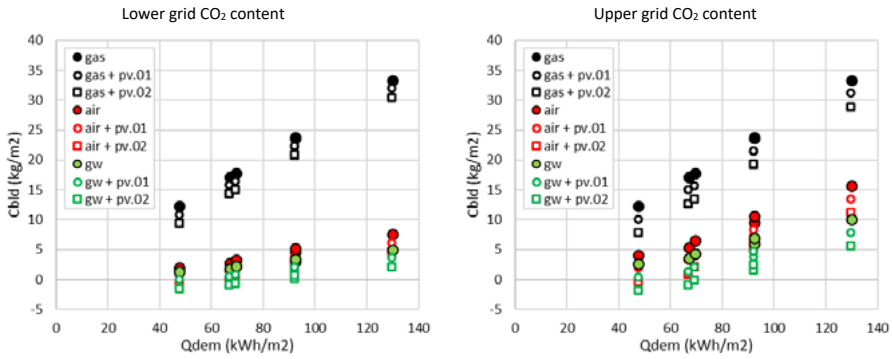

Fig. 7. Gas boiler and HP (with and without PV): Annual area related CO_2 emissions as a function of the building heat demand (for lower and upper grid CO_2 content).

7. Conclusions

The present paper assesses the CO_2 emissions of air-source and groundwater-source HP systems, with and without complementary PV, for a sample of multifamily buildings (new, retrofitted and non-retrofitted) located in Geneva. HP performance is evaluated by way of numerical simulation in hourly time step, and is cross-cut with the hourly CO_2 content of the Swiss electricity mix (taking into account both domestic generation and imports from the neighbor countries).

Latter assessment is done by way of two distinct accounting approaches: i) lower grid CO_2 content, which considers electricity from German blast furnaces CO_2 free (the related CO_2 content being attributed to the iron and steel industry); ii) upper grid CO_2 content, for which the corresponding emissions are attributed to the electricity sector.

The main results are as follows:

- The annual SPF has an average of 3.06 for the air-source HP and 4.42 for the groundwater-source HP (not including ancillary electricity for circulation pumps).
- In both cases, the daily electricity consumption bears a strong relation to the outdoor temperature, with patterns depending on the annual heat demand. A much larger dispersion appears in the case of the CO_2 content of the produced heat, as induced by the dispersion of the grid CO_2 content.
- When comparing with the emissions of a gas boiler, the considered HP systems induce very important annual CO_2 savings, at least for the lower grid CO_2 content of electricity (air-source HP: 81% savings; groundwater-source HP: 87% savings). These savings are somewhat reduced when considering the upper grid CO_2 content of electricity (air: 61%; groundwater: 75%).
- Given the seasonal trend of both the heat demand and the CO_2 content of the grid, latter turns out to strongly underestimate the CO_2 content of the HP system electricity. Such is the case both for lower grid content (grid: 108 g/kWh$_{el}$; air-source HP: 150 g/kWh$_{el}$; groundwater-source HP: 144 g/kWh$_{el}$), as for the upper grid content (grid: 196 g/kWh$_{el}$; air-source HP: 303 g/kWh$_{el}$; groundwater-source HP: 282 g/kWh$_{el}$).
- While PV can substantially contribute to the summer HP demand, the related annual CO_2 savings remain relatively marginal. As a matter of fact, for temperatures below 5°C consumption is very similar to the one without PV; for temperatures above 10°C PV production reaches much more important values than HP consumption, resulting in PV injection to the grid, but related CO_2 savings remain relatively small since such happens when the grid CO_2 content is already low.

Finally, it should be stressed that preceding results are based on numerical simulation, which assumes optimized conditions of HP integration and control, and disregards ancillary electricity of the circulation pumps.

Heat pumps in existing residential buildings

Marek Miara[a], Danny Günther[a], Robert Langner[a]

[a]Fraunhofer ISE, Heidenhofstrasse 2, 79110 Freiburg, Germany

Abstract

Several reasons speak for using of heat pumps in residential buildings. They can provide heating, domestic hot water und cooling in an ecologically friendly and, in the majority of countries, an economical way. Particularly straightforward is the implementation in new residential buildings, typically equipped with a low temperature underfloor heating system. In a number of European countries heat pumps are the predominant heating technology in the new residential buildings.

However, the real challenge, as regards reaching the goals related to climate changes and higher energy efficiency, is to secure heating in existing residential buildings. Despite several technological solutions allowing for implementation of heat pumps in existing buildings, the number of end consumers choosing heat pumps when replacing an old heating system is still very low.

What is the minimal energetic standard of a building suitable for a heat pump? Are heat pumps able to deliver required temperature and expected thermal comfort? What is the efficiency achieved under real operation conditions? When are heat pumps better than fossil systems from energetical, ecological and economical point of view? Is technological development of heat pumps in recent years recognizable in the real field operation?

The author will attempt to answer these questions on the basis of the evaluation of the latest field monitoring program encompassing more than 60 single-family existing residential buildings in Germany.

Keywords: residential building; retrofitting; field efficiency; monitoring;heating systrem supply temperatures, CO_2 evaluation

1. Introduction

Heat pumps will play the major role providing the heat for space heating and domestic hot water in the residential sector of the future CO_2 reduced energy system. A wide range of studies [1-3] consider heat pumps as a crucial technology on the way to energy system transition and targeted CO_2 neutrality.

In a number of European countries, heat pumps are already now the dominating heating technology in new residential buildings. The real challenge for reaching the goals related to climate changes and higher energy efficiency, is to provide for heating in existing residential buildings. Despite several technological solutions allowing for implementation of heat pumps in existing buildings, the number of end consumers choosing heat pumps when replacing an old heating system is still very low.

In the discussion about the applicability of heat pumps in existing buildings, the main argument against this solution is the assumed high heating supply temperature, leading to poor performance of heat pumps and consequently to exclusion criteria. To verify this assumption, in the newest field test the Fraunhofer ISE examined sixty air-to-water and ground source heat pumps under real operation conditions in existing buildings. Extensive measurement setting and high frequency data acquisition system allowed for detailed analyses of the efficiency of the systems, including the temperatures of the heating system.

2. Heat pumps field tests

Since 2006, the Fraunhofer ISE from Freiburg, Germany has been investigating electric heat pumps in single-family dwellings. Nearly 250 air-to-water and brine-to-water heat pump systems have been investigated under real operating conditions in houses with various energetic standards (from low-energy to un-retrofitted stock buildings with high energy demand).

The characteristic of the projects including the characteristic of the investigated buildings, measurement technology, main results and particular aspects, have already been presented during the 11th and 12th Heat pump Conference [4, 5].

The newest program "Smart Heat Pumps in Existing Buildings" includes heat pumps in older, usually un-retrofitted buildings. The measurement period was closed in June 2019. All investigated heat pumps units cover the heating demand, as well as the domestic hot water demand. In the majority of cases it concerns a mono-energetic systems - the heat pump is supported in emergency cases by a direct electrical back-up heater and is the only heat supplier in the building. One of the goals of the project was the investigation of hybrid heat pumps units; however the results of this investigation will not be consideration of the paper.

The heat pumps examined within the frame of the project "Smart HP in Existing Buildings", were installed in single-family houses built between 1850 and 2005. The range of their retrofitting covers from not retrofitted to retrofitted to the energy high efficient standard. This setting was necessary to investigate heat pumps in different operating conditions, including heating system supply temperature.

3. Overview of the efficiency results

3.1. System boundaries

Figure 1 shows the scheme of a typical heat pump installation and illustrates the system boundaries. There are various possibilities to calculate the efficiency of a heat pump system. The outcomes of efficiency calculations presented in sections 3.2 were based on the boundary SPF 2. The same calculation boundary was suggested as a main boundary for presenting the efficiency outcomes of heat pump systems in the European project SEPEMO-BUILD [6].

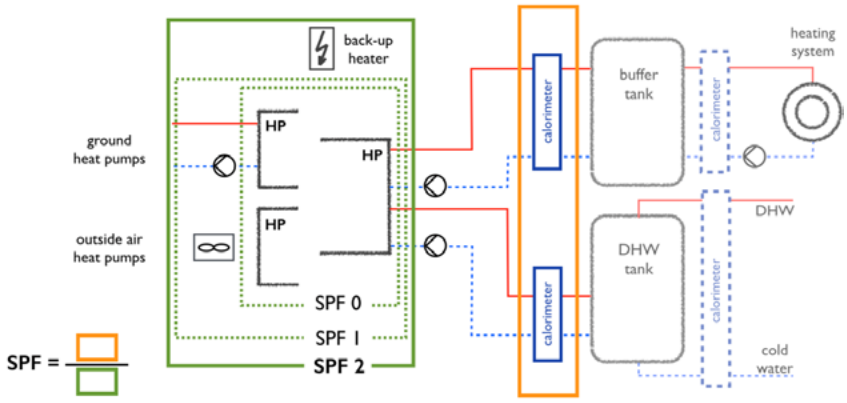

Fig. 1. Heat pump installation and the system boundaries for calculation of SPF values

The SPF is the ratio of the heat energy produced by the heat pump (not including the losses of the heat distribution system and the buffer tanks) and the back-up heater and the corresponding electric need of the heat pump, back-up heater and source fans in case of the A/W heat pump, brine pump in case of the B/W heat pump and well pump in case of W/W heat pump.

3.2. SPF values

Figure 2 shows average values of SPF values among individual projects, as well as the ranges of individual results for all heat pumps units grouped for different heat sources and projects. The comparison takes into

account outside-air heat pumps and ground-source heat pumps. Ground-water heat pumps were omitted due to a neglectable number of the examined installations. Calculation periods differ and are indicated for each project.

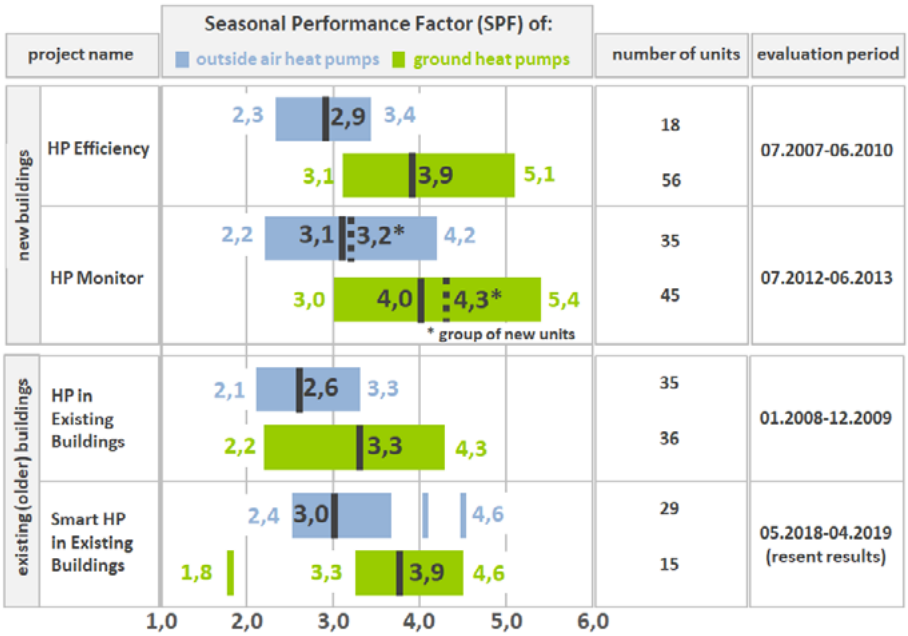

Fig. 2. Averages values and ranges of the SPF in existing residential houses in Germany

The differences in the average SPF values depend on a type of a heat source, type of a building and the period of installation (indicating improvement of technology). The difference between outside air heat pumps and ground heat pumps is evident to the benefit of ground source heat pumps. The ground as a heat source is more beneficial from the point of view of its temperature in the coldest periods with the most demand for heating.

Another important difference was noted between older and newer buildings. It results mainly from a type of the used heat distribution system. Underfloor systems, mostly used in newer buildings, enable lower supply temperatures compared to systems based on radiators in older buildings. Lower supply temperatures contribute significantly to higher efficiency of heat pumps.

In the framework of the "HP Monitor" project, a group of newly installed units (as opposite to the units transferred from the older project "HP Efficiency") was investigated separately (on the graph shown with the symbol *). The outcomes from this group indicate the improvement in the heat pump efficiency resulting from technology development in the recent years.

The results of all projects indicate smaller range of outcomes for individual systems with air-water heat pumps, compared with ground heat pumps. The wide range of SPF achieved by ground heat pumps (at least 2.0 points) indicates a high potential of efficient functioning of ground heat pumps. On the other hand, it shows that the choice of a heat source would not automatically guarantee a high efficiency. Errors in designing, installation and/or running process, result in a decrease of potential efficiency and diminish economical and ecological benefits of theoretically more efficient, but at the same time more expensive, heat source.

The newest results originate from the project "Smart HP in Existing Buildings". One year of evaluation shows following results:

- air-to-water heat pumps achieved the average SPF value of 3.0 with the range between 2.4 and 3.7. Two units with highest results reached the values of 4.1 and 4.6 and have not been reflected in the average value calculation.
- ground source heat pumps achieved average SPF value of 3.9 with the range between 3.3 and 4.6. The unit with the smallest value of 1.8 has not been reflected in the average value calculation.

Compering the results from the latest project with the older project “HP in Existing Buildings”, which has been performed 10 years ago also in existing buildings, the average efficiency increase is significant.

With all restrictions of the direct comparison of various projects (different houses, diverse average heating systems temperatures, unique weather condition for the year of evaluation), it may still be concluded that the efficiency of heat pumps increased in the recent years. Coincidently, the average efficiency results from the latest project with older existing buildings mirrored the results from the project in newly build residential houses conducted 10 years before.

4. Heating systems supply temperatures

The previous section discussed average data from all investigated heat pumps. The focus of this section will be analysis of a group of air-to-water heat pumps. The data are based on a one-year measurement period. The selection criteria for this group was the average heating system temperature. Only units with the temperature 36 °C [97 °F] and above were chosen for the evaluation, in total 16 units.

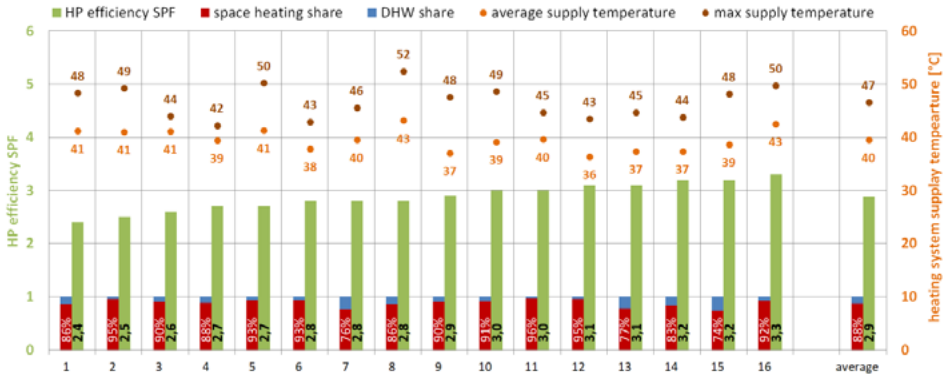

Fig. 3. Heat sink characteristic of 16 air-to-water heat pumps operating in existing residential houses in Germany evaluated over a one-year period

Fig. 3 shows the sink side (heat distribution side) characteristic of the 16 air-to-water heat pumps including their efficiency (green columns). The average SPF value for the whole group of installations amounts to 2.9 with the range from 2.4 to 3.3. The percentage share of the delivered heat in space heating mode (in red) and DHW (domestic hot water) mode (in blue) have been shown on the left side of each efficiency column. The extreme right columns symbolize the average values of all systems. In average, the share of the heat delivered for the space heating equals 88% and the share of DHW heat equals 12%.

Above the columns, two types of the heating system supply temperatures have been shown. The lower one (in orange) indicates the average heating system temperature (supply minus return temperature) over the whole period of evaluation. The higher values (in brown) indicate the maximal daily heating system supply temperatures (only in space heating mode) measured during the heating season.

For the further considerations, it is important to differentiate between three types of heating system temperatures. First one, and usually the highest one, the *design temperature*, is determined by the planning of the heating system and planned for the normative regional lowest outside air temperature. The second one, the lowest, is the *average temperature calculated (or measured) for the whole heating season*. This temperature, indicated on the fig. 3, is significant for the average efficiency of the heat pump and consequently for the ecological and economical results of the system. The third one is the *highest (daily) measured temperature*. This temperature indicates the best the real weather condition, respectively the real lowest outside temperatures.

The investigated group of heat pumps shows considerable low average heating system temperatures, in particular in the light of the fact that the heat distribution in rooms is based on radiators in the majority of the systems. The average value of all units equals to 40 °C (104 °F). The highest average temperature, in the units numbered 8 and 16 equals to 43 °C (109 °F).

The highest maximal daily temperatures are in average 7 K higher. The highest maximal temperature is observed in the unit 8 and equals to 53° C (127 °F). The highest delta between average and maximal temperature is observed in unit 9 and equals to 11 K. In general, the maximum temperatures measured during the heating season are lower than the design temperatures of the systems. The one reason for this situation is

the lower real outside temperature than the normative one used during the planning. The second reason is link to the features of radiators in older buildings. Very often their size is over dimensioned and the actual temperatures required to deliver the necessary amount of heat to the rooms, can be lower than those designed.

Detail analysis of the heating system temperature for exceptional heat pump system is conducted in the next section.

5. Maximal heating supply temperatures

In the discussion about the applicability of heat pumps in existing buildings, the main argument against this solution is the assumed high heating supply temperature, leading to poor performance of heat pumps and consequently to exclusion criteria.

The previous section presented and discussed the average and the maximal heating supply temperatures for a group of heat pumps installations. Bellow, one exemplary installation will be analyzed. It concerns the air-to-water variable speed heat pump installed in a partly retrofitted building. The space heat distribution system bases on radiators (water based system). The investigated time period is the heating season 2018/19.

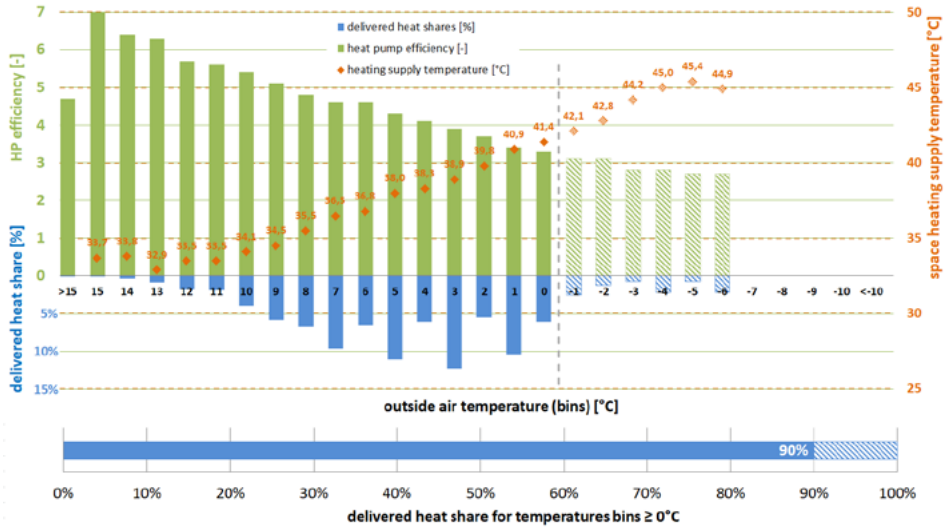

Fig. 4. Delivered heat share for temperature bins in dependency of the efficiency of the heat pump and space heating supply temperature (heating season 2018/2019 in Germany)

Fig. 4 shows the share of delivered heat (blue bars), for space heating, for each temperature bin. The distribution shows a typical bell-shape with the largest share of heating energy delivered by the outside air temperature of 3 °C (37 °F). The shares for the temperature bins below 0 °C and higher than 9 °C, are in the range of 1% to 4% of the total delivered heat and thereby play only a secondary role. The heating energy delivered for the outside air temperatures below 0 °C (32 °F) amounts only to 10% of the total delivered heating energy, which is shown in the lower part of the graph.

Fig. 4 shows additionally the heating system supply temperature (in orange) for each temperature bin and corresponding heat pump efficiency (in green). The supply temperature is clearly depending on the outside temperature and rises from approximately 33 °C (91 °F) to 45 °C (113 °F), which means a temperature rise of 12 K. Obviously, the highest supply temperatures of more than 42 °C (108 °F) are needed for the lowest outside air temperatures (below 0 °C). Also the efficiency of the heat pump clearly depends on the outside air temperature and, consequently, on the supply temperature (delta between evaporating and condensing is getting higher). The overall average efficiency of the heat pump equals to 4.2. The efficiency calculated for the temperature bins 0 °C and higher (without the coldest outside temperatures and highest heating system supply temperatures) equals to 4,0.

As expected, the highest supply temperatures of the heating system meet the lowest outside temperatures, causing the lowest efficiency of the heat pump. However the amount of delivered heat under these conditions

(in the presented example 10%) is rather small and affects the total efficiency of the heat pump only in a minor way.

It has to be noticed, that similar behavior has been noted in several further examples, even if the absolute values of the supply temperature differed.

6. Ecological assessment of the heat pumps efficiency results

The comparison of various heating technologies may be performed by using several indicators. The three most used ones are: economy, ecology and primary energy. The results of such comparison are strongly linked with the local situation and vary considerably from country to country and sometimes from region to region. To illustrate how differently the some technology may be evaluated, following section will show the CO_2 emissions saving potential of heat pumps when compared to a natural gas boiler, in different geographical boundaries.

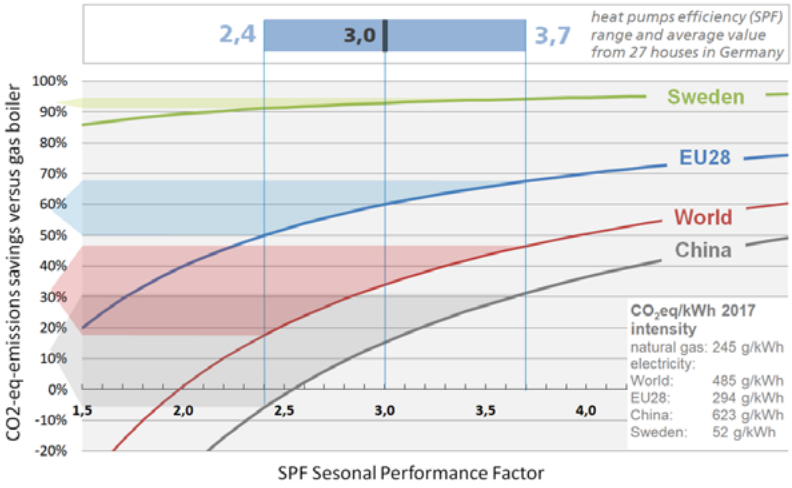

Fig. 5. CO2 emissions saving with heat pumps in dependency of CO2 electricity production intensity

Fig. 5 shows the dependency between the efficiency of a heat pump (impressed in SPF – Seasonal Performance Factor) and CO_2 emissions savings versus natural gas boiler. Crucial for that comparison is the CO_2 intensity of the electricity production in a particular region. The source for the values used for the calculation is the "IEA CO_2 emissions from fuel combustion statistics 2019" and the aggregated data from www.ElectricityMap.org, who track real-time carbon-intensity.

Following geographical regions have been taken in to account: global (the world), 28 European Union countries (EU28), China and Sweden. The CO_2 electricity intensity values are indicated on the lower right corner of the graph. The CO_2 values for the heat generation with natural gas have been taken equal for all regions. To simplify the calculation, the efficiency of the gas boiler has been assumed as 100%. Each colored line on the graph indicates one region (from the top: green – Sweden, blue – EU28, red – the world and grey – China).

The crossing point between virtual vertical line symbolizing the efficiency of the heat pump and the "region" line indicates the CO_2 savings. For example the efficiency of 3.0 means for the EU28 boundary CO_2 savings of 60% compared to natural gas boiler. Second example – the efficiency of 2.0 means for "the world" an even situation (no savings).

The efficiency results from the field measurement of air-to-water heat pumps systems in existing buildings (described in detail in the previous sections), have been indicated in the upper part of the graph.

It is clearly visible, that the same efficiency value leads to varied CO_2 comparison findings. Considering the average efficiency value of 3,0; the saving in China equals to 15%, in "the world" to 34%, in the EU28 – 60% and in Sweden, with the cleanest electricity production, even to 93%.

Also consideration of the efficiency range from 2,4 to 3,7 leads to fully different savings ranges. The largest range from -6% to 31% can be noted in China. The next one – 18% to 47% globally, 50% to 68% in the EU28 and finally 91% to 95% in Sweden.

Concluding, heat pumps or their efficiency may be judged in a diverse way depending on the CO_2 electricity intensity in a particular country or region. The same rule equally applies to the economical evaluation.

Second conclusion is that the "greener" the electricity, the lesser impact has the heat pump efficiency on the CO_2 savings. The countries or regions with less clean electricity have much larger potential for a considerable increase of the savings through increasing the heat pumps efficiency, even if in absolute terms it would be on a lower level (i.e. the increase of CO_2 savings in Sweden may be achieved solely in single percentage, reaching already more than 90%),

7. Case studies

On the website of the project "Smart Heat Pumps in Existing Buildings" in the section "Live Data" (https://wp-monitoring.ise.fraunhofer.de/wp-smart-im-bestand/german/index/live_visu.html) a number of heat pump installations has been visualized. The "live" data are updated daily. The user of the website has the possibility to read description of the house and the heat pump and analyze the hydraulic schema of the installation (including measured values from the sensors). It is also possible to see the efficiency results for different periods of evaluation, and "play" (changing the calculation boundary, for example with or without domestic hot water or back-up heater) with the efficiency results diagram. In addition, the real costs, as well as the ecological and energetical comparison with other heating technologies are shown.

8. Conclusions

Heat pumps are able to provide the required heat for space heating and domestic hot water not only in new but also in partly-retrofitted or even not-retrofitted residential buildings. It has been proven in the field test with sixty heat pump systems in existing buildings in Germany, which investigated both ground source and air-to-water heat pumps.

As evidenced by the field test, the average efficiency for the air-to-water heat pumps amounts to 3.0 with the range from 2.4 to 3.7. Ground source heat pumps reach the average efficiency of 3.9 with the range from 3.3 to 4.6. The efficiency results are very close to the results reached in previous field test project performed six years earlier in new buildings. This indicates the positive development of the technology and of the installations processes. Due to the variety of investigated units and of other influencing aspects, it is not possible to accurately quantify the mentioned developments.

Both measured average heating system temperatures and maximal supply temperatures for space heating in investigated houses are lower than generally expected in existing (oft not-retrofitted houses). The majority of heat for space heating is delivered not in the days with the lowest outside air temperatures. This explains the relatively low average heating systems temperatures. The delta between the real maximal temperature and the design heating system temperature may be explained by milder than assumed weather during the year of investigation, general oversizing of the radiators in older buildings and lower energy demand through renovation measures applied to the house envelope.

Heat pumps or their efficiency may be judged in various ways depending on the CO_2 electricity intensity in a particular country or region. The same rule equally applies to the economical evaluation. Taking as a basis for the evaluation the efficiency reached during the field test performed by the Fraunhofer ISE in the last 15 years in Germany, heat pumps perform well under real operation conditions ensuring in most cases significant CO_2 savings compared to natural gas boilers. It applies to the vast majority of the countries and world´s regions.

Acknowledgements

The implementation of a monitoring project is a challenging and complex task. The execution of the projects and the evaluation of the test results required participation of more than a hundred persons assisting for several years. Thus, special thanks are directed to all employees and former employees who assisted in this task, as well as to all industrial and institutional partners who made the whole implementation possible. This work was supported by the German Ministry of Economics and Technology (BMWi), under the Grant 03ET1272A upon decision of the German Bundestag and supervised by the Project Manager Jülich (PTJ).

Abstract

Hydro-fluoro-olefins and hydro-chloro-fluoro-olefins, such as R1234ze(E), R1234ze(Z), and R1233zd(E), are anticipated to become low global warming potential refrigerants to replace R134a and R245fa for industrial heat pump systems. Experimental data on the heat transfer coefficient of saturated pool boiling of R1233zd(E) on a horizontal fin tube were obtained in this study. The test tube was 19.05 mm in diameter and 400 mm in heat transfer length. The heat transfer coefficients in the two kinds of fin tube were compared. The heat transfer characteristics differed according to the slit on cover of tunnel structure.

Keywords: evaporation, heat transfer coefficient, pool boiling, expansion ;

1. Introduction

Hydro-fluoro-olefins (HFOs) and hydro-chloro-fluoro-olefins (HCFOs), such as R1234ze(E), R1234ze(Z), and R1233zd(E), are expected to become low global warming potential (GWP) refrigerants, which will replace R134a and R245fa for industrial heat pump systems. The normal boiling points of most alternative refrigerant candidate in HFOs and HCFOs are higher than those of hydrofluorocarbons (HFCs). Therefore, suitable tube shape for HFOs and HCFOs is different from that for HFCs. However, the heat transfer characteristics of HFOs and HCFOs have not been investigated.

In this study, experimental data on the heat transfer coefficient (HTC) of saturated pool boiling of R1233zd(E) on a horizontal fin tube are presented.

2. Experiment

2.1. Experimental Apparatus

Fig. 1 shows an experimental apparatus to measure the condensation and pool boiling HTC on a horizontal smooth tube. This is a natural circulation system, in which the liquid refrigerant condensed on a test tube (4) and subcondensers (6) flows down to a boiling chamber, while the vapor evaporated on the test tube and electric heaters (8) returns to a condensation chamber. The flow rate of the condensate flowing down a drain pan (5) is measured by a Coriolis mass flow meter (7). The heat transfer on the test tube is obtained from the temperature change measured in the mixing chambers and the flow rate of the water flows in the test tubes. To determine the refrigerant saturation temperature, the pressure is measured very close to the test tube. The saturation temperature is checked with the temperature measured by K-type thermocouples installed in those chambers. An electric current of 40 A is conducted to the test tube, so that the mean wall temperature is calculated as a function of the electric resistance measured by a voltage meter. The wall temperature is calibrated in the preliminary test; meanwhile, the heat loss from the chambers to ambient air is also measured. The heat flux on the tube wall is defined as follows:

E-mail address: s.fukuda@ip.kyusan-u.ac.jp

$$q_{\text{wall}} = \frac{V_{\text{H}_2\text{O}}\rho_{\text{H}_2\text{O}}\left(h_{\text{H}_2\text{O,o}} - h_{\text{H}_2\text{O,i}}\right) - Q_{\text{loss}}}{\pi D_{\text{o}} L} \tag{1}$$

where V_{H2O}, ρ_{H2O}, and h_{H2O} are the volumetric flow rate, density, and specific enthalpy of water, respectively, evaluated at the arithmetic mean of $T_{\text{H2O,i}}$ and $T_{\text{H2O,o}}$. Q_{loss} is the heat loss correlated to the temperature difference between water and ambient air. D_{o} and L are the outer diameter and effective heat transfer length of the test tube. Therefore, the HTC is expressed as follows:

$$\alpha = \frac{q_{\text{wall}}}{T_{\text{sat}} - T_{\text{wall}}} \tag{2}$$

where T_{sat} is the saturation temperature evaluated at the measured pressure. T_{wall} is the tube wall temperature correlated to the electric resistance. The thermodynamic and transport properties of R1233zd(E) are calculated by REFPROP Ver. 10 [1] with the incorporated coefficients optimized by Akasaka et al. [2].

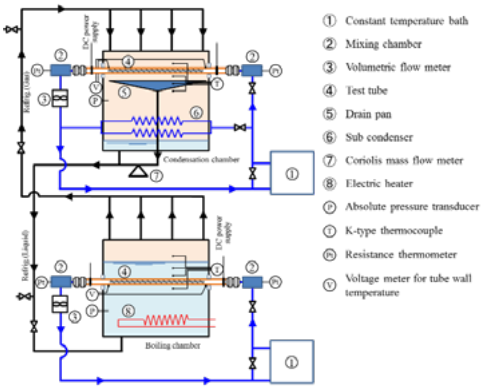

Fig. 1. Schematic diagram of experimental apparatus

2.2. Experimental condition and method

The test refrigerant was R1233zd(E). The HTC was quantified at a saturation temperature of 10°C. The measurement range of heat flux was from 3 to 20 kW·m^{-2} for pool boiling.

2.3. Test tubes

The three kinds of test tubes, which were made of copper, had 19.12-mm outer diameter and 400-mm heat transfer length (tubes A, B, and C), and they were set in a perfectly horizontal configuration. As an example, Fig. 2 shows the external appearance of tube B. The three enhanced tubes had different fin geometries, including the tunnel structure. The difference of the tubes was the size of slit on cover of tunnel structure, as shown Fig. 3. In the order of tubes A, B, and C, the slit on the cover became smaller. For all tubes, the tunnel structure sizes were approximately the same.

Fig. 2. External appearance of tube B

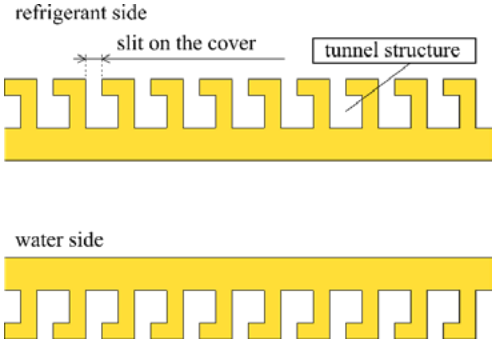

Fig. 3. Schematic diagram of test tubes

3. Results and discussion

Fig. 4 shows the variation in boiling HTC with heat flux in test tubes A, B, and C. The circle, triangle, and square represent tube A, tube B, and tube C, respectively. The symbols are the experimental values of HTC, with the vertical bars indicating the measurement uncertainty of HTC. In general, boiling HTC increases with increase in heat flux.

Boiling HTC of tube B was considerably higher than that of tube A. This was caused by the promotion of the nucleate boiling and the boiling by a thin liquid film. In tube B, when the refrigerant boiled, local pressure became higher by the cover of the tunnel structure. However, in tube A, local pressure did not increase, because the slit on the cover was wide. Then, the nuclear boiling in tube B was promoted. Furthermore, the heat transfer in tube B was promoted by the thin liquid film. In tube B, most of the generated bubbles were exhausted from the upper part of the tube through the tunnel structure, because the slit on the cover was small (a small number of generated bubbles were exhausted by the slit on the cover). A thin liquid film was formed by surface tension as bubbles moved along the tunnel structure. However, in tube A, the generated bubbles were exhausted from the slit on the cover. Then, the heat transfer in tube A was not promoted.

Boiling HTC of tube B was considerably higher than that of tube C. The slit on the cover of tube C was smaller than that of tube B. Then, nuclear boiling in tube C was promoted, as with tube B. However, the HTC of tube C decreased because of a dry patch. In tube C, dryout occurred on part of the heat transfer surface because the slit on the cover was too small, making it difficult for the bubbles to be exhausted.

Therefore, boiling HTC of tube B was considerably higher than those of tubes A and B, because there was an appropriate size in the slit on the cover.

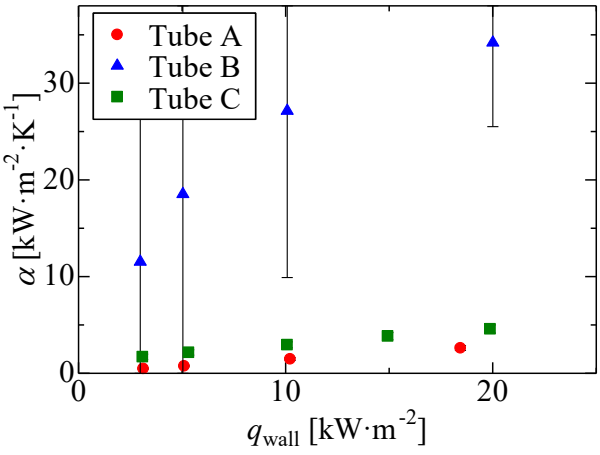

Fig. 4. Variation in boiling HTC with heat flux

4. Conclusion

The experimentally determined HTCs of low-GWP refrigerants of R1233zd(E) on three horizontally installed enhanced tubes were presented. The main conclusions are as follows:

- The HTC was improved by nuclear boiling as well as boiling by the thin liquid film promoted by the tunnel structure and slit on the cover of tunnel structure.
- The slit of the cover of tunnel structure had an appropriate size.

Abstract

This work investigates the performance of a model predictive controller for customer-sited energy transfer substations, installed in fifth generation district heating and cooling networks (5GDHC) that include electrically driven heat pumps and thermal energy storage systems. Using heat pumps effectively couples the thermal and electrical distribution networks at the individual building level, which opens the door to new scenarios in terms of smart management of urban energy systems. The model predictive controller (MPC) implemented includes two key elements based on artificial intelligence: a composite model of the 5GDHC substation based on several artificial neural networks (ANN) and a constrained optimization solver based on particle swarm optimization (PSO). This study focuses on the analysis performed to test the predictive controller and to understand how it affects the substation energy performance and the building owner's energy bill under different boundary conditions. Moreover, the capacity of the MPC in providing demand flexibility to the power grid has been evaluated through a load shifting strategy obtained by exploiting the capacity of the substation's thermal energy storage.

Keywords: Smart energy systems; Artificial neural networks; Receding horizon control.

1. Introduction

District heating and cooling is acknowledged as a sustainable solution to meet heating and cooling demands in high-density urban areas. This technology has evolved in the last decades towards low distribution temperature in the network and decentralized active plants and substations. These developments enhance the inclusion of renewable heat sources, a reduction of heat losses with the consequence of a more complicated energy system. Fifth-generation district heating and cooling (5GDHC) systems operate at a temperature range between 0÷30°C that is not suitable for direct heating purposes even with low-temperature heat emission systems like floor heating or ceiling panels. Because of the neutral temperature of the network with respect to the ground, heat losses are minimized, and all available urban low-temperature excess heat can be recovered and reused according to circular economy principles. These pros are paid for with the fact that water-source heat pumps, usually electrically driven, are needed in the customer-sited energy transfer stations to boost the temperature of the supplied heat to satisfy the user comfort as shown in Fig. 1. 5GDHC substations can be hydraulically complicated compared to traditional district heating (DH) user substation and in general, are operated to supply space heating (SH) and domestic hot water (DHW) or active/passive space cooling (SC). Consequently, a reversible 5GDHC substation can be considered a "prosumer" that can extract heat from the thermal network in heating mode as a common end-user, or that can supply heat to the network in cooling mode as a producer.

The interest in 5GDHC systems is growing in Europe with an installation rate of three systems per year on average in the last decade [1]. Existing 5GDHC networks will be expanded and new ones will be built in the

framework of the Interreg project D2grid [2] and H2020 REWARDHeat [3], both launched in 2019. Several utility companies have started exploiting the advantages of supplying simultaneously heating and cooling by means of a single network, extending the operation of the DHC system and their economic revenues all year round.

This study focuses on the development of an advanced decentralized controller for 5GDHC substations with a focus on the optimization of DHW production. The method adopted for the controller implementation is presented in Section 2 whereas the results of preliminary tests are discussed in Section 3.

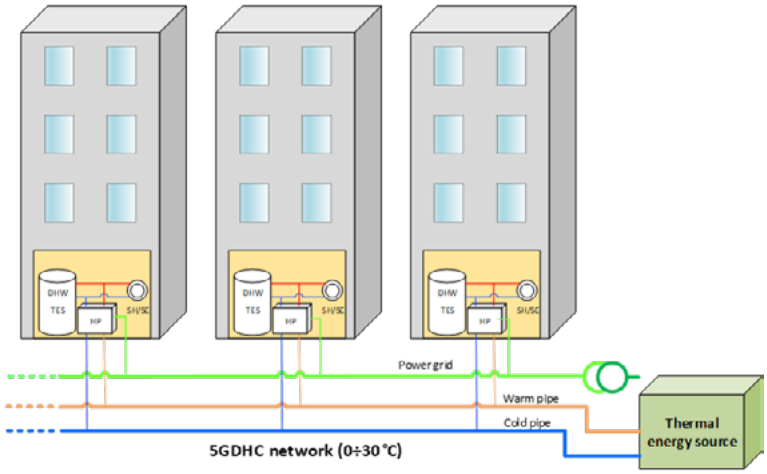

Fig. 1. Layout of a 5GDHC system.

2. Methodology

The advanced controller for 5GDHC substations has been implemented in the form of artificial neural network-based model predictive control (ANN-MPC). A literature review about the MPC application for HVAC systems can be found in Afram and Janabi-Sharifi (2014) [4].

In general, MPC employs an explicit model of the system whose identification phase is usually demanding in terms of development time and effort. At each control timestep, the state of this model is updated from measurements, and the model is used to make several predictions of the future behaviour of the system according to a sequence of the control inputs $\bar{u}(t)$ that are applied. MPC is a form of optimal control since it involves an optimization algorithm that solves in real-time a constrained optimization problem providing the sequence of the control variables that minimises (or maximises) a given objective function over a time window, satisfying the problem constraints. At the current time-step t, only the first value of the optimal trajectory identified by the MPC is applied to the system. At the next control timestep $t+1$, the procedure is repeated with a prediction horizon window shifted by one control timestep. This methodology is known as receding horizon model predictive control approach. To limit the computational effort of the controller, it is a common practice to apply a move blocking strategy so that the length M of the control input vector $\bar{u}(t)$ is shorter than the prediction horizon length N and the last element of control input vector $\bar{u}(t)$ is kept constant for the remaining timestep of the prediction horizon.

MPC can be applied in general in the form of a multi-input multi-output (MIMO) system that aims at minimising an objective function that includes a tracking error with respect to a reference value and the control effort over the prediction horizon. Conversely, as in this study, MPC can be also employed as a supervisory controller developed in the form of an economic MPC since the objective function to be minimised includes system economics. A black-box model of the considered system has been developed in the form of artificial neural networks (ANNs). This reduced-order model (ROM), presented in the next section, has been used as a surrogate model of the real system to perform at each control timestep t a prediction of its performance over the prediction horizon.

2.1. Reduced order model (ROM) of the 5GDHC substation

Reduced order models (ROMs) is the term used for simplified models of complex systems that can capture the system performance maintaining adequate accuracy. The growing application of machine learning algorithms in building energy systems allow the development of ROMs that in general exhibit the following advantages (+) and disadvantages (-) with respect to fully defined physics-based building energy models:

(+) the building and the energy system feature do not need to be fully defined;
(+) simplified models can be aggregated to build complex models with a bottom-up approach;
(+) they have a short simulation runtime that is important especially in real-time systems;
(+) a predefined model architecture can be employed in different case studies;
(-) to create the model a diverse training dataset is needed so that the model can experience different possible conditions;
(-) the model outputs depend on the temporal resolution of the training dataset;
(-) the model outputs cannot be explained by physical laws and must be interpreted.

There are several ways to build data-driven ROMs of HVAC systems. In particular, in Afram and Janabi-Sharifi (2015) [5] artificial neural networks (ANNs) outperform different black-box models as well as grey-box models of the same HVAC components installed in a single-family house. Moreover, in Esen and Inalli (2010) [6], [7] and in Li et al. (2011) [8] it was shown that adaptive network-based fuzzy inference system (ANFIS) models overperform ANN models for a ground-source heat pump (GSHP) system and for the prediction of the building electricity, hot and cold water loads, respectively. Nevertheless, ANFIS models require more complicated architectures as well as more complicated training algorithms. For this reason, the present study focuses on the development of ROMs based on ANNs that can be used in a real-time control system for a 5GDHC substation.

ANN-based MPC consists of the application where a single ANN model or a group of interconnected ANN models are used as a surrogate model of the system in an MPC controller [9]. Afram et al. (2017) [10] performed an extensive review of the application of ANN-MPC for the optimization of HVAC systems operation. The authors highlighted that this approach has been applied especially in commercial, public and office buildings in the last years because the HVAC systems of such large buildings are usually equipped with a building energy management system that can handle the outputs of an MPC controller. This is not the case for residential buildings that represent the largest share of the building stock. Nevertheless, residential buildings can harness several economic and environmental advantages through the exploitation of MPC technology and can provide flexibility to both electrical and thermal grids. Since 5GDHC systems pave the way for decentralised sector coupling exploiting customer-sited energy transfer substations, the ANN-MPC technology has been developed to operate a substation of this kind supplying a small multifamily house.

2.2. Optimization algorithm

As is described in Afram et al. (2017) [10], different nonlinear optimization methods have been used in the field of ANN-MPC like genetic algorithms (GA), Newton-Raphson, branch and bound, etc. Nevertheless, among the metaheuristic methods, GA is the most widely used in ANN-MPC studies. It is able to solve both constrained and unconstrained problems and to deal with integer values. These pros are paid for with slow convergence for complex problems so that it can be not suitable for real-time implementation. Particle swarm optimization (PSO) algorithm is considered a well-balanced method to solve both single and multi-objective optimization problems with low computational time [10]. For this reason, this optimization algorithm has been chosen in this study for the implementation of a real-time MPC controller.

PSO is a biologically inspired meta-heuristic methodology. This population-based algorithm is useful in solving optimization problems where the analytical expression of the gradient of the cost function is not available or difficult to assess. It consists of a population of interacting agents that directly search for the minimum of the cost function in a multi-dimensional domain with no information about the gradient (unknown environment). It is inspired by the collective behaviour of species like birds (flocking) and fishes (shoaling and schooling). This concept is part of the artificial intelligence discipline under the name of “swarm intelligence”. The LabVIEW code used in this work was derived from the “perturbed Particle Swarm Optimization” (pPSO) algorithm that is part of the Advanced Metaheuristics Algorithms library implemented by Derouiche M. L. (2015) [11] on the basis of the work of Xinchao Z. (2010) [12], and available at [13].

The algorithm implemented by Derouiche M. L. (2015) has been designed to have as output a real number. Nevertheless, since the HP of the 5GDHC substation operates in ON-OFF mode the algorithm has been modified to handle a binary output. This has been done according to the proposal of Kennedy and Eberhart (1997) [14] where the velocities of the particles are treated as "probabilities of change" and their position results in a 0 or 1 state.

2.3. Physical model of a 5GDHC substation

In order to build the reduced order model (ROM) of the 5GDHC substation, a physical model in TRNSYS [15] has been set up in order to create a dataset used for training the data-driven model based on artificial neural networks (ANNs). The physical model of the 5GDHC substation has been built using Type 927 of the TESS library to model the water-source heat pump (WSHP) system and Type 534 of the TESS library to model the DHW TES and the SH/SC buffer tanks. The 5GDHC network is not modelled and it is considered an ideal thermal energy source that supplies the substation at a constant temperature of 15°C. The 5GDHC substation has been sized to meet the space heating (SH) and domestic hot water (DHW) demands of a small multi-family house located in Rome and has a thermal capacity of about 23 kWth. The residential building has a total of 10 apartments divided into 5 floors. Every single apartment has a floor area of 50 m2 and an energy net demand level of about 45 kWh/m2 per year for space heating (SH) according to the study performed in Fedrizzi et al. (2015) [16]. Accordingly, the specific DHW load results in 24 kWh/m2 per year and it has been obtained by generating the DHW draw profile by means of the tool DHWcalc V.2.02b [17] considering an occupancy level of 2 people/apartment and specific hot water demand of 40 l/(person day). The building heat emission system consists of ceiling radiant panels that are supplied by the 5GDHC substation. The SH demand profile has been obtained from a separate dynamic numerical simulation of the building using Type 56 and used as a boundary condition for the substation.

The performance map of the water source heat pump (WSHP) has been calibrated and validated by means of dedicated tests at the Energy Exchange Laboratory of EURAC Research in Bolzano-Bozen (Italy) [18]. The tests have been performed by first fixing a constant inlet temperature at the evaporator and varying the inlet temperature at the condenser, thereafter fixing a constant inlet temperature at the condenser and varying the inlet temperature at the evaporator. The results of the calibrated HP model concerning the thermal power measured at the evaporator and condenser as well as the electricity consumption fall within the measurement uncertainty band under almost all operating conditions.

2.4. Reduced order model (ROM) of a 5GDHC substation

The reduced order model (ROM) of the 5GDHC substation has been built by adopting a modular approach and using one ANN to model each single component. The composite model of the 5GDHC substation is obtained by connecting, in a proper way the input-output of an ANN model of the DHW TES system and an ANN model of the HP. To achieve this goal, the two ANN models have been trained separately using a dataset of 20 days obtained from the TRNSYS simulation of the validated 5GDHC substation model. The time resolution adopted to model the system is 10 minutes, short enough to capture the system dynamics and allowing the possibility of taking into account a "cost" for the change of state (ON-OFF) of the HP. This timestep is also large enough to keep the computational effort acceptable. The same control timestep of 10 minutes has been adopted for the optimization problem of the MPC. It is important that the ANN models are developed with the same timestep of the optimization problem so that during the MPC real-time simulation the variables exchanged, that are in this case thermal energy, are the results of the integration of thermal power profiles over the same control timestep. The ANN structure adopted in this study for the two models is the same: nonlinear autoregressive network with exogenous inputs (NARX). This kind of ANN differs from the standard multilayer perceptron (MLP) because includes feedback from the outputs.

The variables considered in the development of a 5GDHC substation ANN model are listed in Table 1. The thermal energy delivered by the HP to the DHW TES ($E_{th,HP,DHW}$) in one control timestep (4 kWhth) represents the control variable and its trajectory is provided according to the binary output of the MPC. During the MPC simulation, the trajectories of $E_{th,HP,DHW}$ are provided to the ANN model to perform an on-line simulation. This variable is provided to both the TES and HP models, simultaneously. The DHW TES system ANN model inputs are the thermal energy supplied to the DHW TES by the HP ($E_{th,HP,DHW}$) and the DHW load covered by the DHW TES ($E_{th,load}$). The two outputs are the temperature at the top (T_{top}) and at the bottom (T_{bot}), respectively. The ANN has 15 neurons in the hidden layer where the tangent-sigmoid activation function has been used, whereas for the output layer the linear activation function has been adopted.

The ANN model of the HP has 15 neurons in the hidden layer. The tangent-sigmoid and the linear activation functions have been adopted in the hidden and output layer, respectively. The model inputs are three: the thermal energy provided by the HP to the DHW TES ($E_{th,HP,DHW}$), the inlet temperature of the HP at the condenser ($T_{in,load}$) and the inlet temperature of the HP at the evaporator ($T_{in,source}$). The model provides as outputs the electricity consumption of the substation ($E_{el,SUB}$) and the thermal energy extracted by the HP from the DHC network ($E_{th,SUB}$).

Table 1 Inputs and outputs description of the implemented ANN models.

		ANN Model of the TES		**ANN Model of the HP**	
		Input variables	Output variables	Input variables	Output variables
Input at	$t = t_k$	1- $E_{th,HP,DHW}$ $[kWh]$ 2- $E_{th,load}$ $[kWh]$	1- T_{top} $[°C]$ 2- T_{bot} $[°C]$	1- $E_{th,HP,DHW}$ $[kWh]$ 2- $T_{in,load}$ $[°C]$ 3- $T_{in,source}$ $[°C]$	1- $E_{el,SUB}$ $[kWh]$ 2- $E_{th,SUB}$ $[kWh]$
Input TDL at	$t = t_{k-1}$	3- $E_{th,HP,DHW}$ $[kWh]$ 4- $E_{th,load}$ $[kWh]$		4- $E_{th,HP,DHW}$ $[kWh]$ 5- $T_{in,load}$ $[°C]$ 6- $T_{in,source}$ $[°C]$	
Output TDL at	$t = t_{k-1}$	5- T_{top} $[°C]$ 6- T_{bot} $[°C]$		7- $E_{el,SUB}$ $[kWh]$ 8- $E_{th,SUB}$ $[kWh]$	

The validation of the ANN models has been performed comparing the outputs with a dataset from a physical model simulation of 24 hours (144 timesteps of 10 minutes) not used for the ANN training. The performance metrics assessed for this purpose over the entire simulation are the normalised mean bias error and the coefficient of variation of the root mean square error for the variable ζ_j presented in Equations 1 and 2, where m_i the measured value and s_i is the simulated one of the variable ζ_j.

$$NMBE_{\zeta_j} = \frac{1}{\bar{m}_j} \frac{\sum_{i=1}^{n}(m_{j,i} - s_{j,i})}{n} \cdot 100(\%) \quad (1)$$

$$CVRMSE_{\zeta_j} = \frac{1}{\bar{m}_j} \sqrt{\frac{\sum_{i=1}^{n}(m_{j,i} - s_{j,i})^2}{n-1}} \cdot 100(\%) \quad (2)$$

For the ANN model of the DHW TES a CVRMSE of 2.1% has been obtained for the temperature at the top (T_{top}) and a CVRMSE of 4.9% for the temperature at the bottom (T_{bot}). For the ANN model of the HP a CVRMSE of 1.3% has been achieved for the electricity consumption ($E_{el,SUB}$) and a CVRMSE of 0.8% has been achieved for the thermal energy extracted by the HP from the source ($E_{th,SUB}$). The NMBE for all the variables resulted in less than 1%.

2.5. Cost function

The MPC controller has been implemented as an economic MPC task since the objective function to minimise is the operating costs of the 5GDHC substation over the prediction horizon with N timesteps $[t_0, \dots, t_k, \dots, t_{k+N-1}]$. As shown by Equation 3 the operating cost calculation considers at each timestep t_j, $E_{el,SUB}(t_j)$: the electricity consumption of the substation and its auxiliaries, $c_{el}(t_j)$: the specific cost of electricity, $E_{th,SUB}(t_j)$: the thermal energy supplied by the 5GDHC network to the substation and $c_{th,dhc}(t_j)$: its specific cost.

$$J(t_j) = \sum_{j=k}^{k+N-1} c_{el}(t_j) E_{el,SUB}(t_j) + \sum_{j=k}^{k+N-1} c_{th,dhc}(t_j)\, E_{th,SUB}(t_j) \quad (3)$$

Moreover, in order to minimise the number of ON-OFF switching events of the HP that are cause of inefficiencies and stress for both electrical and mechanical components as shown by Curtis and Pine (2012) [19], a "state change cost" $K(t_j)$ has been added in the cost function and implemented according to Equation 4: the state variations of the HP over the prediction horizon N are counted and weighted by a factor β that has been set equal to 1 in this study.

$$K(t_j) = \beta \sum_{j=k}^{k+N-1} \left| s(t_j) - s(t_{j-1}) \right| \quad (4)$$

The PSO algorithm used here has been conceived to solve unconstrained problems. To handle the MPC problem, the constraints have been included in the cost function in the form of soft constraints as suggested by Derouiche et al. (2016) [11]. The method applied here is the external static penalty technique so that the value of the objective function increases proportionally to the degree of constraint infeasibility. The constrains must be verified over the control horizon and are implemented as follows:

- the temperature at the top of the DHW TES must be higher than 45°C to satisfy the comfort needs as described by Equation 5:

$$\min_{t_j \geq 0} T_{top,DHW}(t_j) > T_{top,DHW,min} = 45°C \quad (5)$$

- the temperature at the top of the DHW TES must be lower than 55°C to satisfy the operating limits of high temperature and high pressure of the refrigerant at the HP condenser that has been verified through dedicated tests at the Energy Exchange Laboratory:

$$\max_{t_j \geq 0} T_{top,DHW}(t_j) < T_{top,DHW,max} = 55°C \quad (6)$$

The overall cost function is implemented so that at each control timestep it is called by the optimization algorithm and it is assessed considering the different trajectories of the ANN model outputs and of the boundary conditions over the prediction horizon N. To increase the robustness of the controller, the MPC outputs are filtered through a back-up rule-based controller (RBC) so that the DHW TES is charged if the temperature at the top accidentally drops below 45°C or it is no longer charged if the temperature at the top could reach a value higher than 55°C.

In the next section, the results of two separated tests are presented with a perfect prediction of the DHW load. In both cases, a prediction horizon of three hours $(N = 18)$ and a control horizon of one hour $(M = 6)$ have been selected. Test 1 deals with the assessment of the behaviour of the MPC controller both with and without model mismatch between the model used in the MPC and the one used to simulate the controlled system. In Test 2 the results of different scenarios over a simulation of one month (January 2017) are presented. The boundary conditions include a time-of-use (TOU) electricity price variation as a form of demand response (DR) strategy based on the Italian tariff D1 taken as a reference. According to this, the peak period is defined as the time between 8:00 and 19:00 on work days. The aim is to compare the results of a standard rule-based control (RBC) strategy versus MPC only to cover the DHW load through the assessment of the following KPIs:

- $T_{top,max}$ and $T_{top,min}$ are the maximum and minimum temperature value at the top of the DHW TES (controlled variable) over the simulation period;
- T_{ave} is the volume average temperature the DHW TES over the simulation period;
- $E_{el,sub}$ and $E_{th,sub}$ are the electricity and thermal energy consumptions of the substation coming from the electrical and thermal grids during the DHW operation mode;
- E_{load} is the DHW load covered by the substation;
- COP_{sub} is the coefficient of performance of the substation including the HP and auxiliaries in DHW operation mode calculated as the ratio between E_{load} and $E_{el,sub}$;
- N_{on} is the total number of the HP start-ups in DHW operation mode;
- $E_{el,sub,off\text{-}peak}$ and $E_{el,sub,peak}$ are the electricity use of the substation during the off-peak and peak hours;
- t_{disc} is the percentage of time with respect to the entire simulation period where the DHW is available for the user at a temperature lower than 44°C. This limit has been fixed as a threshold to assess a form of discomfort for the final user.

The simulations of Test 2 are performed in TRNSYS and have a time step of one minute that allows observing with enough resolution the interaction between the HP and the DHW TES that influence the TES stratification process. The controller that includes the MPC and the backup controller is implemented in LabVIEW. The MPC optimization problem is solved with a control timestep of 10 minutes. To exchange information between TRNSYS and LabVIEW in real-time a dynamic link library (DLL) connection has been developed.

3. Results and discussion

3.1. Test 1: No model mismatch vs. model mismatch

The first test involving the MPC controller aims at comparing its operation through the two platforms developed for the debugging phase: the first one realised completely in LabVIEW and the second one includes a co-simulation between TRNSYS and LabVIEW. A model to emulate the real system is needed in the debugging phase to test the ANN-MPC. In both cases, the emulator is updated at each control timestep by receiving the first input u* of the optimal trajectory resulting from the MPC calculations and returns back state information about the "virtual system" to update the state of the MPC model before the optimization process starts again. In the first platform, the same ANN model of the MPC controller is used as an emulator of the 5GDHC substation (no model mismatch) whereas in the TRNSYS platform a physical model of the substation is used for the same purpose with the introduction of a mismatch between the MPC model and the system emulator.

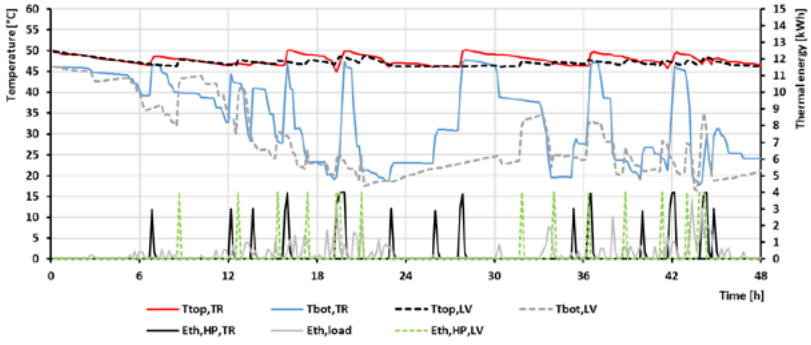

Fig. 2. Simulation results of the "no model mismatch" case VS the target values.

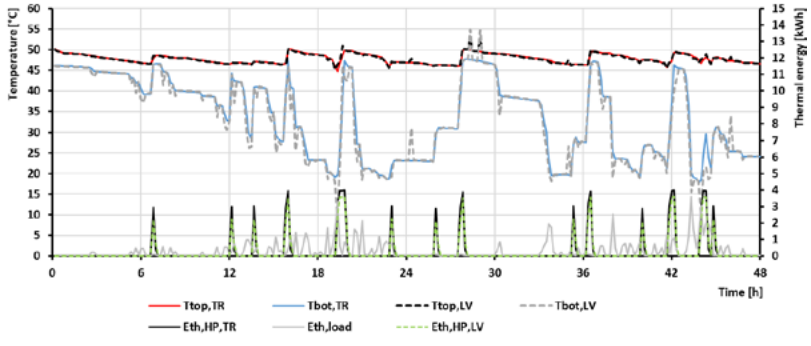

Fig. 3. Simulation results of the "model mismatch" case VS the target values.

In Fig. 2 the simulation results of the two cases with model mismatch (TRNSYS platform) and without model mismatch (LabVIEW platform) are compared under the same boundary conditions for testing the MPC during a simulation duration of 48 hours: the DHW TES model starts with the same state-of-charge in the two

simulations and the identical DHW load is applied. On the primary axis, there are shown the temperature profiles at the top and at the bottom of the DHW TES. The solid lines Ttop,TR, Tbot,TR represent the target temperature profiles that are the result of the physical model of the substation developed in TRNSYS. The dashed lines Ttop,LV, Tbot,LV represent the temperature profiles of the ANN model of the substation developed in LabVIEW. On the secondary axis, there are shown the thermal energies supplied by the HP to the DHW TES in the two cases (Eth,HP,TR, Eth,HP,LV) and the DHW load considered (Eth,load) with a timestep of 10 minutes. It can be noticed that after a few hours of simulation the temperature profiles of the ANN model in LabVIEW (no model mismatch case) diverge from the true profiles that one obtains from the TRNSYS model (model mismatch case). A normalised error for the temperature at the top ($CVRMSE_{Ttop,LV}$) of 3% and for the bottom one ($CVRMSE_{Tbot,LV}$) of 28% for the entire simulation is observed. These results are a consequence of the use of NARX ANNs models that propagate the errors for the output variables at the current timestep to the model inputs at the next timestep.

In Fig. 3 the same profiles of the previous case are shown, but the comparison is made between the outputs of the TRNSYS model and the real-time outputs of the surrogate ANN model of the MPC (model mismatch case). It can be noticed that since at each control timestep the ANN model state is initialised from the true measurements of the system (output of the TRNSYS model) the error that it provides to the outputs is very small and is not propagated along the simulation. This small error is also due to the delay of one simulation timestep (1 minute) that occurs during the exchange of information between the TRNSYS-LabVIEW co-simulation process. The errors of the temperature profiles are reduced to a value of 0.7% for $CVRMSE_{Ttop,LV}$ and a value of 6.3% for $CVRMSE_{Tbot,LV}$. Beyond this comparison, it can be observed that the MPC satisfies the constraints of the top temperature of the TES described by Equation 5.

3.2. Test 2: rule-based control vs. model predictive control

The test of the MPC controlled described in this study aims at comparing its performance with respect to a baseline that represents a simulation with the same boundary conditions where the 5GDHC substation is operated by a rule-based control strategy. Three scenarios have been developed to test the MPC operation and to perform an energetic and economic performance assessment of the 5GDHC substation for supplying the DHW load. The difference between the three MPC scenarios is the profile of the electricity price. It is flat and equal to 0.15 [EUR/kWh] for the scenario 1, whereas it is 0.15 [EUR/kWh] during the off-peak hours and equal to 0.30 [EUR/kWh] and 0.60 [EUR/kWh] during the peak-hours for the TOU scenario 2 and 3, respectively. The price of the thermal energy extracted from the 5GDHC grid has been considered constant and equal to 0.05 [EUR/kWh]. Thus, a TOU-based demand response is implemented only in scenarios 2 and 3 since in scenario 1 the electricity price is constant and the MPC operates to minimise the energy consumptions and state change of the substation.

The results listed in Table 2 show that in scenarios 1, 2 and 3 the MPC operates by charging the DHW TES more frequently with respect to the baseline scenario. In fact, the number of start-up signal (Non) of the HP in DHW mode increases by about 70.3%, 57.4%, and 67.3%, respectively. Thus, on average it results that less thermal energy is provided by the HP to the DHW TES during a single charge with respect to a standard charging process that occurs in the baseline scenario. The same occurs for the average electricity extracted by the HP from the power grid in a single charging process. The MPC always operates to further increase the temperature of the TES when a peak in the load is predicted. This occurs also in scenario 1 where the electricity price is flat. Nevertheless, the temperature at the top of the TES never reaches the upper bound of 55°C. The extra-charging process of the MPC has an impact on the average temperature of the TES over the simulation period that increases between 1.4% and 1.9% for the different scenarios with respect to the baseline with resultant higher thermal losses of the TES but achieving a reduction of the discomfort period (tdisc) for the occupant. Since the temperature at the evaporator is maintained constant, a higher temperature at the condenser has a negative impact on the COPsub that drops by about 3÷3.7% in the different scenarios with respect to the baseline. Lower COPsub and higher thermal energy losses have a direct impact on the energy consumed to run the 5GDHC substation. In fact, there is an increase of the consumptions of electricity and thermal energy from the 5GDHC grid between 3.2÷4.2%.

It is also important to highlight how the MPC operation contributes to the electricity peak-load shaving by comparing the electricity consumption of the substation for the different scenarios during the off-peak and peak hours defined according to the TOU demand response strategy. It can be noticed that, in scenario 1 where a TOU price variation is not implemented, the effect of the MPC is to reduce the electricity consumption during the peak hours by 2.1% and to increase the one during the off-peak hours by 7.7%. Because a peak DHW load occurs in the morning between 7:00 and 9:00, the prediction of the MPC leads to the production of DHW

before the peak load occurs. When the TOU price variation is implemented in scenarios 2 and 3, this shift is further boosted. The higher the price variation, the higher is the amount of electricity consumption that is shifted to off-peak hours.

The economic performance of the different scenarios is summarised in Table 3. For the different cases, the total costs of the electrical (CEel,tot) and thermal energy (CEth,tot) consumption over the simulated period are calculated for the baseline scenario with the corresponding energy tariffs. For scenario 1 with a flat electricity price, the extra-charging processes with a peak temperature above 50°C due to the MPC outputs lead to higher electrical and thermal energy consumption with a total utility energy bill (UEBtot) that is higher than the baseline one by 3.7%. With the introduction of a TOU electricity tariff in scenario 2, the 5GDHC substation operation due to the MPC implicates a shift in the costs with a small reduction of the electricity bill and an increment of 3.2% of the thermal energy bill. Nevertheless, the relative difference in UEBtot is less than 1%. This means that a TOU energy tariff of that kind is still not effective for a final user that would like to install a predictive controller as already presented in a previous study [20]. This because the saving obtained by the limited price variation between off-peak and peak hours that occurs only two times a day during working days, does not compensate for the additional energy consumptions due to the drop in the 5GDHC substation performance and additional thermal losses of the TES. Finally, in scenario 2 it can be noticed that the situation is changed. The peak hours electricity tariff is four times that of off-peak hours. Here, the electricity bill savings achieved is about 6% whereas the thermal energy bill increases by 4.1% with respect to the baseline. The UEBtot has a reduction of 3.5% with respect to the baseline that makes the MPC system attractive with respect to a standard RBC system.

4. Conclusions

This work presents the implementation of an MPC controller that has been developed to optimise the operation of a 5GDHC substation to cover the DHW load by exploiting the thermal capacity of the DHW thermal

energy storage system. The controller structure is based on artificial neural networks (ANN) that have been used in a modular approach to create a surrogate model of the 5GDHC substation and the binary particle swarm optimization (BPSO) algorithm has been used in the optimizer to find the best trajectory over the prediction horizon according to the boundary conditions. The investigation reported in this study deals with two preliminary tests of the MPC controller. The results of test 1 highlight that using the same ANN model of the system as an emulator of the system can be useful in the debugging phase of the controller. Nevertheless, the results of the simulation are not representative for an accurate assessment of the system performance since the use of NARX ANN models involves the propagation of the errors of the outputs onto the input at each simulation timestep. To overcome these drawbacks, a platform that includes a co-simulation TRNSYS-LabVIEW has been developed. It includes a physical model of the system as an emulator and allows a reliable and accurate assessment of the MPC operation and system performance under close-to-reality boundary conditions.

The results of the second test presented in this study deal with the energetic and economic performance assessment of the 5GDHC substation comparing the system operation under a model predictive control (MPC) strategy compared to a standard rule based controller. Different scenarios have been analysed considering different electricity prices. In particular, a comparison between a flat electricity tariff with respect to time-of-use tariff is performed considering two different peak prices. The results show that the extra-charging process of the TES leads to a drop in system performance due to lower COP and higher thermal energy losses. This results in additional energy consumption of electricity and thermal energy that are not always compensated economically by the savings achieved by charging in a smart way the TES during the off-peak hours. In the best scenario, total bill savings of 3.5% have been achieved thanks to the MPC controller. Nevertheless, it is important to highlight how the MPC operation contributes to shaving the electricity peak-load providing flexibility to the power grid. For the two TOU scenarios, part of the electricity consumption is shifted to the off-peak period achieving a reduction of 9.5% and 14.2% in the peak-hours period with respect to the baseline. Further research is needed to extend the analysis to annual simulations and considering the MPC operation under real-time pricing (RTP) programs.

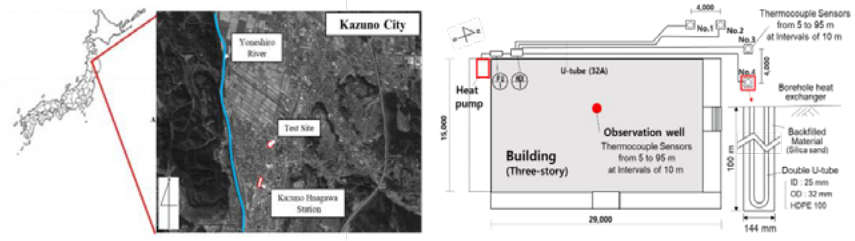
Abstract

The objective of this study is to estimate a cooling and heating performance of the ground source heat pump system with the borehole heat exchangers affected by rapid groundwater flow. The performance prediction is especially performed according to the required length of the borehole heat exchangers. For the evaluation of the performance, the measured data are analyzed in a three-floor building installed on the ground source heat pump system with four borehole heat exchangers (BHE s) in Kazuno City, Japan where the area has the groundwater flow actively. Based on the thermal properties of the soil and the groundwater velocity analyzed by the thermal response test, the measured circulating fluid temperature corresponding with the building load is compared with the calculated circulating fluid. The calculated fluid temperature was in agreement with the measurement data when an effective thermal conductivity of soil and a groundwater velocity were 4.7 W/(m K) and 120 m/y. An average coefficient of performance in a cooling/heating period was 4.5 and 7.8 respectively.

Keywords: Performance analysis, ground source heat pump system, groundwater, borehole heat exchanger;

1. Introduction



Ground source heat pump system (GSHPs) has been used to supply heating and cooling to buildings, using the ground as a heat source or a heat sink. The GSHPs installed in some areas with groundwater flow can achieve high performance. Some areas in Japan have an active groundwater flow owing to a steep slope of the mountains and the coefficient of permeability of the soil. Since the effect of the groundwater flow makes the ground temperature constant, the length of the ground heat exchanger (GHE) and initial cost can decrease. Ingersoll et al. [1] mentioned that the 286 m/y of the groundwater velocity results in the heat exchange rate (HER) to increase by 19 %.

A lot of research has been analyzed a coefficient of performance (COP) of the GSHP system to deliberate the optimal design of the GSHP system under widely divergent conditions. However, there is little research reflecting the effect of the groundwater velocity estimated from the thermal response test to consider the COP of the GSHP system. This study is carried out the calculation of the circulating fluid temperature at inlet and outlet pipes, based on the building load and the soil properties from the TRT results reflecting the effect of the groundwater flow. As a result of the previous study [2], the groundwater velocity and effective thermal conductivity were estimated at 120 m/y and 4.7 W/(m･K)), respectively. The calculated fluid temperatures are compared with the measurement data. The performance prediction is especially performed according to the required length of the borehole heat exchangers.

2. Site description

The test site was located in Kazuno city (40°19'N and 140°78'E), Akita Prefecture where the groundwater flow was expected to move actively by surrounding mountains and Yoneshiro River in Figure 1 (a). Figure 1 (b) shows the ground plan of the target building. The target building was a three-floor building, and the floor area was 435 m^2. The four GSHPs were installed for cooling and heating at intervals of 4 m. The diameter and length of the borehole were 144 mm and 100 m. A double U-tube was inserted in the borehole. The U-tube was high-density polyethylene, and an outer and an inner diameter of the U-tube was 32 and 25 mm respectively. A grout material was filled from a ground surface toward a bottom side of the borehole. The soils of the test site were mainly composed of gravel, gravelly sand and sandy gravel, and the effective thermal conductivity of the soil calculated by the thickness-weighted average of the soils was 2.4 W/(m·K). The experiment data was measured from 1st to 14th January 2018 in the heating period and from 1st to 14th July 2018 in the cooling period. Table 1 shows the description of the building in test site.

(a) Location of test site (b) Ground plana of target building

Fig. 1. Location of test site and Ground plana of target building

Table 1. Description of the building in test site

Category	Description
Total floor area	435 m^2 (Three floor building)
Total length of BHEs	400 m (Four BHEs)
Borehole diameter/U-tube size	144 mm / Double U-tube (outer:32 mm, inner:25 mm)
Measurement period	Heating (January 1 - 14th, 2018) / Cooling (July 1 - 14th, 2018)

3. Method

3.1 Analysis method of the measurement data

In the heating period, the heating load of the building is the sum of the HER and the power consumption of the heat pump in Eq (1). on the other hand, in the cooling period, the sum of the HER equals the sum of the cooling load of the building and the power consumption of the heat pump in Eq (2). The HER is calculated in Eq (3) or (4).

$$Q_c \approx Q_{inj} - W_{hp} \quad (1)$$

$$Q_h \approx Q_{ext} + W_{hp} \quad (2)$$

$$Q_{\mathrm{inj}} = \dot{m}_{\mathrm{f}} c_{\mathrm{f}} (LWT - EWT) \quad (3)$$

$$Q_{\mathrm{ext}} = \dot{m}_{\mathrm{f}} c_{\mathrm{f}} (LWT - EWT) \quad (4)$$

Here, Q_{c} and Q_{h} are the cooling/heating load of the building. Q_{inj} and Q_{ext} are the heat injection/extraction rate from/to the ground. W_{hp} is the power consumption of the heat pump. LWT and EWT are the leaving water temperature from the heat pump and the entering water temperature to the heat pump respectively. $\dot{m}_{\mathrm{f}}$ is the flow rate of the circulating fluid and c_{f} is the specific thermal capacity of the circulating fluid.

The coefficient of performance (COP) of the GSHP in the cooling period and the heating period is calculated as follows;

$$COP_c = \frac{Q_c}{W_{hp}} \approx \frac{Q_{inj} - W_{hp}}{W_{hp}} \quad (5)$$

$$COP_{\mathrm{h}} = \frac{Q_{\mathrm{c}}}{W_{\mathrm{hp}}} \approx \frac{Q_{\mathrm{ext}} + W_{\mathrm{hp}}}{W_{\mathrm{hp}}} \quad (6)$$

Here, W_{cp} is the power consumption of the circulating pump.

3.2 Calculation of the fluid temperature with the groundwater flow

The moving line source theory is applied for calculation of the fluid temperature, considering the groundwater flow. The soil in this method is treated as homogeneous medium which do not change physical properties with the temperature in Eq (7) [3,4].

$$\theta(r, \varphi, \tau) = \frac{q}{4\pi\lambda_{\mathrm{S}}} \exp\left(\frac{Ur}{4\alpha_{\mathrm{s}}} cos\varphi\right) \int_0^{\frac{r^2}{4\alpha_S \tau}} \frac{1}{\beta} \exp\left(-\frac{1}{\beta} - \frac{U^2 r^2 \beta}{16\alpha_{\mathrm{S}}^2}\right) d\beta \quad (7)$$

Here, θ is the temperature rise in medium, $\theta = T - T_0$, T_0 is an initial temperature of the soil, $\boldsymbol{r}$ is radius coordinate, φ is a polar angle, q is a heat flux per meter, λ_{S} is an effective thermal conductivity of the soil and α_{s} is a thermal diffusivity, U is a Darcy velocity, β is an integration parameter.

The previous study of the authors [2] analyzed the thermal response test data in the same field and estimated the groundwater velocity and the effective thermal conductivity of the soil. The fluid temperature was calculated by applying superposition of the thermal response with hourly heat extraction and heat injection and the estimated groundwater velocity and the effective thermal conductivity. The calculated results were compared with measured data. The estimated groundwater velocity and the effective thermal conductivity were 120 m/y and 4.7 W/(m K)

4. Results and discussion

4.1 Measurement data of the units

Figure 2 shows the outdoor temperature, the mean ground temperature in the observation wall and the heating/cooling load. During the measurement period, the minimum and maximum temperatures of the outside were -4.5 and 33.9 ℃. On the other hand, the average soil temperatures in the observations well, which is 15 m away from the BHEs, were constant to be 11.2 ℃. The results indicate that the outdoor temperature and the BHEs injecting/extracting the heat to/from the ground do not affect the temperature of the observation wells due to the effect of the groundwater flow. During the heating period, the GSHPs was operated continuously, and the average heating load was 9.8 kW. On the other hand, in the cooling period, the GSHPs was operated intermittently, and the average cooling load was 2.5 kW.

Figure 3 illustrates the power consumption of the heat pump and the circulating pump and the flow rate. The power consumption of the heat pump of the heating period was higher than that of the cooling period because of the relative high-temperature difference between the outdoor temperature and the indoor temperature. The mean power consumption of the heat pump in the heating period and the cooling period was 3.1 and 0.6 kW respectively. The power consumption of the circulating pump was constant to be 0.2 kW regardless of the period. The mean flow rate in the heating period and cooling period was 48.5 and 40.7 L/min respectively.

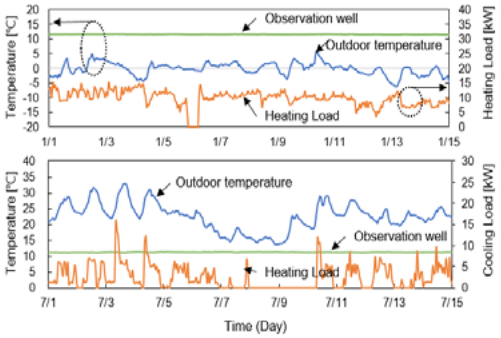

Fig. 2 Outdoor temperature, the mean ground temperature in the observation wall and the heating/cooling load.

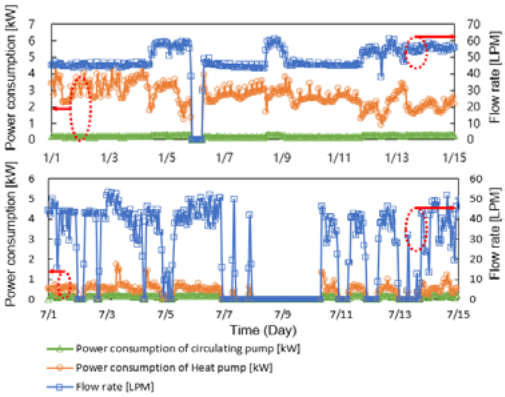

Fig. 3. Power consumption of the heat pump and circulating pump and the flow rate.

4.2 Temperature variation of the circulating fluid

Figure 4 indicates the temperature variation of the LWT and the EWT in the heating/cooling period. The LWT showed large fluctuations due to the ununiform power consumption of the heat pump whereas the fluctuation of the EWT was relatively constant. Especially, the results were regarded that the effect of the groundwater flow makes the EWT constant despite the continuous operating for the heating in the heating period.

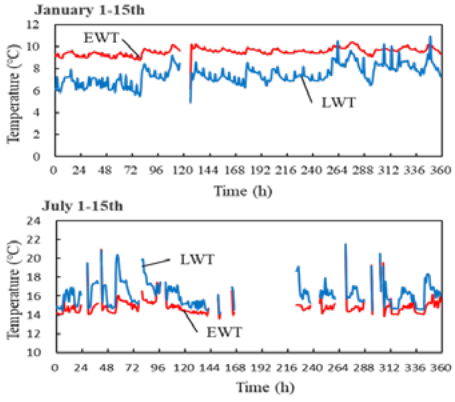

Fig. 4. Temperature variation of the LWT and the EWT

4.3 Performance analysis of ground source heat pump system

Figure 5 shows the variation of the heat exchange rate, the COP. Each result was calculated in Eq (4), (5), (6) and (7). The mean COP during the heating/cooling period was calculated to be 8.4 and 4.0 respectively. The heating load was bigger than the cooling load over 3.9 times, and the heat exchange rate of the heating period was also bigger that of the cooling period over 2 times. On the other hand, the average COP of the heating/cooling period was 3.6 and 6.2 because the power consumption of the heat pump of the heating period was lower than that of the cooling period over 5 times.

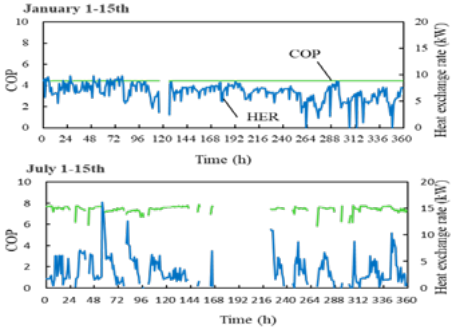

Fig. 5. Variation of the heat exchange rate, the COP

Table 2. The results of COP, Heat exchanger, EWT and LWT

Period	COP	Heat exchange rate [kW]	EWT [℃]	LWT [℃]
Heating period	4.5	6.7	9.5	7.5
Cooling period	7.8	3.3	15.0	16.2

4.4 Variation of EWT and LWT each case

Figure 6 shows the variation of EWT and LWT each case. The Cases were classified by the analysis method of the TRT, and the results of estimated parameter each case show in Table 3. As results, the calculated temperature results of the case 1 reflecting the groundwater velocity were similar to that of the measurement data. The temperature error between the case 1 and measurement data was under 6 % and 1 % during the heating period and cooling period, respectively.

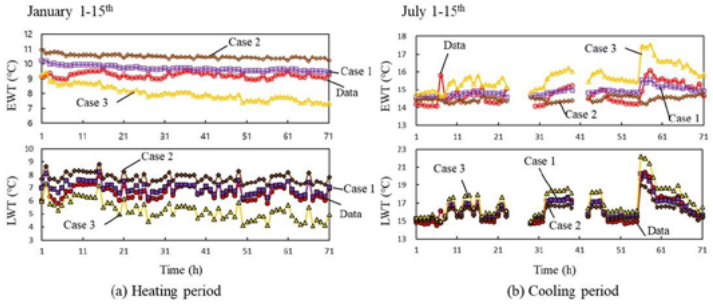

Fig. 6. Variation of EWT and LWT each case.

Table 3. Cases classified by the analysis method of the TRT

Case	λ_{eff} $(W/(m \cdot K))$	v (m/y)
Case 1 (Results calculated by MLS theory)	4.7	120
Case 2 (Results calculated by ILS theory)	8.9	0
Case 3 (Results from the column section)	2.4	0

4.5 Variation of EWT and COP according to total borehole length

Figure 7 shows the variation of EWT and COP according to the required total length of the borehole heat exchanger. Based on the parameters of the case 1, the EWT and COP were calculated according to the total borehole length. The shorter total borehole length resulted in the more significant fluctuation of EWT. In the analysis of the COP according to the total borehole length during the short-term period, the variation of COP during the heating period was insignificant, but the variation of COP during the cooling period was significant. Each COP according to the total borehole length was summarized in Table 4.

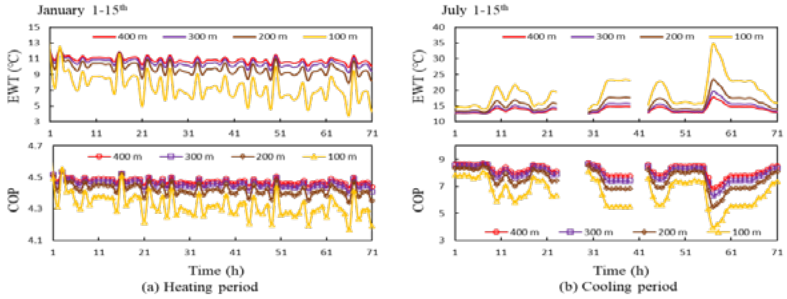

Fig. 7. Variation of EWT and COP according to total borehole length

Table 2. Variation of EWT and COP according to the required total length of the borehole heat exchanger.

Period	COP	Heat exchange rate [kW]	EWT [℃]	LWT [℃]
Heating period	4.5	4.5	4.4	4.3
Cooling period	7.8	7.7	7.5	6.6

5. Conclusion

The main objective of the present study is to investigate the cooling and heating performance of the ground source heat pump system with the borehole heat exchangers affected by groundwater flow. The EWT and LWT calculated by the MLS model based on the thermal properties of the ground (groundwater velocity= 120 m/y, effective thermal conductivity=4.7 W/(m･K)) [2] according to the building loads were compared with that of measurement data. The following is a summary of this study.

1) The performance analysis of the GSHP system was conducted by using the field data which is measured in the three-floor building located in Kazuno City.
2) The COP in measured heating and cooling period was 4.5 and 7.8.
3) The variation of EWT and LWT calculated by the MLS theory with the estimated parameters in the previous study was similar to that of measurement data.
4) In the analysis of the COP according to the total borehole length during the short-term period, the variation of COP during the heating period was insignificant, but the variation of COP during the cooling period was significant.

The decrease in the total length of the BHEs during the short-term period did not affect the COP of the GSHP system significantly when groundwater flows. therefore, the initial cost can be saved by decreasing the total length of the BHEs.

Abstract

This paper reports on ongoing work integrating a variable-capacity heat pump with additional heating and cooling technologies to provide efficiency and other benefits for residential customers. The Next-Generation Residential Space Conditioning System (Next-Gen RSCS) was tested in three leading U.S. laboratories as well as field evaluated at three homes in California. The Next-Gen RSCS integrates advanced HVAC technologies, including a variable-capacity compressor and variable-speed indoor blower, auto demand response, fault detection and diagnostics, intelligent dual-fuel heating, integrated heat recovery ventilation, and zonal control. An alternative refrigerant, R-32, was evaluated in laboratory testing as a possible future enhancement. An assessment was also performed on duct losses for single- versus multi-zone duct configurations with variable-capacity equipment. The field evaluation saw positive customer feedback, with users appreciating how quiet the units were, how quickly they cooled or heated the space, and their ability to control the temperature in individual spaces. The paper also begins a discussion to extrapolate project results beyond California climates, conditions, and demographics.

Keywords: Variable-capacity heat pump; alternative refrigerant; auto demand response; zonal control; field demonstration; energy savings; non-energy savings

1. Introduction

Cooling and heating of buildings to achieve comfortable temperature and humidity levels accounts for a large portion of the residential energy use in the United States (48%) and California (31%). Improving cooling and heating system efficiency are clear targets for improving residential energy use. Many emerging space conditioning technologies offer improvements in efficiency, but they were not integrated into a single heating, ventilation, and air-conditioning (HVAC) system, nor were they optimized for local climates. This project evaluated individual heat pump technology improvements and integrated them into a variable-capacity heat pump system that could provide higher efficiency space conditioning for California climate zones.

Results of early project work were presented at the American Council for an Energy-Efficient Economy (ACEEE) Summer Study in 2018 [1] followed by a presentation of updated project results at the American Society for Heating Refrigeration and Air Conditioning Engineers (ASHRAE) Winter Meeting in January 2019 [2]. Both papers and presentations focused on laboratory results for the Next-Gen RSCS obtained at three leading U.S. laboratories (Electric Power Research Institute in Knoxville, TN, Pacific Gas & Electric Applied Technology Services in San Ramon, CA, and Western Cooling Energy Center in Davis, CA). A final report, issued in April 2019 [3], documented project findings and included early field test results obtained at three residential sites in California. This IEA paper uses information presented in the final report and additional field test data obtained since April 2019 to provide a discussion of heating and cooling field test results. Also

included in this paper is a discussion of Next-Gen RSCS advantages: how they can satisfy customer needs and provide utility benefits and how they might be extrapolated beyond California applications.

2. Next-Gen RSCS System Features

The portfolio of advanced features incorporated into the Next-Gen RSCS (See Figure 1) included a variable-capacity compressor and variable-speed fan using state-of-the-art inverter technology; integrated heat recovery ventilation to exchange heat between the incoming air and the exhaust air to and from the conditioned space; intelligent dual-fuel technology to select the most economical means of heating to decrease energy cost and empower consumers to choose between electricity and natural gas; zonal control using mechanical dampers controlled by thermostat setpoints to avoid conditioning unoccupied rooms; demand-response strategies that take advantage of variable capacity to save energy; advanced fault detection and diagnostics to facilitate proper installation, operation, and maintenance; and alternative refrigerants for improved efficiency and reductions in global warming. Figure 2 summarizes which features were evaluated in the laboratory (Phase 1 and Phase 2) and field evaluation (Phase 3) portions for the study.

2.1 Benefits and Potential Barriers

An assessment of the benefits and potential barriers of the Next-Gen RSCS features was performed as part of the technology transfer planning effort and is summarized in Table 1.

Table 1 Benefits and Potential Barriers of Next-Gen RSCS Features

Feature	Benefits	Potential Barriers
Variable Capacity	Greater comfort, lower energy costs, improved noise, smoother operation, possible reliability improvements	Higher equipment cost and complexity, harmonics
Alternative Refrigerants	Lower Global Warming Potential (GWP), performance improvement, and lower energy cost	Requires regulatory approval
Dual Fuel	Lowest possible heating costs based on fuel selection	Higher equipment costs
Fault Detection and Diagnostics	Improved maintenance and reliability, lower energy costs	Higher cost of control systems
Integrated Ventilation/Heat Recovery Control	Lower energy costs	Higher equipment costs
Zonal Control	Lower energy costs, better controllability, greater comfort	Higher equipment costs require additional user training
Auto Demand Response	Lower demand charges, greater comfort	Higher equipment costs

2.2 Energy Cost Savings

The testing and analysis in this project and the literature review provided information on the potential operating savings resulting from deployment of the Next-Gen RSCS. In summary, the energy savings for each feature determined by this project, and in a cursory review of the literature review, are provided in the following paragraphs. (More details are provided in Section 6.3 of the Final Report [3] regarding the work reported in the literature on each system feature.)

- Variable capacity[1] – Current study - 22% to 32% energy savings; 35% [4] and 36% [5] energy savings in other studies.
- Alternative refrigerant – Current study - R-32 shows 1.2% to 3.0% improvement in cooling efficiency and improvement in heating capacity by 5% at 25°F and by 10% at 62°F; 1% [6] to 9% [7] energy savings in other studies.
- Dual fuel – Current study - for average electric and gas prices, the highest energy cost savings were 22% for California climate zone 3 (Oakland); no quantitative results were found in the recent literature.
- Fault detection & diagnostics – Current study - Inform maintenance alerts to avoid inefficient operation (no quantitative results obtained): High energy reductions were found to be possible in the literature depending on the nature and severity of the faults detected and resolved [8].
- Integrated heat recovery ventilation control – Current study - 1.3% to 3.8% energy savings in this study; 30% or more energy efficiency improvement in other studies [11, 12].[2]
- Zonal control – Current study - up to 50% savings at 40% capacity; 10% load reduction would result in 12.8% power reduction; 16% to 25% [13, 14] in other studies.
- Auto demand response – Current study - 50% power reduction resulted in only a 38.2% capacity reduction, and a 70% power reduction resulted in only a 61.8% capacity reduction; savings depend on specific utility and customer conditions.

[1] The efficiency savings obtained with variable speed are due to reduced temperature differences in the system at part-load conditions as the compressor speed is reduced as well as reduction/elimination of start and stop transients as the load is followed compared to on-off modulation with a single-speed system.

[2] Energy savings were greatest when the climate was extreme (very hot or very cold) and the residence was tight and well insulated.

Examining and accumulating the savings achieved by each feature indicates that energy savings of approximately 50% are achievable by integrating all the features studied.

2.3 Non-Energy Cost Savings

The technologies deployed in the Next-Gen RSCS will generally have higher first costs than the technologies they are replacing, but these costs will be offset by lower energy costs and lower maintenance costs as well as other benefits discussed below, including improved reliability and greater comfort.

2.4 Reliability

The use of fault detection and diagnostics (FDD) will increase reliability of the units by anticipating failures and alerting the occupant and contractor to permit timely maintenance and repair to reduce system downtime. Variable capacity should provide smoother operation, reducing equipment stops and starts, thus reducing stress on components, resulting in increased equipment life.

2.5 Safety

The anticipated higher reliability of the Next-Gen RSCS should provide greater occupant safety when comfort is a safety issue (as in extreme climate situations). Since R-32 is classified as A2L refrigerant (lower flammability and lower toxicity), regulation will need to provide the appropriate usage guidelines to address flammability issues in the equipment design, placement, and operation to ensure that safety is equivalent to or better than the equipment that it is replacing.

2.6 Consumer Appeal

In addition to the reduced operating cost, improved reliability, and safety issues aforementioned, the following Next-Gen RSCS advantages should appeal to consumers:

- The Next-Gen RSCS will provide greater comfort during normal operation due to use of variable capacity to permit load following, closer temperature control, and less on-off cycling.
- The timely use of FDD will increase reliability of the units, reducing downtime, repair bills, and intermittency of space-conditioning.
- The use of a furnace and a heat pump as heating options affords the user with the opportunity to take advantage of the lowest price source of heating. This should appeal to cost-conscious consumers.

2.7 Demand Benefits

According to California's Energy Efficiency Strategic Plan [15], HVAC is the single largest contributor to peak power demand in the state, comprising up to 30% of total demand in the hot summer months. The auto demand response and variable-capacity features of the Next-Gen RSCS can significantly reduce HVAC system peak demand.

Intelligent, variable-capacity space-conditioning equipment has been demonstrated to reduce power by 60% during peak events, while continuing to provide cooling to the conditioned space [16]. Variable-capacity systems have the unique attribute of going to a state of higher operating efficiency when the compressor speed is reduced. This Next-Gen RSCS project confirmed that power reductions would exceed capacity reductions when operating the unit below maximum speed. This provides demand savings and increased cooling capacity compared to equivalent single-speed units. According to the Strategic Plan, the California Energy Commission estimates that a peak demand reduction of 1,096 MW in the residential and small commercial sectors could be achieved through high-quality HVAC installations by 2020. (Next-Gen RSCS installations would certainly qualify as high-quality installations.) Assuming market penetration of 20% and the ability of the system to reduce peak demand by 60%, the cumulative peak demand reduction for California would be approximately 1.5 GW. Thus a 1–1.5 GW in demand reduction due to deployment of units similar to the Next-Gen RSCS appears to be an aggressive but potentially achievable goal. These savings, if achieved, will enable electric utilities to avoid building new power plants and consequently avoid adding substantial capital costs to their systems. Customers will benefit accordingly as reduced utility system costs should result in lower rates than would otherwise be mandated.

2.8 Energy and Environmental Benefits

As indicated in Section 2.2, energy cost savings of 50% appear to be technologically achievable when deploying the Next-Gen RSCS compared to commonly used residential HVAC systems. This could result in savings of 475 GWh/yr or $83 million annually in California, assuming market penetration of 20%, 4750 GWh/yr for single-family HVAC energy use in California in 2014 [17], and an average residential electric rate of $0.176/kWh. Assuming an equipment life of 15 years, the Next-Gen RSCS could save California ratepayers over $1 billion over the lifetime of the equipment. Based on the standard emission factor (0.331 kg/kWh saved) and energy savings of 475 GWh/yr or 475 million kWh/yr, the Next-Gen RSCS could provide a reduction of 157 million kg of CO_2 emission per year in California.

In addition to these CO_2 emissions savings, use of a refrigerant such as R-32 could also contribute to a reduction in global warming. Assuming typical leakage rates, an R-32 system (GWP of 675) will emit only 33% as much CO_2-equivalent direct emissions as the equivalent R-410A (GWP of about 2100) system over its lifetime. This value may be even lower in reality because systems using R-32 will have a lower refrigerant charge than R-410A systems. These global warming savings, while substantially less than the equivalent CO_2 emissions savings due to lower energy use, are still significant.

The environmental benefits achieved by deploying the Next-Gen RSCS compared to commonly used residential HVAC systems could be a major step in helping utilities achieve their environment mandates.

3. Field Evaluation

A field evaluation of the Next-Gen RSCS was performed in three occupied residential households, one in each of the California investor-owned utilities (IOU) service territories (Pacific Gas & Electric [PG&E], Southern California Edison [SCE], and San Diego Gas & Electric [SDG&E]). The field study included retrofitting each home with a new ducted split variable-capacity heat pump unit (VCHP) with refrigerant R-410A, provided by Daikin/Goodman. Table 2 lists the specifications of the three homes that participated in the field evaluation.

Table 2 Field Testing Host Sites Specifications

Host Site	**West Sacramento**	**Chino Hills**	**San Diego**
Utility	PG&E	SCE	SDG&E
CA Climate Zone	12	10	7
Area (ft^2)	2507	1850	1906
Home Vintage	2008	1993	1980
Existing Ducting, Heating System (pre-install)	Ducted AC with Gas Furnace	Ducted AC with Gas Furnace	Ducted AC with Gas Furnace
Location of Ducts	Attic	Attic	Attic
AC Size (tons) (pre-install)	3-ton Condenser 4-ton AHU	4	4
Floors	2	2	1
Number of Residents	4 + 1 pet	4 + 1 pet	1 + 3 pets

The objective of the field evaluation was to assess the functionality of the Next-Gen RSCS features in residential homes and evaluate the performance with respect to the customer experience. For the field evaluation, each home—depending on its configuration and climate—evaluated a subset of the key features discussed next. After installing the Next-Gen RSCS with new ducting insulation, each home was instrumented with power meters for the indoor and outdoor units, temperature and relative humidity sensors in each zone, and pressure differential sensors across each zone damper in the attic ducting. Data collection spanned over one year to capture both the heating and cooling season. Data analysis included comparing variable-capacity heat pump performance to a single-speed Seasonal Energy Efficiency Ratio (SEER) 14 HVAC unit, as well as comparing the field-testing data with the lab-testing data.

3.1. Variable-Capacity Compressor and Blower Field Performance

The cooling and heating seasonal analysis of the field data for the Next-Gen RSCS both show energy consumption within 20% of the lab data model, which was developed with steady-state testing. A 2-ton model

of the system was tested in laboratories at outdoor temperatures at 10˚F increments from 65˚F to 105˚F for cooling, and at 62˚F, 47˚F, 35˚F, 25˚F, and 15˚F for heating. The indoor condition was kept constant at 75˚F dry bulb and 63˚F wet bulb for cooling and 70˚F and 57˚F, respectively, for heating, and each condition was tested at high (100%), intermediate (50%), and low (30%) compressor speed. While the lab- and field-tested systems are of different rated capacities and different setpoints may have been used, the efficiency of the system should be comparable. The cooling performance of the units shows a range of Energy Efficiency Ratio (EER) between 10 and 25, which agrees with the range of EER found in the laboratory testing performed earlier in the study. Figures 4, 5, and 6 show the West Sacramento site field data compared to the laboratory testing results as well as a SEER 14 baseline system. The results clearly illustrate the benefits of a variable-capacity system, with much higher efficiency as the system reduces its compressor speed to intermediate and low stage.

Fig 4. West Sacramento Site High-Stage Field Data

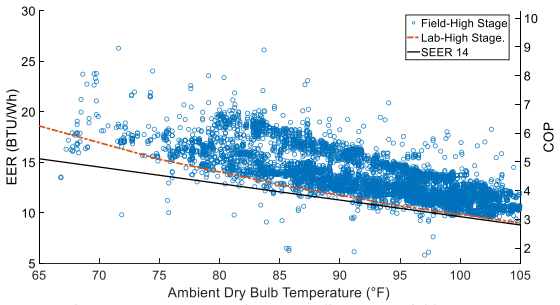

Fig 5. West Sacramento Site Intermediate-Stage Field Data

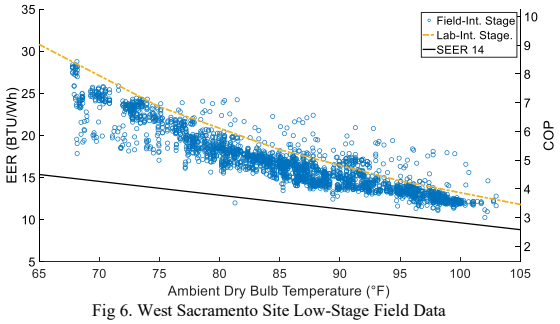

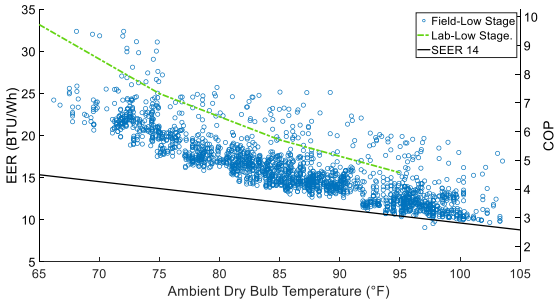

Fig 6. West Sacramento Site Low-Stage Field Data

3.2. Dual-Fuel (Intelligent Heating) Field Performance and Operation

Once the breakeven temperature[3] was set for each of the three host sites, the Next-Gen RSCS performed as expected in the heat pump mode and gas furnace mode throughout the duration of the heating season. The Next-Gen RSCS dual-fuel capability provides an important choice for the residential customer to adjust the unit settings based on economic factors (utility rates), efficiency factors (heat pump vs. gas furnace), or environmental factors (reduction of carbon footprint).

Having a controller that automatically receives pricing information and sets the breakeven temperature accordingly would minimize the need for customer interaction (unless they chose to do so.) Future work is needed to develop a versatile/intelligent heating controller that can receive a signal based on utility prices and customer choice/preference (price, efficiency, fuel mix distribution), which would optimize the Next-Gen RSCS's performance in the heating mode.

3.3. Auto Demand Response (ADR) Field Performance

The unit capacity reduction is less than the unit power reduction when operating below maximum speed and capacity; therefore, customer comfort is not as compromised while energy and demand savings can be realized during a utility-led demand response event.

Field ADR testing was conducted in both the heating and cooling mode. Heating mode demand response of 30% or 50% demand reduction both resulted in 4.9% variation between power and capacity change (the power reduction was 4.9% more than capacity reduction). During the cooling mode test, a 50% demand reduction resulted in 8.4% variation between power and capacity change.

3.4. Zonal Control Field Performance

The three host sites for the field evaluations were set up with variable-speed heat pumps and new insulated ducting that was zoned into either two, three, or four zones depending on the housing configuration and square footage. An important observation learned from the field evaluation is the significance of setting up the zoning controls through the zone weightings to minimize the possibility of overflow in small zones.

When installing variable-capacity equipment with ductwork located in unconditioned space, zoning controls provide added system efficiency where the system would operate in part-load capacity when not all the zones are called on for conditioning.

3.5. Customer Feedback Regarding Field Test Units

The following summarizes the homeowners' feedback on their experience with the Next-Gen RSCS:

- They appreciate how much quieter the Next-Gen RSCS operates compared to their previous single-speed AC unit.
- They like how quickly it cools or heats the space.[4]
- They like having an app-based controller for the thermostats to turn on and set the temperature of individual zones.
- They like the ability to control temperatures in individual spaces (that is, an advantage and nice attribute of zonal control is to control zones independently).
- While zonal control is a convenient feature for the occupants, it added complexity to the VCHP system when there were more than two zones. Airflow was too forceful in certain zones, making it noisy in some rooms. Once the weighting of the zones was adjusted, this mitigated the effect of the airflow imbalance.

The laboratory and field evaluation of the Next-Gen RSCS features in residential homes resulted in recommendations to extend the benefits of the Next-Gen RSCS concept, which are summarized in Section 4.

4. Configuring the Next-Gen RSCS into Different Models

Two of the recommendations made in the study final report [3] are worth exploring in this forum and in terms of extending the scope of the project beyond California. The first is to examine the suitability of each

[3] The *breakeven temperature* is defined as the temperature at which the cost of heating using the gas furnace and the electric heat pump is equal. Above the breakeven temperature, it is more economical to run the heat pump; below the breakeven temperature, it is more economical to run the furnace.

[4] This is in comparison to the older, poorly operating system that was replaced.

feature of the Next-Gen RSCS for the conditions being considered: climate, customer demographics,[5] electricity rates, configuration, and delivery system. The second is to integrate the most desirable features into a model of the Next-Gen RSCS most suitable for those conditions.

The premise of both recommendations is that each feature will differ in value depending on customer demographics, utility rates, and climate. What features are most likely to be of value, and what are the variables affecting this value? The reported study focused on forced air delivery systems for single-family residential systems in California climates.[6] How would the features perform if incorporated into other delivery systems and in other climates?

Variable-capacity inverter-driven technology is the key to many of the system advantages. Being able to vary the compressor and fan speed to follow the load provides smooth, efficient, unobtrusive operation. It is also the key to efficient **demand response**, providing more efficient operation while also reducing demand. Capacity modulation is also the key to efficient zonal control. Variable capacity is the cornerstone of the Next-Gen RSCS and is likely to be incorporated into all models of future units.

Variable capacity can be, and is, used with other delivery systems, including systems using refrigerant piping for distribution as well as hydronic systems. As such, it should be applicable to a wide range of HVAC configurations in the United States and abroad.

The advantages of variable capacity are most apparent at off-design conditions and may not be useful when many hours occur at high-temperature conditions. Nonetheless there should be sufficient hours in "shoulder" periods and the need for zoning and demand response to make this feature valuable.

Fault detection and diagnostics are a robust technology that, with proper sensors and controls, should be viable across the entire range of customer demographics, climates, and delivery systems. Early detection of inefficient operation and impending failures is needed for all HVAC systems. Potential savings are likely to be highest when the need for heating and cooling are highest, but FDD systems should be generally applicable across the United States and abroad.

Zonal control can be managed effectively with a variable-capacity system that can respond to changes in occupancy. Matching the Next-Gen RSCS to operate with a variety of delivery systems should make it applicable across the United States and abroad. Climate and demographic differences should not hamper its operation.

Integrated heat recovery ventilation preheats or precools the air entering the conditioned space, providing fresh air ventilation efficiently by exchanging heat between a fresh air and exhaust air stream. This system requires a heat exchanger and flow path that can be independent or integrated with the HVAC system and thus can be effectively added to any delivery system that requires a forced ventilation system. Energy savings should be highest at extreme temperatures (high outdoor temperatures for cooling and low outdoor temperature for heating), but the savings are modest compared to the savings achievable by other features.

R-32 as an **alternative refrigerant** to R-410A appears to have cooling mode performance advantages over R-410A that are highest at high outdoor temperature and thus would be most advantageous as a replacement in hotter climates. This could apply to other climates in the United States and abroad but not typically in heavily populated areas of Europe. R-32 has already been approved and has seen wide adoption in Japan and is seeing more penetration in China and European countries. The environmental advantages of R-32 compared to R-410A are clear, and performance appears comparable for milder cooling and heating conditions.

Dual fuel is the feature that is most sensitive to electricity and gas rates and climate. Dual fuel using a gas furnace or other gas heating device and an electric heat pump works best economically when there are many heating hours at moderately cold temperatures where the both the furnace and the heat pump can each operate for enough hours to offset their capital cost. If most of the heating is at low temperature and gas prices are economical, it would likely pay to just have a furnace for heating. Where most of the heating is at mild temperatures and the electricity prices are economical, just a heat pump with or without electric resistance backup might be most economical for heating.

Economical operation of the dual-fuel option depends on both the gas and electric rates and the climate. Since heat pump efficiency degrades as the outdoor temperature is reduced and gas furnace efficiency is relatively constant with outdoor temperature, there is a temperature at which the heat pump and furnace operating costs are the same—the breakeven temperature. If gas prices are very low or electric prices are very high, the breakeven temperature will be high and the furnace will carry the crux of the heating load. The

[5] Pertinent customer demographics include number, mobility, and age of occupants and how it affects factors such as occupancy and the usefulness of zoning and sensitivity to temperature settings.

[6] For the most part, the results in the study were obtained for relatively dry climates. For hot, humid climates, coils will need to be designed for greater latent load removal, and thus, likely need to be deeper. The RSCS's integration of the multiple features studied should remain applicable to such climates.

opposite is true when electric prices are low and gas prices are high. Gas and electric prices vary dramatically globally as does local climate, so the operation of the dual-fuel heat pump needs to be evaluated on a case-by-case basis with regard to these variables.

In configuring the Next-Gen RSCS for a particular customer segment or climate, the features discussed above should be considered and built upon to develop a model best suited for the demographics, configuration, and climate of interest.

A premium model might include all energy efficiency features of the Next-Gen RSCS. The base model could be a variable-capacity heat pump with demand response, fault detection and diagnostics, and zonal control—all of which are crucial features to benefit from the efficient operation of variable-capacity heat pump. The intermediate model could include intelligent heating as an additional feature to the base model.

5. Concluding Remarks

While the current project conducted the testing and evaluation of each of the features to quantify the potential for energy savings and performance benefits, a future project would be needed to develop a model that evaluates the cost effectiveness of each feature. The model would need to evaluate energy and demand cost savings for each feature for different climate zones for representative housing, demographics, and occupancy situations.

Acknowledgments

The authors would like to acknowledge the California Energy Commission for its support and funding of this project under award number CEC EPC-14-021. Also, they would like to acknowledge Daikin/Goodman who supplied the variable-capacity heat pump units and provided research guidance.

Abstract

In this paper, simulation model of thermophysical properties test have been established and the accuracy of which have been verified by actual test data. Using linear heat source model to process simulation data for the analysis of different factors influences on simulation results. It shows that when using linear heat source model as the regression model for rock-soil thermophysical properties, in order to improve the thermophysical property accuracy identification, test duration should be 72 hours with elimination of the first 12 hours data and ensure a strong turbulent state for the flow velocity in pipes.

Keywords: Borehole heat exchanger；thermophysical properties test；linear heat source model

1. Background

Technology of thermophysical properties of rock-soil test is the premise and foundation of the highly efficient and energy-saving operation of the ground source heat pump (GSHP) system. By simulating the heat transfer characteristics of the borehole heat exchanger under the actual working conditions and with the help of theoretical analysis model or professional simulation software, an effective bridge is built between obtaining thermophysical properties of rock-soil and guiding the design of the actual GSHP system which effectively promote the scientific nature and rationality of GSHP system design.

The common test methods of under-ground rock-soil thermophysical properties include geotechnical types identification method, steady-state plate test, probe test and thermal response test, etc. [1,2], among which the most widely used type is the thermal response test. And currently, the most commonly used ones are the constant heat flow method and constant temperature method. The constant heat flow method was first proposed by C.eklof in 1996 [3-6], which has been recommended by the IGSHPA and ASHRAE standards as the international practice. This method only test the exothermic condition which uses the electric heater to provide stable heating quantity, records the water temperature at the inlet and outlet of the buried tube at each time, and uses the mathematical model to obtain the thermophysical properties of the rock and rock-soil, that is easy to operate and widely used and is also applied by the national standard of GB50366 *Technical code for ground source heat pump system* for thermophysical properties measurement of soil and rock [7].

The main calculation method of rock-soil thermophysical property test is to deduce the thermophysical parameters by inverse algorithm which requires input of the test results in the computer and compare them with the simulation results. By repeatedly adjusting the thermophysical parameters of the rock-soil in the heat transfer model until the variance of the average temperature value and the minimum value are obtained, it is considered that the thermophysical parameters in the heat transfer model are exactly those of the rock and soil in the location.

2. Model establishment and verification

In this paper, simulation model of the soil and rock thermophysical properties test has been established through TRNSYS as is shown in Fig.1. Duct Ground Heat Storage Model (DST) has been applied for borehole heat exchanger which is a typical mixed solution of both analytical and numerical methods. Verified by the actual test results, reliability of the model has been confirmed, and input conditions are changed to obtain the operation results under different boundary conditions. Taking simulation results as the true value, influence of different test factors on the accuracy of identification results is analyzed by using linear heat source model to process the data.

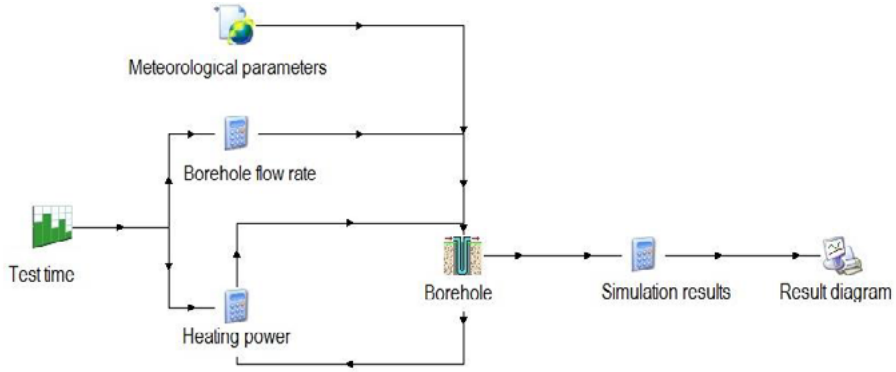

Fig. 1. TRNSYS Simulation model

In order to verify the simulation model of rock-soil thermophysical test, simulation study on an actual GSHP test was conducted for comparison between simulation and test results. In the thermal response test, the constant heating power is 5.938kw, the fluid carrying capacity is 0.854m3/h, and the structural parameters of DN32 single U-type borehole heat exchanger are shown in Table 1. In order to measure the temperature of rock-soil, 10 temperature sensors are arranged along the depth, with an interval of 10 meters between each two temperature sensors. After 48 hours, the values of the 10 temperature sensors are added and averaged. The initial temperature of rock-soil is 20.05℃, and its physical parameters are shown in Table 2.

Table 1 Structural parameters of buried tube heat exchanger

Drilling depth/m	Hole radius/mm	Tube internal diameter/mm	Tube wall thinkness/mm	Center distance/mm
100	65	26	3	64

Table 2 Physical parameters of borehole heat exchanger

Substance	Density/kg/m^3	Specific heat capacity /J/(kg·K)	Thermal conductivity /W/(m·K)
Soil and rock	1600.0	1645	2.71
Backfill	1860.0	840	2.00
Buried tube	950.0	2300	0.44
Fluid carrying	998.2	4182	0.60

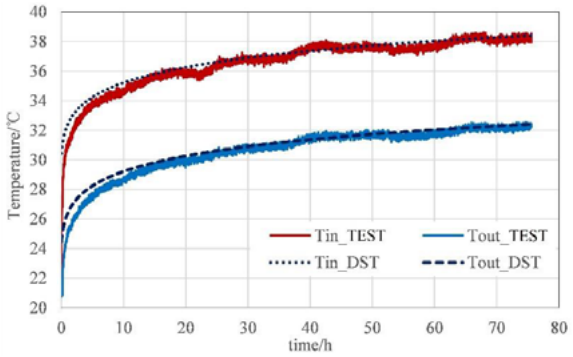

Fig. 2. Comparison between simulation and test values of inlet and outlet temperature

Fig.2 shows that during the 75 hours of simulation calculation, Simulation values of the model (based on DST) have a good agreement with the heat response test data which verifies the accuracy of simulation model.

3. Influence factors of thermophysical properties identification

Using the simulation model to calculate thermophysical properties of the borehole heat exchanger, simulation results are taken as the true values. Comprehensive thermal conductivity of rock-soil based on the simulation results is obtained by using the linear heat source theory to process the data for the analysis of the pattern of various influence factors on thermal response test results.

According to the characteristics of large length to diameter ratio of borehole heat exchanger, the model assumes that heat transfer process is between an underground linear source and the surrounding semi-infinite rock and soil. Therefore, the linear heat source model not only ignores the vertical heat transfer, but also omits the heat capacity inside the hole, namely, the linear heat source model cannot reflect the transient heat transfer process inside the hole, so that when data processing is carried out for the thermophysical property test of rock and soil, linear heat source model fails to process the data before a to-be-steady state inside the hole. In this paper, factors such as test duration, abandoning the early data period, heating power, flow velocity of the fluid inside the tubes are have been respectively analyzed, and the influence of these factors on thermophysical parameters identification of rock-soil are studied.

According to the linear source model, after taking the natural logarithm of the test duration (T), the average temperature T of the carrying fluid corresponding to each time point has a linear relationship with the logarithm value ln (T) of time.

Linear heat source model formula is shown as follows：

$$T = k \cdot \ln(t) + b \tag{1}$$

$$k = \frac{Q}{4\pi\lambda H} \tag{2}$$

$$b = \frac{Q}{4\pi\lambda H}\left[\ln\left(\frac{4\alpha}{r_b^2}\right) - \gamma\right] - \frac{Q}{H} \cdot R_b + T_0 \tag{3}$$

Where T is the average value of the temperature at the inlet and outlet of the fluid in the ground heat exchanger, ℃；

Q is the total heating power under the test condition, W;

H is the buried pipe depth, m;

λ is the thermal conductivity of soil and rock, w / (m.k);

α is the thermal diffusivity of soil and rock and, m^2/s;

t is the test duration, s;

r_b is the drilling radius, m;

R_b is the thermal conductivity, (m.K)/W;

T_0 is the incipient soil and rock temperature, ℃;

γ is the Euler constant, （γ=0.5572）。

The T-ln (T) curve of the average water temperature at the inlet and outlet of the buried pipe and the test time can be obtained according to the simulation data of the thermophysical properties test of the rock-soil. Least square method is used to estimate the parameters of the simulation data, which minimized the variance between the average temperature and the simulation value of the regression model of the carrier fluid to obtain the slope of the T-ln (T) curve, and thus, acquiring the K value in the formula. Finally, the K value can be calculated. Finally, comprehensive thermal conductivity of rock-soil is obtained. For the convenience of data analysis, the relative error of comprehensive thermal conductivity of rock-soil is defined as follow:

$$EER = \frac{\lambda - \lambda_0}{\lambda_0} \times 100\% \tag{4}$$

Where λ represents the comprehensive thermal conductivity obtained through simulation calculation of linear heat source model; λ_0 represents thermal conductivity of rock and soil set in simulation model W/(m-K).

3.1. Test duration influence

The stable value of comprehensive thermal conductivity of rock-soil needs certain calculation time interval, and the guarantee of such calculation time interval needs a certain test duration first which is related to the test conditions of specific project. In this paper, based on the simulation model, the linear heat source model is used for data regression, and the curve of comprehensive thermal conductivity of rock-soil with the test duration is shown in Fig.3.

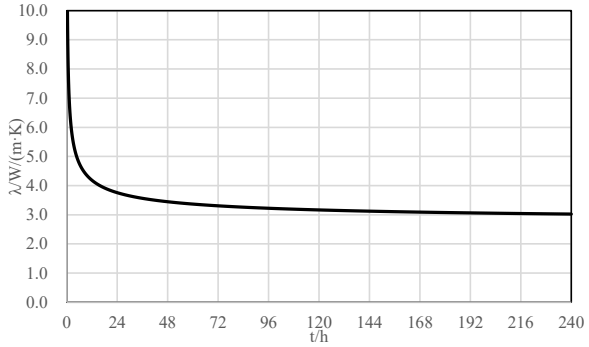

Fig. 3. Curve of comprehensive thermal conductivity of rock and soil with test duration

Fig.3 shows that with the extension of test duration, comprehensive thermal conductivity of rock-soil became closer to the true value. The relative error in early stage of the test decreases rapidly with the increase of time (the early time slope is larger) which indicates that in order to ensure the accuracy of the test results, it is necessary to extend the test duration as much as possible. When test duration is longer than 48h, the comprehensive thermal conductivity of rock-soil has become stable, and the error is within the acceptable range of the project. If the duration is 72h, the error will be further reduced. According to the regression calculation results and the relevant research results at home and abroad, it can be seen that 48h is the necessary test duration, and the optimal one is 72h [8,9].

3.2. Elimination length of transient data influence

From the above calculation, it can be seen that the linear heat source model cannot reflect the transient heat transfer process inside the hole, and the comprehensive heat transfer coefficient obtained from the data regression in this stage changes dramatically which has great deviation from the true value. If part of the transient heat transfer process data is removed, and data under steady state heat transfer process is used for regression simulation, the obtained thermophysical parameters will be more reliable. In this paper, influence of different elimination length of transient data on thermophysical parameters of soil is analyzed as is shown in Figure 4, the comprehensive thermal conductivity curve of rock-soil varies with the length of elimination time, and the accuracy is positively related with this elimination length.

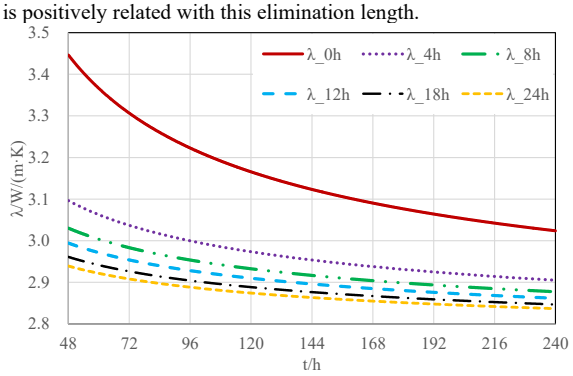

Fig. 4. Curve of rock-soil thermal conductivity under different elimination length of transient data

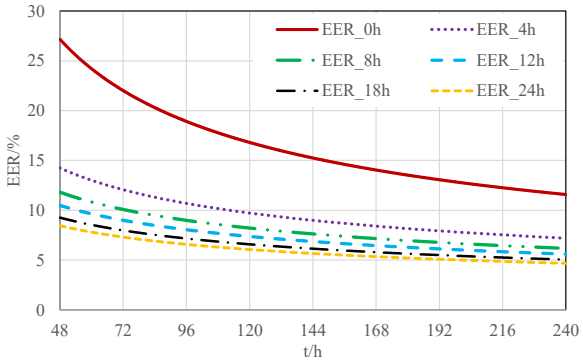

Fig. 5. Curve of rock-soil thermal conductivity relative error under different elimination length of transient data

Error change between rock-soil comprehensive thermal conductivity and the true value caused by the elimination length of transient time is shown in Figure 5. It can be seen for that when eliminating length is 12h, error rate is within 10%, and then with the increase of eliminating time, the error rate is significantly reduced. When the rock-soil comprehensive thermal conductivity is obtained by the inverse calculation of linear heat source model with the elimination of the first 12 hours of unsteady test data, more scientific and reasonable

results can be obtained.

3.3. Influence of different heating power

Influence of different heating power on the identification results of rock-soil thermophysical properties test are analyzed. Under the same flow rate, heating power difference is realized through different inlet and outlet temperature ΔT, as shown in Figure 6, the following conditions are set as: 2 ℃, 4 ℃, 6 ℃, 8 ℃, 10 ℃. When different heating power is used, comprehensive thermal conductivity of rock-soil changes as shown in Figure 7.

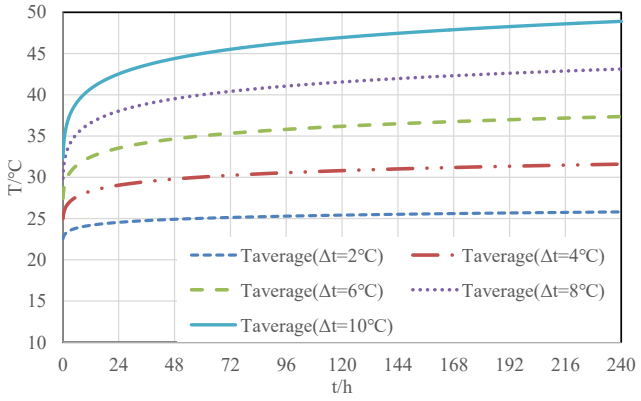

Fig. 6. Curve of average temperature under different heating power by different inlet and outlet temperature ΔT

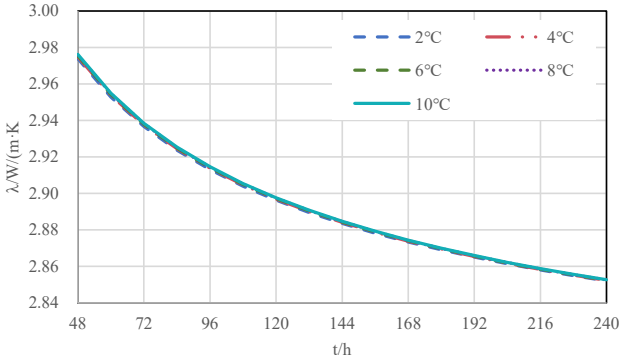

Fig. 7. Curve of rock-soil comprehensive thermal conductivity under different heating power by different inlet and outlet temperature ΔT

It can be seen from Figure 7 that under different heating power conditions, linear heat source model is used to regress the thermophysical parameters of rock-soil, and the results obtained by analyzing and comparing the comprehensive thermal conductivity are basically the same which indicates that the identification results of soil and rock thermophysical properties are not affected by heating power.

However, in the actual thermal response test, with the increase of the power of the heater, the thermal conductivity of the rock and soil tend to increase, which is caused by the leakage of groundwater. Because the buried depth of the underground tube is generally 50-200m where groundwater exists, heat transfer process inside and outside the hole will both be affected, thus the test results of rock-soil thermophysical properties are influenced. When using linear heat source regression calculation, the influence of groundwater is not considered, so the calculation results are not significantly different because of heating power. Therefore, the influence of groundwater leakage must be considered in the thermal response test. When there is no or little ground water leakage, the influence of the power of the heater can be ignored.

3.4. Flow velocity influence

Under the same condition of temperature difference between the inlet and outlet of the buried tube heat exchanger, influence of different velocity in the tube on the back calculation results of the thermophysical properties test is analyzed. The flow velocity in the pipe is set as follows: 0.1m/s, 0.15m/s, 0.2m/s, 0.3m/s, 0.4m/s, 0.6m/s, and the corresponding Reynolds number is shown in Table 3. Obtained comprehensive thermal conductivity curve of rock and soil is shown in Figure 8.

Table 3 Working condition group of simulation

No.	Velocity m/s	Flow rate kg/h	Re
1	0.1	190.79	3238.1

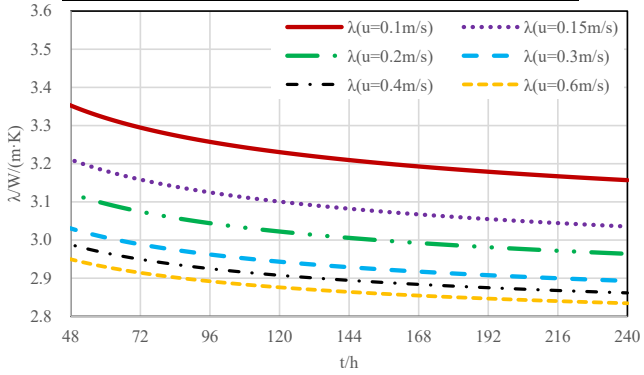

Fig. 8. Variation of rock-soil comprehensive thermal conductivity with test duration under different velocity

It can be seen from the above figure that when the velocity in the tube is in the laminar flow and transition area, error between the simulation and testing value of rock-soil comprehensive thermal conductivity is large with slow change. After turning into turbulence area, the deviation from the true value is rapidly reduced. Therefore, in order to get the most accurate parameters of thermal properties of rock-soil in limited testing duration, it is necessary to increase the flow velocity in the buried tube to maintain a strong turbulent flow.

4. Conclusions

In this paper, the simulation model of rock-soil thermophysical properties has been established, the linear heat source model is used to process the data. Influence of four factors on the accuracy of the identification results of thermophysical properties of rock-soil is analyzed including test duration, eliminating length of transient data, heating power and flow velocity. Results show that test duration is positively related to the accuracy of identification results of soil and rock thermophysical parameters. In order to ensure the accuracy of identification of these parameters, it is necessary to ensure a no-less-than 48hours test duration. Eliminating length of transient data is also positively related to the accuracy of identification results of soil thermophysical parameters, but considering the operability and accuracy of the test, the transient data in the first 12 hours is eliminated which can effectively improve the accuracy of parameter identification and have better operability. Under the linear heat source model with no or little groundwater leakage, heating power has no effect on the

identification results of rock-soil thermophysical properties. By increasing flow velocity in the tubes and maintaining a strong turbulent flow state, the accuracy of identification results can be effectively improved and with less test duration.

Through the analysis of the four factors above, it can be seen that in order to achieve the accurate identification of rock-soil thermophysical parameters, it is necessary to emphasize the setting of several key influencing factors in the test link, and provide more scientific and reasonable basic data of thermophysical parameters for the design of ground source heat pump.

Abstract

In this paper, the cooling load of refrigerated display cases and the load of air conditioners in a grocery store were simulated by using computational fluid dynamics (CFD) models to understand the relationship between the loads of refrigerated display cases and air conditioners in summer and winter. In the summer, the results show that a higher preset temperature of the air conditioner led to an increase in the cooling load of the display cases and a decrease in the cooling load of the air conditioners. For this reason, the total electricity consumption was minimized when the preset temperature was set to 25℃, and the temperature was neither the highest nor the lowest explored. In the winter, the total electricity consumption of both display cases and air conditioners increased with increasing preset temperature. Furthermore, by replacing the frozen multi-deck display cases with frozen reach-in cases in the summer, the electricity consumption of the display cases decreased to half, while that of the air conditioners somewhat increased; in the winter, the electricity of the display cases and air conditioners both decreased.

Keywords: Grocery store; Air conditioner; Refrigerated display case; Energy consumption; CFD

1. Introduction

Supermarkets and grocery stores play an important and energy-intensive role in the commercial sector. The average electrical energy intensity of these stores varies from 1500 kWh/m^2 to 850 kWh/m^2 per year as the sales area increases from 280 m^2 to 1400 m^2 [1]. In Japan, grocery stores occupy 8% of the energy consumption in the commercial sector [2].

Refrigerated and frozen display cases (DCs) are widely used in grocery stores. According to the research data presented by Narumi, 84% of the energy consumption of grocery stores was related to chillers [3], while another study in the UK reported that the power consumption ratio of refrigeration and HVAC (heating, ventilation, and air conditioning) equipment was 60% and 26%, respectively [4].

In addition, HVAC equipment and refrigerators can influence each other in energy consumption, but most studies investigate air conditioners and DCs separately rather than regarding them as a combined working system. Hence, it is essential to explore the interaction between the load of refrigerators and air conditioners in grocery stores. To achieve this goal, the energy consumption of stores should be measured. However, the energy consumption measurement in stores is not easily performed because of the high costs and difficulties in controlling conditions.

CFD models can simulate the leakage of DCs and airflow of air conditioners; thus, the abovementioned obstacle can be overcome. Based on a series of experimental results, we built models of DCs in this study that can imitate their load and low-temperature air leakage under different temperatures or humidity environments.

MD-F	Frozen multi-deck display case
RI-F	Frozen glass door reach-in display case
TUB-F	Frozen tub display case
DAG	Discharge air grille of a display case
RAG	Return air grille of a display case

A small grocery store situated in Kobe, Japan, was chosen to be simulated to evaluate the interaction between the load of the DCs and air conditioners in the store. The DC CFD models were arranged in the CFD model of the store.

2. Methodology

The main contents of this study can be divided into three parts: (1) setting up an experiment to measure the performance of 5 kinds of DCs at different temperatures and humidities, (2) building the CFD models of the DCs from the data obtained in experiments, and (3) evaluating the interaction between the load of the DCs and that of the air conditioners in a grocery store at different air conditioner preset temperatures and applying energy-saving strategies. These details are provided in the following sections.

2.1. Performance of Display Case Measurements

The experiment measuring the performance of DCs in a laboratory with constant temperature and humidity was divided into 2 types: refrigerated and frozen experiments. The refrigerated DCs measured in the experiment consisted of one open refrigerated multi-deck DC (MD-R) and one open refrigerated semi-multi-deck DC (SMD-R); the frozen DCs consisted of a frozen multi-deck DC (MD-F), a frozen glass door reach-in DC (RI-F) and a frozen tub DC (TUB-F). Table 1 lists specifications of the 5 kinds of DCs. The 2 experimental plans are separately shown in Fig. 1(a) and Fig. 1(b). Plastic cardboard of approximately 1.7 m in height were fixed at the air exhaust to simulate a real store environment. A series of experiments were conducted to evaluate the effect of indoor air temperature and relative humidity on the cooling load of the 5 kinds of DCs, and the environment of the outdoor chamber remained at steady-state conditions (32°C and 40% relative humidity). The experimental conditions are summarized in Table 2. To build CFD models and to check the reliability, temperature and humidity and flow rate of the inlet and outlet vents of the DCs, the room temperature distribution and the cooling load of the DCs were measured.

2.2. Display case CFD Model

2.2.1. Detailed CFD Model

The laboratory model is shown in Fig. 2, which was built on the basis of the real laboratory. Detailed DC models, using the MD-R as an example shown in Fig. 3, were built based on the data obtained from the experiments. The commercial code STREAM Ver. 14 (November 2018. Software Cradle Co., Ltd. Oosaka, Japan) was employed for calculations in this study, and a high-Reynolds number-type κ-ε turbulence model was used to solve a steady-state simulation because the inaccurate imitation of viscous sublayers close to solid walls can be ignored in this study. A termination criterion of 10^{-4} is used for all variants in this study. The view factor method was used to calculate radiation. Additional details of the conditions are summarized in Table 3.

As the boundary conditions, the heat was insulated at all boundaries between the defined and undefined areas. The speed of flow from the air conditioner outlet surfaces was maintained at a constant speed. The air

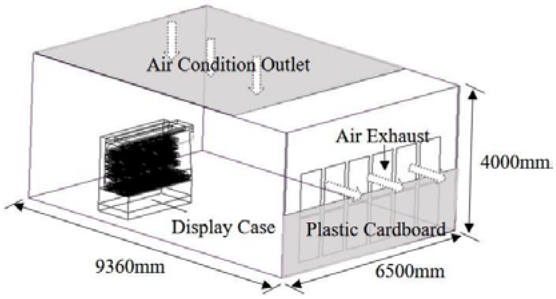

Fig. 2. Laboratory CFD model

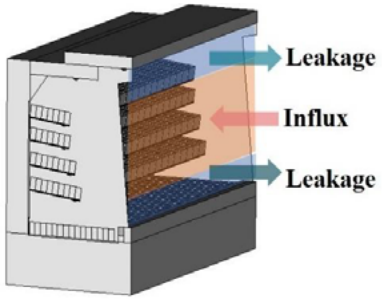

Fig. 3. Detailed model of MD-R

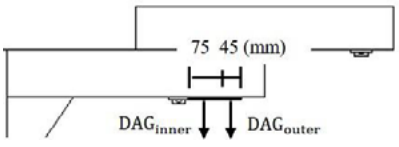
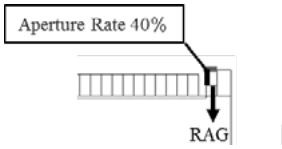
conditioner outlet temperature and relative humidity conditions were in accordance with the experiment (Table 3). The air conditioner exhaust surface was fixed as natural air outflowing and inflowing (the aperture ratio was fixed while under 1.7 m to simulate the plastic cardboard). Because plastic cardboard is not spliced tightly, the aperture may not remain constant through experiments. The aperture ratio values of the refrigerated and frozen experiments are discussed separately and determined as shown in Table 3. The DAG and RAG settings are shown in Fig. 4, using the MD-R as an example. The flow rate, temperature, and humidity of RAG and DAG were based on data measured from the experiment.



It was found that the air in front of a DC model was always divided into two air leakage parts and an influx part, as shown in Fig. 3.

The cooling load, which was calculated from enthalpy differences between the DAG and RAG of a DC, and vertical temperature distribution in front of the DC were used to inspect the reliability of the detailed DC CFD model. The MD-R is taken as an example, whose results are presented in Figs. 5 and 7. The positive reliability of the detailed DC CFD models was confirmed.



2.2.2. Simplified CFD Model

If the scale of a domain expands, the computational load increases when simulating the energy consumption of the store by using CFD with detailed DC models. Hence, a simplified DC CFD model was used to decrease the computational load.

Without building models in detail, such as shelves and goods, only leakage and influx surfaces are set, as shown in Fig. 6. The airflow volume, temperature, humidity of leakage and influx surface were fixed from the association between them and the average temperature of the influx surface. The relations were obtained from the results of the detailed models. Fig. 8 displays the volume of influx surfaces as an example. Formula (1)-Formula (5) show the relationships between the cooling load of the DCs and the average temperature and humidity of the influx surface, which can be used to obtain the energy consumption of the stores.

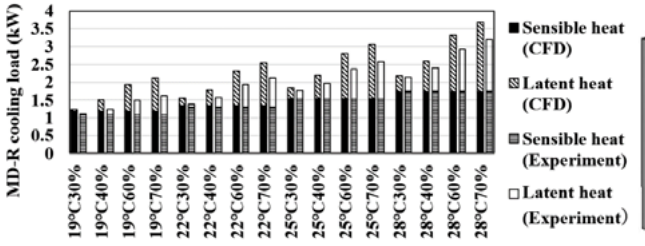

Fig. 5. MD-R cooling load reliability

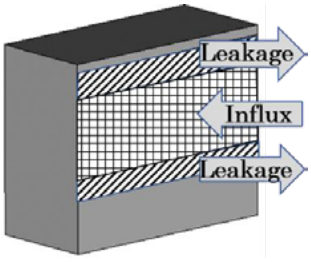

Fig. 6. Simplified model of the MD-R

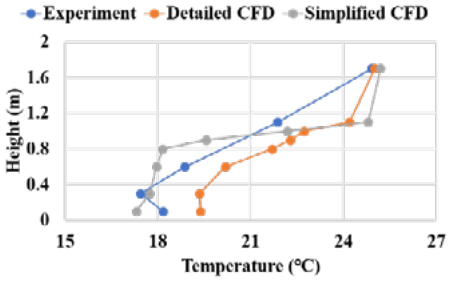

Fig. 7. Vertical temperature distribution (2 m away from the MD-R)

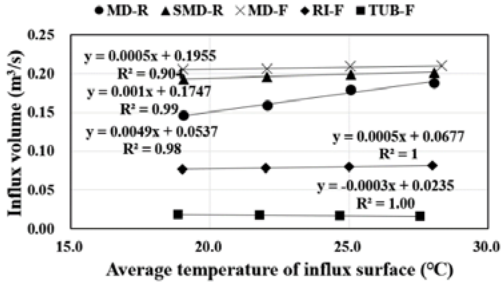

Fig. 8. Relationship between the influx volume and a measurement point temperature

The vertical temperature distribution in front of the DC were used to inspect the reliability of the simplified DC CFD model. The MD-R is taken as an example, whose results are presented in Figs. 7. The positive reliability of the simplified DC CFD models was confirmed.

$$Q_{MD-R} = 143.75 \times H_{in} + 0.083 \times T_{in} - 1.02 \quad (1)$$

$$Q_{SMD-R} = 182.17 \times H_{in} + 0.070 \times T_{in} - 0.67 \quad (2)$$

$$Q_{MD-F} = 124.62 \times H_{in} + 0.099 \times T_{in} + 7.43 \quad (3)$$

$$Q_{RI-F} = 0.070 \times H_{in} + 0.00215 \times T_{in} + 2.5 \quad (4)$$

$$Q_{TUB-F} = 4.286 \times H_{in} + 0.0022 \times T_{in} + 2.54 \quad (5)$$

2.3. Evaluation of the Energy Consumption of a Grocery Store

2.3.1. Description of the Grocery Store

The grocery store simulated in this study is a typical small grocery store that is approximately 261 m^2 in size and is located in Kobe. The plan of the store is provided in Fig. 9. There are 9 open refrigerated multi-deck DCs (MD-R), an open refrigerated semi multi-deck DC (SMD-R), 2 frozen multi-deck DCs (MD-F) and 2 hybrid-type frozen DCs, which were regarded as 2 frozen tub DCs (TUB-F) in this study. For the HVAC equipment, there are 4 four-way cassette indoor air conditioner units, 3 ducted exhaust ventilation fans used in the summer and a ducted in-line ventilation fan with four vents used in the winter.

2.3.2. Grocery Store CFD Model

Fig. 10 displays an exploded view of the CFD store model. The model consisted of refrigerated and frozen DCs, unrefrigerated DCs, HVAC equipment, architecture components, and people. The architecture components were external walls, an internal wall, the ceiling, the roof, the floor and windows, whose detailed settings are provided in Table 4.

A high-Reynolds number-type κ-ε turbulence model was used because the inaccurate imitation of viscous sublayers close to solid walls can be ignored in the store. Additional details of the basic conditions are summarized in Table 5. Radiation analysis was omitted due to the limitations of the CFD analysis code employed in this analysis, where radiation analysis and solar radiation cannot be activated simultaneously. Both surfaces of the DCs and HVAC devices were fixed as boundary conditions; therefore, only the walls and floors were influenced by radiation. Therefore, the error induced by neglecting radiation slightly influenced the airflow and temperature distribution results in this study.

The simulation time was set to Aug. 8th and Dec. 21st, whose solar radiation data were input from a database called METPV-11 [5]. In this paper, we only simulated starting at 12:00 by transient analysis whose interval time was 0.1 s per calculation cycle. The number of guests generating heat from bodies and leading to influx

from outside was determined to be 631 people per day based on the *Annual Statistical Report on Supermarkets* [6]. The total amount was distributed per hour according to the guest distribution of the store, which was obtained from Google Maps data [7]. The average time of stay of each guest was fixed as 10 minutes, which matched the size of the store. In addition, a staffer was set in the model. As a result, there were 63 people in total being set in the store model at the start of simulation at 12:00. The surface temperature of the guests and the staff was maintained constant at 36.5°C (Table 5).

As the boundary conditions, the heat was insulated in all boundaries between the defined and undefined areas. Inflow and outflow boundaries are shown in Fig. 10. Additional details of the boundary conditions are summarized in Table 5. The inflow boundaries consisted of the outlet surfaces of the air conditioners, the leakage surfaces of the abovementioned simplified DC models, and the outside influx surfaces of the entrance and backdoor. The outflow boundaries consisted of the inlet surfaces of the air conditioners and air exhaust surfaces of the ventilation fans. Additional details are supplied in the following sections.

Simplified refrigerated and frozen DC CFD models were arranged in accordance with the real store Although there is a range of set temperatures in the real store, the set refrigeration temperature was unified at 1°C, and the freezer temperature was at -28°C in the simulation because an accurate reproduction is not the purpose of this study. Unrefrigerated cases were placed in the center of the store. Moreover, to simulate the gap between goods placed in unrefrigerated cases, the refrigerated cases were built by surfaces with an opening ratio of 60%.

For air conditioner models, the outlet temperature and humidity were calculated from those of the inlet flow, which can be determined in a solver during the simulation. The power of the air conditioners set up in the store model was controlled by the inlet temperature. The power changed linearly over a range of ± 0.5°C around the set temperature from 0 kW to the maximum temperature and remained at constant values outside the temperature range. For example, when the preset temperature was 25°C in the summer, the power remained at 0 kW before 24.5°C, then the power increased as the temperature rose and was maintained at a maximum after 25.5°C. For the purpose of making the computations easy to converge, the power control function was set in a simplified way despite being different from the real function. Other detailed settings of the HVAC system, such as the ventilatory volume, are shown in Table 6.

Table 6 HVAC system and influx conditions

Item	Season	Conditions
Air conditioner	Summer	Mode: Cooling Volume: 0.0875*4=0.35 m^3/s, Maximum power: 14 kW
	Winter	Mode: Heating Volume: 0.15*4=0.6 m^3/s, Maximum power: 15 kW
Ventilation fan	Summer	The number of vents: 3 Total volume: 2115 m^3/h
	Winter	The number of vents: 4 Total volume: 610 m^3/h

Regarding the outside influx volume from the entrance or backdoor, 3 assumptions were considered in this study: (1) the automatic door at the entrance keeps opening for a duration of 10 s once someone passes, (2) the influx only originates from the entrance when the door keeps opening; in the other situation, the influx originates from the backdoor where the temperature remains at 22℃ in the winter and 25℃ in the summer, (3) without simulating the door opening and closing, the influx originates from both the backdoor and the entrance all the time in the CFD model to make the computation converge easily. Hence, the influx volume compensating for the outflow ventilation volume was separated from the backdoor and the entrance by the ratio of the time of the door opening and not opening.

The calculations were conducted for six cases each season, as summarized in Table 7. They were divided into two types: various preset temperature experiments and energy-saving strategies experiments. CASE3 was the standard of these cases. Four preset temperature experiments (from CASE1 to CASE4) were adopted to evaluate the effectiveness of the air conditioner temperature changes in the energy consumption of the store. One energy-saving strategy was halving the ventilation volume in the summer and tripling it in the winter (CASE3-V), and the other strategy was replacing the frozen multi-deck DCs with frozen glass door reach-in DCs (CASE3-R). In each case, an initial temperature indoor was set to be the preset temperature of air conditioners to make the computations faster to converge.

Table 7. Cases list

Experiment type	Case name	Display cases	Ventilation Volume(m^3/h)	Preset temperature
Temperature experiment	CASE1	MD-R, SMD-R, MD-F, TUB-F	Summer: 2115, Winter: 610	19℃

	CASE3	MD-R, SMD-R, MD-F, TUB-F	Summer: 2115, Winter: 610	25℃
	CASE4	MD-R, SMD-R, MD-F, TUB-F	Summer: 2115, Winter: 610	28℃
Energy-saving strategies	CASE3-V	MD-R, SMD-R, MD-F, TUB-F	Summer: 1058, Winter: 1830	25℃
	CASE3-R	MD-R, SMD-R, RI-F, TUB-F	Summer: 2115, Winter: 610	25℃

2.3.3. Energy and Electricity Calculation Method

The energy (load) consumption calculation was divided into 2 parts: DC and air conditioner. The formulas summarized above were used to calculate the cooling load of the DCs. For air conditioners, the cooling load or the heating load was calculated from enthalpy differences between the outlet air and inlet air.

The electricity can be calculated from the load by using the coefficient of performance (COP). In the summer, the COP of the air conditioners was 3.59, the refrigerated DC COP was 1.90, and the frozen DC COP was 0.75. In the winter, the COP of air conditioners was 4.06, the refrigerated DC COP was 1.86, and the frozen DC COP was 0.79.

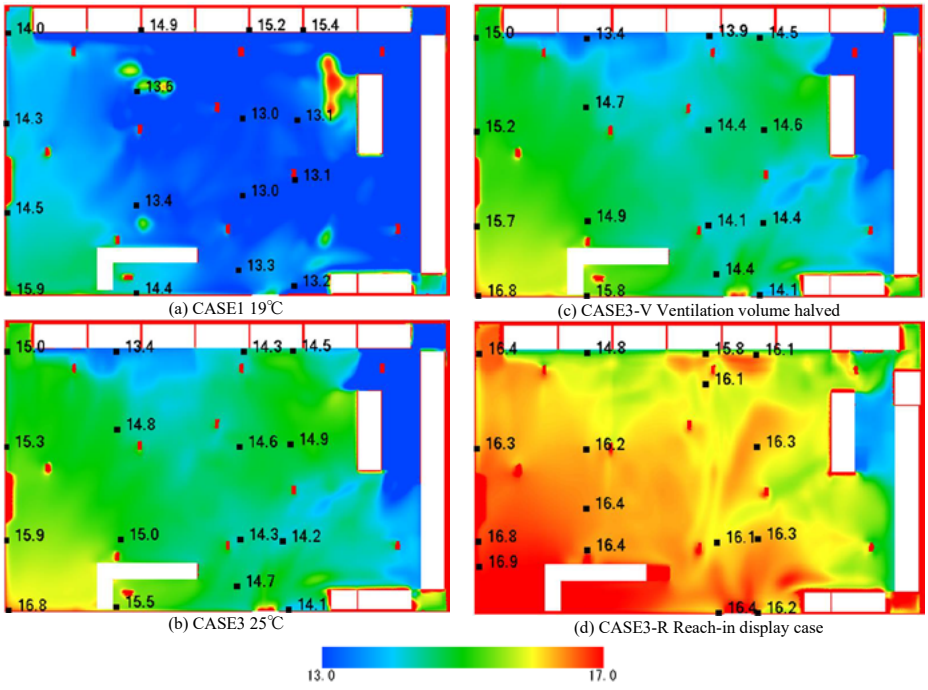

Fig. 11. Temperature plan distribution at the height of 0.7 m

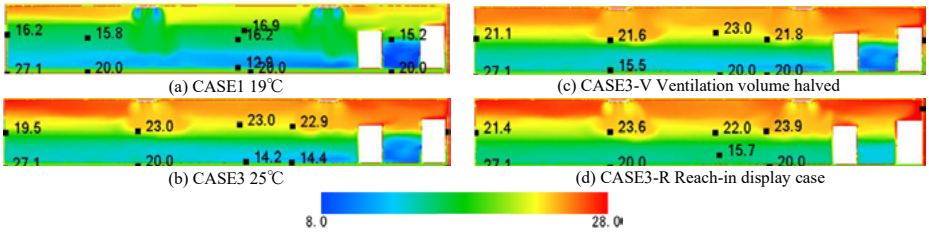

Fig. 12. Section plan temperature distribution

3. Results

3.1. Summer

3.1.1. Stability

The transient temperatures of the air conditioner outlet air and an indoor measurement point at a height of 1.6 m were used to check the stability of the simulations. The outlet air temperatures remained stable after 1000 cycles, while the indoor air temperatures remained stable after 6000 cycles. Therefore, the results of 10000 cycles were stable enough to be adopted.

3.1.2. Temperature

Fig. 11 compares the temperature plan distribution at a height of 0.7 m for different cases, and the temperature distribution of the section plan shown in Fig. 9 is provided in Fig. 12.

As a result, the higher the preset temperature was, the higher the temperature was in the upper part of the store, where high-temperature air accumulated. On the other hand, low-temperature air accumulated in the lower part of the store and hardly changed as the preset temperature increased. Therefore, the vertical temperature distribution was obviously separated into a low-temperature part and a high-temperature part. The

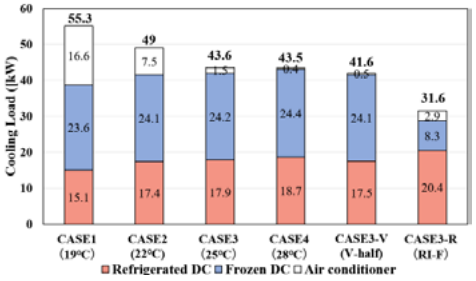

Fig. 13. Cooling load of the air conditioner & the DCs in the summer

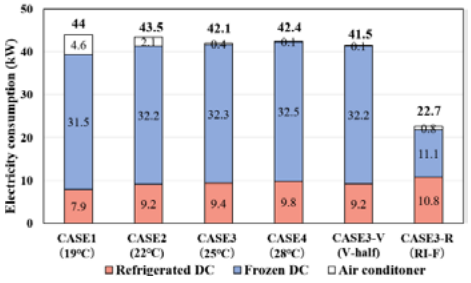

Fig. 14. Electricity consumption in the summer

maximum difference can reach 10℃. For the temperature plan distribution, the temperature decreased from the entrance to the innermost part of the store in every case. The average temperature of the 0.7 m plan was 13.6℃ when the preset temperature was 19℃, and it increased to 15.2℃ as the preset temperature increased to 28℃, which illustrates that the average plan temperature increased as the preset temperature increased.

When the ventilation volume was halved, the high-temperature part of the store became cooler because of the lower high-temperature influx air from outside; in contrast, the low-temperature part of the store hardly changed. The low-temperature part of the store became warmer when the frozen multi-deck DCs were replaced with frozen reach-in DCs.

3.1.3. Load and Electricity Consumption

The energy and electricity consumption in the summer are shown in Fig. 13 and Fig. 14, respectively. The result shows that with an increase in the preset temperature, the cooling load of the DCs increased while the space cooling load of the air conditioner decreased. The total cooling load of the DCs and the air conditioner increased with the increasing preset temperature of the air conditioners. Although the highest preset temperature of air conditioners and the highest total cooling load of DCs and the air conditioner were in the 28°C case, the total electricity consumption was minimized when the preset temperature was set to 25°C. Furthermore, the frozen multi-deck DCs strongly affected the total energy consumption of the store. By replacing the frozen multi-deck DCs with frozen reach-in DCs, the indoor air temperature increased. Therefore, the electricity consumption of DCs was halved, while that of air conditioners somewhat increased. In the aggregate, the total electricity consumption of the DCs and air conditioners obviously decreased while replacing the frozen multi-deck DCs with frozen reach-in DCs.

3.2. Winter

3.2.1. Stability

In the winter, the outlet air temperature remained stable after approximately 1000 cycles. Therefore, the results of 3000 cycles can be adopted.

3.2.2. Temperature

Fig. 15 compares the temperature plan distribution at a height of 0.7 m for different cases, and the temperature distribution of the section plan is provided in Fig. 16.

The results were similar to those for summer; the higher the preset temperature was, the higher the temperature was in the upper part of the store, where high-temperature air was accumulated. Simultaneously, low-temperature air accumulated in the lower part of the store and increased as the preset temperature increased, which is different from the summer. Also, with winter having a general opposite temperature compared to the summer temperature, the temperature increased from the entrance to the innermost part of the store. The indoor temperature decreased slightly when the ventilation volume was tripled. The low-temperature part of the store became warmer when the frozen multi-deck DCs were replaced with frozen reach-in DCs.

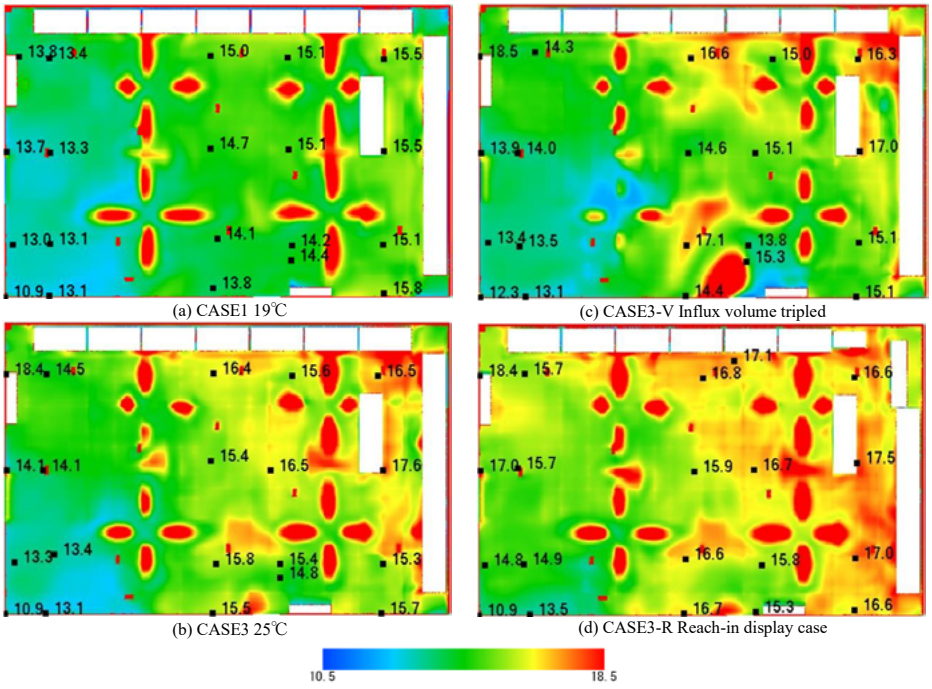

Fig. 15 Temperature plan distribution at the height of 1.4 m

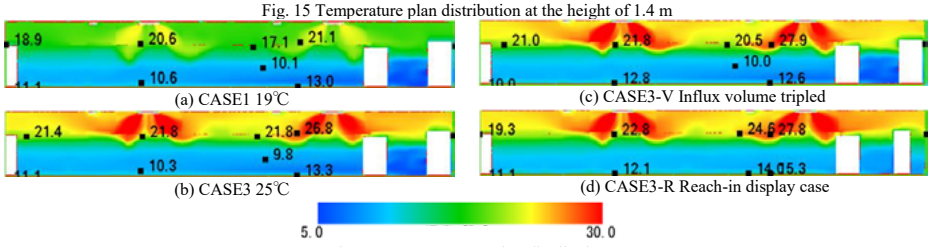

Fig. 16 Temperature section distribution

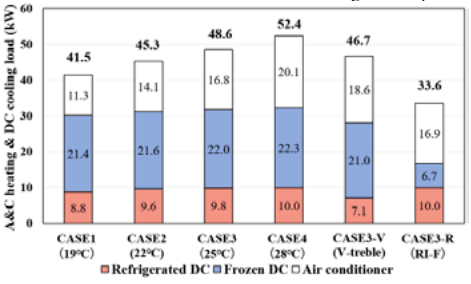

Fig. 17. Air conditioner heating & DC cooling load in the winter

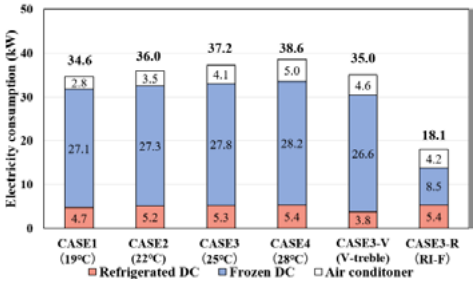

Fig. 18. Electricity consumption in the winter

3.2.3. Energy and electricity consumption

The energy and electricity consumption in the winter are shown in Fig. 17 and Fig. 18. The cooling load of the DCs and the heating load of the air conditioner both increased with increasing preset temperature. Additionally, the total electricity consumption of the DCs and air conditioners increased. Similar to summer, frozen multi-deck DCs also strongly affected the total energy consumption of the store in the winter. The total electricity consumption of the DCs and air conditioners decreased to half by replacing frozen multi-deck DCs with frozen reach-in DCs. In addition, the total load and electricity consumption both decreased when the

ventilation was tripled.

4. Discussion

We have shown that the CFD method can assist in simulating the energy consumption of DCs and air conditioners in a store and evaluating the interaction between them without assuming that the temperature is uniform anywhere indoors. By applying simplified DC CFD models, which can be adopted to calculate the cooling load of DCs in different conditions, to study changes in the energy consumption of a grocery store under different conditions, we found that the total energy consumption of the store changed when changing the preset temperature of air conditioners or adopting other energy-saving strategies. In the summer, the result shows that a higher preset temperature of the air conditioner leads to increases in the cooling load of the display cases and a decrease in air conditioners cooling load. In the winter, both the total electricity consumption and the total load increased with increases in the preset temperature. Furthermore, by replacing the frozen multi-deck DCs with frozen reach-in DCs in the summer, the electricity consumption of DCs decreased to half, while that of air conditioners somewhat increased; in the winter, the electricity and the load of the DCs and air conditioners both decreased.

The main cause of the load interaction between the DCs and air conditioners may be explained by the fact that the indoor temperature distribution changed under various conditions. It is surprising that the total electricity consumption in the summer was minimized when the preset temperature was set to 25°C, and the temperature was neither the highest nor the lowest explored. In contrast, the total cooling load of air conditioners and DCs became largest when air conditioners were set to 28°C. This is because the COP of air conditioners is larger than that of the DCs. Tripling the ventilation in the winter, which can lead to a more low-temperature air influx from outside, reduces the energy consumption of the store. An explanation is that the influx air restrained the cooling load of the DCs and comparatively induced a slight increase in the heating load of air conditioners because of the delamination of air. We believe that there might be an appropriate ventilation volume that can lead to the lowest energy consumption of the store, which is worth investigating in the future.

The method we adopted to build the DC CFD models was partly successful because it was able to simulate the cooling load under different temperatures and humidity environments. However, the limitation of the models we built is that they can only be applied under a particular condition, where the preset refrigerant evaporation temperature is -10°C and -40°C for refrigerated DCs and frozen DCs, respectively.

We also found that a vertical air temperature distribution was obviously separated into a low-temperature part and a high-temperature part. Research by Endo et al. shows a similar result [8]. A possible explanation for this is that the density of high-temperature air is lower than that of low-temperature air, which makes the lower air easily accumulate in the upper part of a room. In addition, to make the store model easy to converge computationally, we ignored the air mixing caused by guests moving or doors opening and closing, which might be able to strengthen the delamination in this study. The influence of air mixing should be evaluated in the future.

5. Conclusion

This study set out to develop a CFD store model to imitate the cooling load of DCs and air conditioners in a store and to evaluate the interaction between them. We changed the preset temperature of air conditioners and applied some energy-saving strategies to understand the interaction between the load of air conditioners.

The findings clearly indicated that changing the air conditioner preset temperature or altering the equipment arrangement in stores is in favor of reducing the energy consumption of stores.

- The DC CFD models in this study can be used to calculate the cooling load of DCs under different conditions and to imitate the transient energy consumption of grocery stores.
- If the temperature was increased by the air conditioners, both the load of the DCs and air conditioners increased in the winter; however, in the summer, the load of the DCs increased, while that of air conditioners decreased. The lowest electricity consumption occurred when the preset temperature was 25°C in the summer. An appropriate temperature should be set to save energy rather than being set as high as possible in the summer.
- Replacing open DCs by reach-in door DCs can obviously reduce the load of the store. Reducing the ventilation volume in the summer or increasing it in the winter can also help save energy in the store.

- In the future, factors such as people moving and doors opening should be considered to improve the precision of store CFD models.

Abstract

An automotive air-conditioning system and refrigeration truck is normally used refrigeration R134a and R404A. The natural refrigerant R744 is one of alternative refrigerant for refrigeration truck. In this study, the theoretical study on the performance comparison between R744, R134a, and R404A for the refrigeration truck. The cooling capacity, compressor work, and COP of R744 refrigeration system were analyzed according to outdoor air temperature and compressor rotating speed. Also, those are compared with those of R404A and R134a system. As a result, the performance of all systems with the outdoor temperature was rapidly decreased. The performance decrement of R404A is relatively higher than that of other system. In the change of RPM, the increasing rate of cooling capacity and compressor work of the R404A, R134a, and R744 system reached the highest at 1500 RPM. The data of this study is to provide the basic performance data of refrigeration system of refrigeration truck.

Keywords: Compressor work; COP; R134a; R404A; R744; Refrigeration capapcity

1. Introduction

As parcels and distribution supply recently increased, energy consumption for the storage and transport of parcels is increasing. In particular, the energy consumption for delivery has increased even more as the demand for delivery has increased compared to the storage of items. In addition, as the delivery of products requiring freshness from among the delivered products increases, the demand for a refrigeration truck using a refrigeration system is increasing to keep the temperature of the product storage room constant at all times.

Refrigeration trucks consume more energy than general trucks by using a refrigeration unit to maintain a constant temperature in the product storeroom. Therefore, research on improving the performance of refrigeration truck is essential for energy saving. The Ozone Depletion Potential (ODP) of R404A and R134a refrigerants, which are widely used in the refrigeration industry, is currently 0, but the Global Warming Potential (GWP) is very high at 4,700 and 1300, respectively. Regarding refrigerants used in automotive air conditioning systems, the European Commission has decided to regulate the use of refrigerants more than GWP of 150 for new vehicles since 2022. R744 refrigeration system can miniaturize because R744 refrigerant has a smaller specific volume than R404A and R134a. In addition, it can be used even at low temperatures since the boiling point is low. Table 1 showed the properties of refrigerant used in this study.

In this study, R404A, R134a and R744 refrigerants were applied to the refrigeration system of refrigeration trucks, and the performance of refrigeration truck refrigeration system was compared under various operating conditions. The results of this study may provide basic data on the performance of refrigeration truck refrigeration system with alternative refrigerants.

2. Simulation modeling and analysis

The refrigeration truck refrigeration system used in this study was developed by selecting the refrigeration truck currently operating on the road as the main analysis model. And the developed system shown in Fig. 1 is consist of compressor, condenser, expansion valve and evaporator. This simulation is conducted using the EES program and the flow of performance analysis was carried out as shown in Fig. 2.

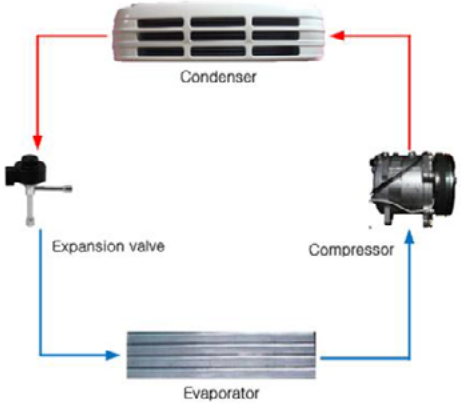

Fig. 1. Refrigeration cycle of refrigeration truck

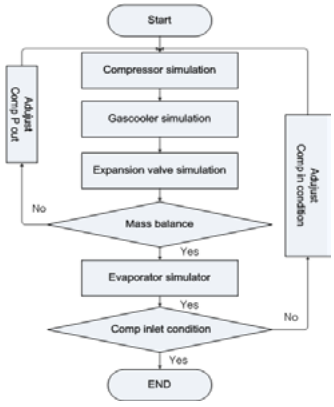

Fig. 1 Flow chart for the refrigerator cycle

2.1. Compressor modeling

The compressor of R404A, R134a and R744 used in the analysis of this study was selected due to its durability and widely used as swash plate compressor of automobile air conditioning systems. In the case of R744, as the rate of heat capacity is bigger than R404A and R134a, the stroke volume of the compressor is controlled to obtain the same refrigeration capacity from the system. The equation (1) was used to calculate the mass flow rate of R404A, R134a and R744. The volumetric and isentropic efficiency of R404A, R134a, and R744 in this study was used based on the experiment of previous study [1-3]. The volumetric and isentropic efficiency of the refrigeration system for R404A were used the equation (2) and (3) [1], respectively. In case of the refrigeration system with R134a, It was calculated by the equation (4) and (5) [2]. The volumetric and compression efficiency of refrigeration system for R744 was calculated by the equation (6) and (7) [3].

$$M_r = n\frac{\pi}{4}d_c^2 S_p N\frac{\eta_v}{v_s} \tag{1}$$

$$\eta_{v,R404A} = 0.3596 + 1.1072 \times S_p - 0.08132 \times \varepsilon + 0.0001175 \times N - 0.4025 \times S_p^2 - 2.449 \times 10^{-8} N^2 \tag{2}$$

$$\eta_{i,R404A} = 0.2402 + 1.4187 \times S_p - 0.09698 \times \varepsilon + 0.000123 \times N - 0.5852 \times S_p - 2.457 \times 10^{-8} N^2 \quad (3)$$

$$\eta_{v,R134a} = 0.8263 \left[1 - 0.09604 \left(\varepsilon^{\frac{1}{\gamma}}\right) - 1\right] \quad (4)$$

$$\eta_{i,R134a} = 0.9343 - 0.04478 \times \varepsilon \quad (5)$$

$$\eta_{v,R744} = 1.149768 + 0.001025 \times P_{c,in} - 0.003592 \times P_{c,in} - 13.660815 \times V_s + 0.000059 \times N \quad (6)$$

$$\eta_{c,R744} = 0.781749 - 0.000956 \times P_{c,out} - 0.003812 \times SH_{c,s} - 0.003565 \times T_{c,s} + 0.000033 \times N \quad (7)$$

2.2. Heat exchanger modeling

The condenser consists of four rows and is divided into two tubes. And the evaporator is divided into six tubes and consists of eight rows each. Detailed specifications of the heat exchanger are shown in Table 2. In this study, the heat transfer and pressure drop correlation of single-phase and two-phase used for modeling of R404A, R134a and R744 system is shown Table 3. In addition, the heat transfer coefficient and pressure drop for the analysis of air side used the correlation of the Wang [14].

Table 2 Specification of heat exchanger

Specification	Condenser	Evaporator
Fin interval [mm]	2.1	4.56
Fin height [mm]	25.78	22.64
Fin width [mm]	24.83	26.13
Tube diameter [mm]	9.5	9.5
Tube thickness [mm]	0.5	0.5
Total size [mm]	760.2(L)×283.5(H)×99.3(W)	864.6(L)×135.8(H)×209(W)

Table 3 Heat transfer coefficient and pressure drop of R404A, R134a, R744 for heat exchanger modeling

	R404A		R134a		R744	
	Single- phase	Two- phase	Single-phase	Two-phase	Gascooler	Evaporator
Heat transfer coefficient	Wang[4]	Traviss[6]	Dittus and Boelter[8]	Gungor and Winterton[10]	Gnielinsk [11]	Yoon et al [13]
Pressure drop	Blasius[5]	Fridel[7]	Fanning and Pierre[9]	Fanning and Pierre[9]	Churchill [12]	Yoon et al[13]

2.3. The expansion device modeling

The expansion device used in the R404A, R134a, and R744 system used the electron expansion valve. The electron expansion valve is comprised of the orifice, needle and the drive stepping motor. The orifice diameter used to the modeling of R404A and R744 system was 1.6 mm. It used the equation of the Hwang and Kim [15]. The orifice diameter of the R134a system was 1.4 mm and it used the equation of the Chung et al [16].

2.4. The frost analysis

The frost growth in the evaporator has an bad effect on the system efficiency due to the decrease of heat transfer area in the heat exchanger. The thermal resistance and heat transfer coefficient of the frost layer was applied to the heat exchanger analysis of the R404A, R134a and R744. Thermal conductivity and density of the frost layer was calculated according to the equation proposed by Lee at al. [17] and those are calculated by the equations (8) and (9).

$$k_f = k_{ice} \times 0.26259 (Re_d)^{0.49406} (Fo)^{0.18733} (w_a)^{-0.25087} (T_a^*)^{-7.20328} (T_c^*)^{5.5004} \quad (8)$$

$$\rho_f = \rho_{ice} \times 0.00008 (Re_d)^{0.44785} (Fo)^{0.21083} (w_a)^{-0.53939} (T_a^*)^{23.90830} (T_c^*)^{5.69576} \quad (9)$$

3. Results and discussion

In this study, the performance characteristics of the system were investigated the performance for refrigeration cycle of the designed refrigeration truck refrigeration system using R134A, R404A, and R744 refrigerant. Fig. 3 showed the variation of COP, compressor work, and cooling capacity according to the change of outdoor air temperature. As the outdoor air temperature increased from 25℃ to 35℃, the compressor work of R404A, R134a, and R744 system increased by 19.1%, 13.1%, and 16.8%, respectively and the refrigeration capacity ratio decreased by 43.1%, 9.0%, and 41.5%, respectively.

Fig. 4 showed the variation of COP, compressor work, and cooling capacity according to the change of compressor rotating speed. As the compressor rotating speed increased from 1000 rpm to 3000 rpm, the ratio of compressor work and of refrigeration capacity rapidly increased at the system of R404A, R134a, and R744. Accordingly, the ratio of COP decreased because compressor work more increased than refrigeration capacity. The COP ratio of R404A and R744 system showed maximum value at the compressor rotating speed of 1500 rpm.

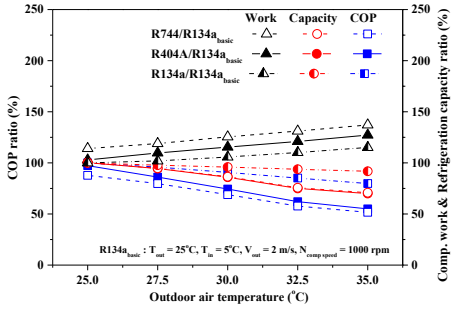

Fig. 3. Variations of compressor work, capacity, COP with outdoor air temperature

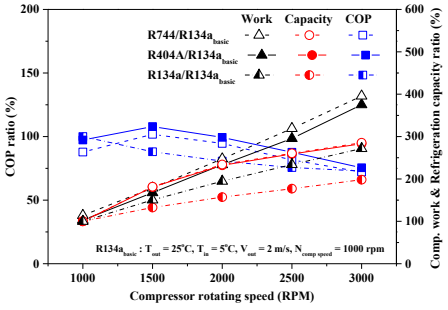

Fig. 4. Variations of compressor work, capacity, COP with compressor rotating speed

4. Conclusions

In this study, R404A, R134a and R744 refrigerants were applied to the refrigeration system of refrigeration trucks, and the performance of refrigeration truck refrigeration system was compared under various operating conditions. An automotive air-conditioning system and refrigeration truck is normally used refrigeration R134a and R404A. The natural refrigerant R744 is one of alternative refrigerant for refrigeration truck. In this study, the theoretical study on the performance comparison between R744, R134a, and R404A for the refrigeration truck. The cooling capacity, compressor work, and COP of R744 refrigeration system were analyzed according to outdoor air temperature and compressor rotating speed. Also, those are compared with those of R404A and R134a system. As a result, the performance of all systems with the outdoor temperature was rapidly decreased. The performance decrement of R404A is relatively higher than that of other system. In the change of RPM, the increasing rate of cooling capacity and compressor work of the R404A, R134a, R744 system reached the highest at 1500 RPM. The data of this study is to provide the basic performance data of refrigeration system of refrigeration truck.

Abstract

An air-source heat pump for floor heating system was developed and tested which produced hot water for heating the floor of residential buildings by heat pump cycle. The field test of the air-source heat pump for the floor heating system has been conducted in winter for 93 days. During the test, the compression ratio (π) was controlled stable based on the exergy performance analysis. The theoretical η_x of the system decreases with the increase of the compression ratio (π). The values of π were maintained as small as possible from 2 to 6 approximately in the ideal control method in the winter test. Based on the control strategy, the system was proved to be robust. The energy efficiency ratio (EER) ranged from 2.32 to 4.71 while the heat capacity ranged from 3.8 to 10 kW. Especially, the performances of the system in the warmest and coldest days were compared. The results indicate good environmental adaptability of the heat pump system.

Keywords: heat pump; floor heating system; field test

1. Introduction

Building energy consumption has become an important aspect that cannot be ignored. Some studies have shown that energy consumption can be saved by 20% to 30% via optimizing system operation and efficient energy management without changing the building structure and internal equipment [1]. Heating ventilation and air conditioning (HVAC) system is the main energy consumption system in residential buildings, which generally accounts for 30%~50% of the total energy consumption [2]. At present, heat pumps are widely used for domestic hot water (DHW) preparation and space heating (SH), which can offer the possibility to substitute conventional heating systems (direct electric, oil boiler, gas boiler, etc.) and reduce the primary energy consumption [3]. Especially, air-source heat pumps (ASHP) are widely used in residential heating and cooling systems due to the low installation costs and high efficiency [4]. In this paper, an air-source heat pump system used for floor heating was proposed and tested. The operation performance was evaluated.

2. System description

A schematic diagram of the proposed air-source heat pump system is shown in Fig. 1. The system consists of an inverter compressor, an electronic expansion valve, a fin-tube heat exchanger in the airside, and a plate heat exchanger in the waterside. When the heating model is operated, hot water is produced through the plate heat exchanger by the heat pump cycle.

The adaptive defrosting strategy is applied in the system for improving the adaptation to environmental variations [5]. The whole defrosting process is conducted in time and barely does not affect the indoor temperature. The operation test was conducted and the main working conditions are shown in Table.1.

Table 1 Test condition of the air-source heat pump for floor heating system

Nominal Condition	Outdoor dry/wet bulb temperature (T_{od}/T_{ow}:)	Water flow rate(Q)	Outlet water temperature (T_o)	Refrigerating/ Heating capacity(C_R/C_H)	Inlet power(P_{in})	EER
Refrigerating	35/- ºC	1.2 m^3/h	7 ºC	2 kW	2.77 kW	3.08
Heating	7/6 ºC	1.2 m^3/h	45 ºC	9.02 kW	2.87 kW	3.14
			35 ºC	9.56 kW	2.38 kW	4.02

3. Application test in winter

The air-source heat pump system is used on the third floor of a 6-storey unit building in Chuzhou, Anhui Province, China，in which the building area is about 120 m^2. The whole heating load in the winter season is calculated to 2.19KW. In Fig. 2, residential structure and geothermal hot water circuit design can be seen that four separated hot water circuits are respectively installed in the master bedroom A, second bedroom B, master bedroom C and study room D. Besides, the temperatures of the water inlet and outlet were tested outside to control the condensing temperature for the stable air temperature in the room, and the evaporating temperature varied with ambient temperature by the fin-tube evaporator in Fig. 2.

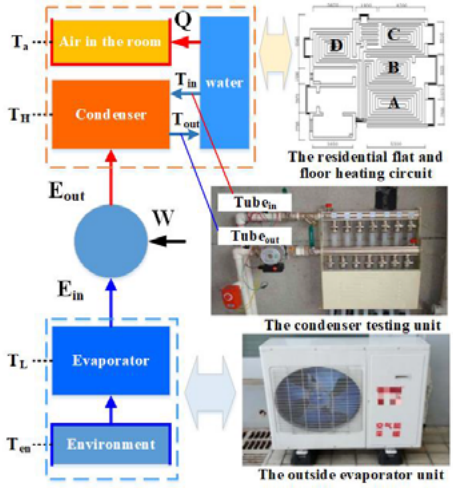

Fig. 2. The diagrammatic sketch of the principle of the air-source heat pump for floor heating system

The Energy efficiency ratio (*EER*) of the heat pump unit is the long-established evaluation parameter that is the ratio of heating energy and energy consumption of the system. Energy consumption (W) is the inlet

electric energy, and heating energy (Q) is the energy from the environment (E_{in}) plus electric energy (W) shown in Fig. 2. W is measured by the power meter every one minute.

3.1. Exergy efficiency

For the vapor compression system, the external power is supplied by the compressor for the major components: evaporator, condenser, and expansion valve. Heat transfer between the chiller and the environment shown as Qcond in Fig. 3 takes place at a finite temperature difference, which is a major source of energy losses for the cycle. Irreversibility causes system performance to degrade. The irreversibility in the cycle is supposed to be evaluated considering individual thermodynamic processes that composed the cycle. To show the individual process energy balances, exergy calculations provide increased and deeper insight into the process for improvements. Exergy analysis of the heat pump system for heating floor is performed by analyzing the components of the system separately. Identifying the main sites of exergy destruction shows the direction for potential improvements. The goal of exergy analysis for the system is to find the minimum power required for a certain desired result. The expressions for the exergy efficiency and exergy loss for the individual processes that make up the cycle as well as the energy efficiency ratio (EER) and second law efficiency for the entire cycle are analyzed.

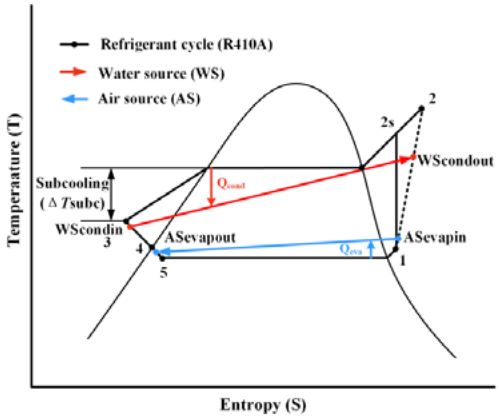

Fig. 3. T–s diagram of the refrigerant cycle and heat sources (water and air sources).

T–S diagram of the system is shown in Fig. 2. In the diagram, process 1-2s is isentropic compression in the compressor. The real compression process is the state 1-2. The other states viz. 2-3, 3-5, and 5-1 show condensation, throttling in the expansion valve, and evaporation in the evaporator respectively. The special lines in red and blue of the refrigerant (R410A) states in Fig. 2 indicate the heat exchange processes of air source and water source.

The mathematical formulation for exergy analysis in different components can be arranged in the following way:

Specific exergy in any state is:

$$\psi = (h - h_d) - T_d(s - s_d) \tag{1}$$

where h is the specific enthalpy, s is the specific entropy, and T_d, h_d and s_d are the temperature, the enthalpy, and the entropy at the dead state.

For evaporator, the heat addition in the evaporator is:

$$Q_{evap} = \dot{m}(h_1 - h_5) \tag{2}$$

The exergy destruction of the evaporator is:

$$I_{evap} = \dot{m}(\psi_5 - \psi_1) + Q(1 - \frac{T_d}{T_{ev}}) \\ = \dot{m}(h_5 - h_1) - T(s_5 - s_1) + Q(1 - \frac{T_d}{T_{ev}}) \quad (3)$$

For the compressor, the compressor work is:

$$W_{com} = \dot{m}(h_2 - h_1) \quad (4)$$

For non-isentropic compression, the electrical power is:

$$W_{el} = \frac{W_{com}}{\eta_{mech}\eta_{el}} \quad (5)$$

where the mechanical efficiency (η_{mech}) and the electrical efficiency (η_{el}) of the motor are 90% respectively.

The exergy efficiency (η_x) is:

$$\eta_x = \frac{\psi_1 - \psi_5}{W_{el}} \quad (6)$$

The energy efficiency ratio (*EER*) is:

$$EER = \frac{h_1 - h_5}{W_{el}} \quad (7)$$

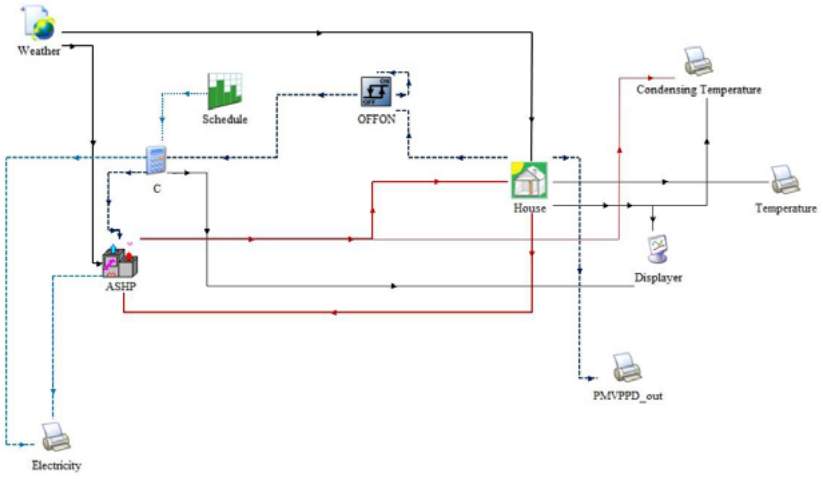
To improve the *EER* of the heat pump, the refrigerant cycle should be controlled for enlarging (h_1-h_4) based on equation (7) and reducing (h_2-h_1) based on equations (4) and (5). It could be concluded that h_1 is positively correlated with *EER*. Based on equations (1), (5), and (6), the η_x could be improved by controlled for the proper h_5 which is mainly controlled by point 3 in the cycle under varied ambient conditions. To improve the *EER* of the heat pump, the refrigerant cycle should be controlled for enlarging (h_1-h_4) based on equation (7) and reducing (h_2-h_1) based on equations (4) and (5). It could be concluded that h_1 is positively correlated with *EER*. Based on equations (1), (5), and (6), the η_x could be improved by controlled for the proper h_5 which is mainly controlled by point 3 in the cycle under varied ambient conditions. In conclusion, points 1 and 3 should be controlled for closing the states of inlet air (point ASevapin in Fig. 3) and inlet water (point Wcond in Fig. 3) to decline the temperature difference between the heat sinks and the heat sources. Based on the researches for the best performance according to the energy and exergy efficiency of the system, exergy efficiency can be improved by controlling sub-cooling temperature to 5 °C. It can be done for reducing the pressure rises in the compressor and hence reduce the irreversibility in the compressor because it is found that most of the irreversibility occurs in the compressor parts. The temperature difference of the evaporating and condensing temperature should be reduced because exergy loss increases as the temperature of the evaporator decrease. For a fixed indoor temperature heated by the condenser, the condensing temperature varies with the inlet water source temperature. The components that contribute most to the heat pump exergy efficiency improvement with the sub-cooling state are the expansion valve and the condenser. To decline irreversibility which can lead to the reducing exergy destruction ratio (*EDR*) and the increasing exergy efficiency of the heat pump system, the sub-cooling temperature should be maintained close to 5 °C, also the compression ratio (π) is kept stable. The inlet water temperature for the test in winter varied from 2 to 12 °C, and the inlet air temperature varied from -10 to 12 °C. Therefore, π of the compressor unit should be maintained from 2 to 6 and the actual π in the practical test is controlled from the range of 2.67 to 5.73 by the expansion valve and the variable frequency compressor in the test.

3.2. Operation test

The approach of the air-source heat pump for the floor heating system has been implemented in TRNSYS software for accurately modeling the dynamic simulation of the system. The simulating data for 93 days in winter were performed in Fig. 5 (a) to verify the theory of the ideal control method. The field test of the air-

source heat pump for the floor heating system has been conducted comparing with the simulating data in winter for the 93 days. Based on the fixed compression ratio (π) controlled by the system, the tested heating capacity (*HC*(Test)) and energy efficiency ratio (*EER*(Test)) of the heat pump system, which nearly are the same as those of simulation (*HC*(Sim) and *EER*(Sim) in Fig. 5 (a)), showed opposite variation trends. The tested heating capacity of the system ranged from 3.8 kW to 10 kW, while *EER* ranged from 2.32 to 4.71. It means that the required heating capacity varied with the change of environmental temperature, and the relatively stable temperature field can be obtained due to the fixed π during the heating period.

As shown in Fig. 5 (b), the average measured temperatures at different height of 0.1m, 1m, 1.5m, and 2m were 20.5ºC, 19.5ºC, 19ºC, and 18.4ºC in the heating periods, during which the outdoor temperatures were ranging from -10ºC to 14ºC with the average temperature of 3.7ºC. Therefore, people could feel comfortable owing to the relatively stable temperature field in the house.



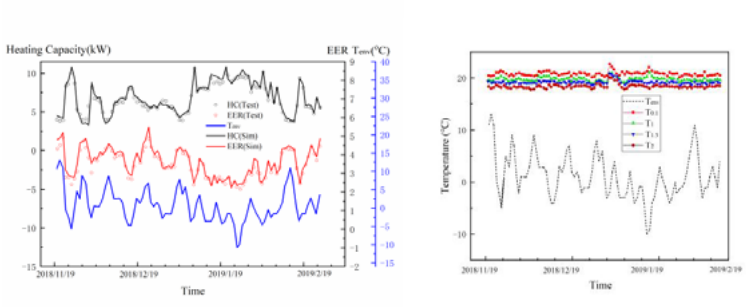


Fig. 4. The diagrammatic sketch of air source heat pump for floor heating system in TRNSYS software

(a) (b)

Fig. 5. The performance of the air-source heat pump in winter (a. Tested temperatures b. EER and *Q* in winter)

The operation performances of the heat pump system in the coldest and warmest days were listed in Table.2 based on the tested data. The results show that: 1) In the whole period, there was a great difference between the outdoor temperatures on the coldest and warmest days. The indoor temperature keeps relatively stable at about 19 ºC which indicates good environmental adaptability of the heat pump system. 2) The heating capacity and *EER* on the coldest day are relatively stable, while the fluctuation is relatively larger on the warmest day. The average *EER* in the warmest day is much higher than that of the coldest day by 159%. 3) The difference between suction pressure and exhaust pressure in the coldest day and the warmest day is small and within a reasonable range based on the required stable indoor temperature.

Table 2 The operation data of the heating system on the typical days during the heating period

Typical weather day	Environmental temperature(T_{env})	Heating capacity(Q_h)	EER	Suction/Exhaust pressure(P_s/P_e)	Condensing/Evaporating temperature(T_c/T_e)
The coldest day(2019/1/23)	-4.3~-10.0ºC	8.6~9.61 kW	2.01~2.54	0.44/2.52MPa	48.3/-16.3 ºC
The hottest day(2018/11/21)	8~16 ºC	2.1~6.03 kW	3.62~5.33	0.79/2.11 MPa	37.9/-0.3 ºC

4. Conclusion

The air-source heat pump system for floor heating was presented. Based on the theoretical analysis of the exergy efficiency (η_{ex}), the related simulation and operation tests were conducted and its performance was analyzed. Some conclusions are shown as follows.

(1) The theoretical η_x of the system decreases with the increase of the compression ratio (π). According to the actual demand, the sub-cooling temperature should be maintained close to 5 ºC, also the compression ratio (π) should be kept stable theoretically. The values of π were maintained as small as possible from 2 to 6 approximately in the ideal control method in the winter test.

(2) The average measured temperatures in different heights show a relatively stable and uniform indoor temperature field during the heating period in the winter test. Under the different outdoor temperatures, the heating capacity of the presented heat pump varied from 3.8 to 10 kW with the *EER* changed from 2.32 to 4.71. The required heating capacities in the coldest and warmest days can be both satisfied owing to the controlled compression ratio (π), which shows the good environmental adaptability of the system.

(3) The actual *EER* is not only correlated with η_{ex} but also the coefficient of performance and rate of the heating of evaporator, condenser, and water source. There is a clear positive correlation among them, and thus η_{ex} could be the only objective function theoretically. The real gap between *EER* and η_{ex} is the ignored error in measurement and the product of the coefficient of performance and rate of the heating source which could be researched further.

Abstract

The present study aims to investigate the characteristics of evaporating thin film (ETF) in the interfacial region during evaporation. High-resolution imaging technology was used for visualization of a sessile droplet based on the surface plasmon resonance phenomena. In particular, the influence of surface wettability on the depinning behavior and the evaporation flux near the edge of a sessile droplet was examined. To resolve the singularity problem occurring at the edge of a droplet, the current study suggests a single-valued boundary limit which can be imposed at the edge, based on the experimental data. From the result, it is found that the estimated ETF distribution shows a similar order of magnitude to the profiles predicted by the Maxwell equation. There is also little influence of droplet volume on the ETF thickness and width, indicating that interfacial phenomena in the contact line region are affected mainly by wettability, not by droplet volume.

Keywords: Evaporating thin film (ETF); Surface plasmon resonance (SPR) imaging; depinning behavior;contact line region

1. Introduction

Droplet evaporation is regarded as one of commonly occurring processes in the surrounding nature and an important physical phenomenon that controls heat and mass transfer through a phase change. It can also be applied to various industrial fields such as spray cooling, direct injection engines, and heat exchangers [1]. As a matter of fact, a lot of studies have reported the dynamic behavior of droplet evaporation, related to heat transfer enhancement [2]. Using the theoretical equation based on Fick's law, the infinite flux was shown at the edge of a droplet showing singularity [3]. This singularity wouldn't be real because finite but maximum evaporation takes place in the contact line region. Cachile et al. [4] obtained the local flux distribution explicitly for the droplet with very high wettability, and Hu and Larson [3] estimated the local evaporation flux which rapidly increased at the edge of the droplet. Xie at al. [5] tried to resolve this singularity by using the molecular dynamics simulations on hydrophilic and hydrophobic surfaces, and they showed there is finite evaporation flux in the contact line. Physically, the contact line region has three regions such as adsorbed film, evaporating thin film (ETF), and bulk meniscus regions [6]. The ETF represents a liquid thin film evaporating between adsorbed film and bulk meniscus. Due to the sub-micron scale, it is very difficult to directly visualize the ETF region. Instead, most of the studies on the ETF have been carried out by theoretical and numerical manners [7].

Hence, the near-field visualization methods should be adopted for showing the ETF and examining its characteristics. As one of earlier efforts, we used the confocal microscopy for visualization of the ETF [8], successively showing micro-scale thin film emanating from the bulk droplet. The present study used the surface plasmon resonance (SPR) imaging to capture the sub-micron scale ETF because this method is capable of being of very high vertical resolution with a few tens nanometer. Indeed, we have successfully visualized the sub-micron frost layer between the frozen droplets and conducted quantitative measure of frozen layer thickness by using the surface plasmon resonance imaging microscope (SPRIM) [9]. Based on the previous study, the present study aims to visualize the ETF region of the sessile droplet on the surface and to estimate

E-mail address: shlee89@cau.ac.kr

the thin film thickness by using the SPR imaging. In particular, we suggested the new evaporation flux model with the measured length of the ETF region by estimating a finite boundary limit. In the following sections, the present study describes the details of experiments and the theoretical modeling, and also presents the experimental results. In the end, the results are summarized in the conclusion.

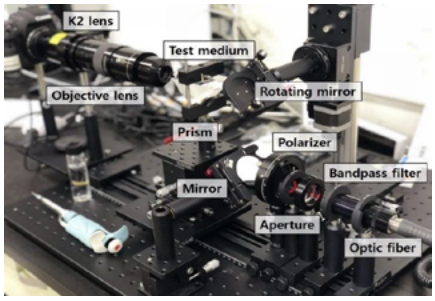

Fig. 1. Experimental setup (SPRI system).

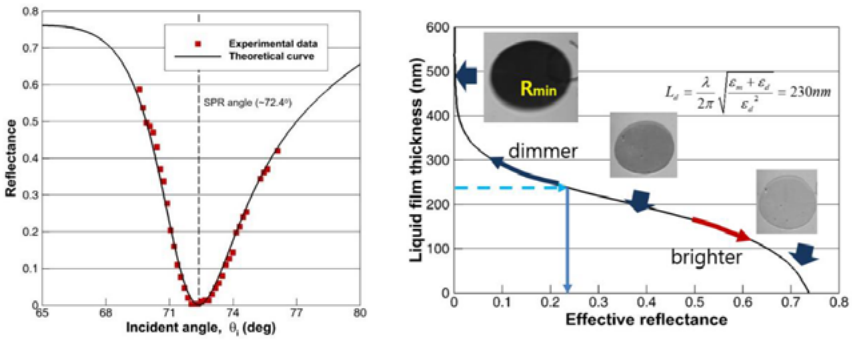

Fig. 2. a) reflectance variation with incident angle, b) liquid film thickness with respect to effective reflectance.

2. Experiment and modeling

To determine the flux profile along the liquid-vapor interface of the sessile droplet, most of the previous works have adopted the diffusion-limited model, assuming that the transfer rate depends on the diffusion of saturated vapor during evaporation [10]. Moreover, the evaporation flux along the liquid-vapor interface of the droplet is eventually determined by the overall shape of droplet [11]. So, we used the analogy between vapor concentration and electrostatic distribution, the evaporation flux can be expressed by [12]. We can estimate the evaporation flux along the interface by

$$J(r) = \frac{D(1-RH)c_{sat}}{R_i}\left[\frac{1}{2}\sin\theta + \sqrt{2}(\cosh\alpha + \cos\theta)^{3/2} \times \int_0^\infty \frac{\cosh\theta\tau}{\cosh\pi\tau}\tanh[(\pi-\theta)\tau]P_{-1/2+i\tau}(\cosh\alpha)\tau\, d\tau\right] \quad (1)$$

where J is evaporation flux, D is diffusivity of 26.1 mm^2/s [13], c_{sat} is saturated vapor concentration of 2.32 $\times$ 10^{-8} g/mm^3 [3], RH is relative humidity, R_i is droplet contact diameter, r is the radial position, θ is contact angle of the sessile droplet, and P is the representation of Legendre function.

As shown in Fig. 1, the present study uses the surface plasmon resonance imaging (SPRi) system because this method has very high vertical resolution, making it possible to visualize the evaporating thin films in the contact line region. The long-distance K2 lens with 9.6× magnification was attached to CMOS camera (CANON, EOS 7D), with a pixel resolution of 680 nm. The CMOS camera captured the single-wavelength light reflected from the prism at one frame per second. The right-angle prism consists of BK7 glass (Edmund Optics), and its corresponding refractive index is 1.516 (at λ = 632 nm). The coverslip with a 50 nm gold thin layer (Platypus Tech., Au.0500.CSS) on the 2.5 nm titanium adhesion layer was attached to the prism by using an index

matching liquid (Norland, IML150) with the same refractive index of the BK7 glass. The light irradiated from the halogen lamp (Dolan-Jenner) is converted into a single wavelength light beam through a bandpass filter (632 ± 5 nm, Edmund Optics). A collimation lens array is installed to convert the diverging light beam into a parallel light beam.

As shown in Fig. 2(a), the measure reflectance shows very good agreement with the theoretical solutions from Maxwell equation and thin film optics theory. The surface plasmon is representing the energy carrier being charged, and the evanescent wave propagates along the interface between two dissimilar layers. For water phase, the incident angle of 72.4 degree is called SPR angle at which the minimum reflectance occurs, indicating that mostly absorbed energy is converted into evanescent waves. At this condition, SPRi system enables to capture the images with different contrast levels between zero and 256 based on 8 bits. Figure 2(b) shows the change of liquid film thickness estimated theoretically with the reflectance. This figure indicates that the liquid film thickness can be directly matched with the corresponding reflectance. It means once the reflectance is measured, the liquid film thickness can be estimated through the relationship shown in Fig. 2(b). As the captured image gets dimmer, the liquid film gets thicker, vice versa. Interestingly, we can get 500 nm thickness with very high vertical resolution, being of approximately 1.8 nm based on our facility. We used Kretschmann's configuration for SPR imaging with the white light illuminated from an LED light source which was passed through the optic arrays. A single wavelength light (632 ± 5 nm) and p-polarized ray was used for visualization. The ray is guided onto the prism by using the rotatable mirror with a specific incident angle (72.4°). The gold coated thin film is attached to the prism.

Once the liquid film thickness is measured with SPRi system, the evaporation flux at the droplet edge can be modeled as illustrated in Fig. 3. Geometrically, the inflection point on the droplet interface can be estimated by using the measured film thickness. Hence, we finally determine the width of evaporating thin film as shown in Fig. 3. Here, we suggest a new parameter called the averaged evaporation flux (AEF), as shown in Eq. (2). Using this equation, we can get the averaged value over the contact line region by mass conservation, showing the finite (not infinite value) evaporation flux limit can be obtained.

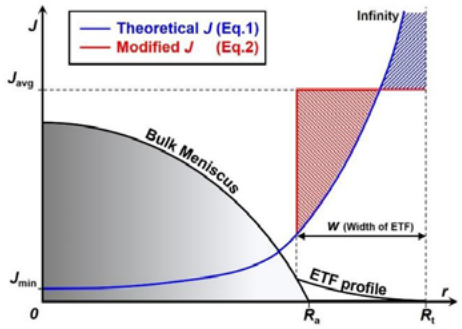

Fig. 3. Concept of the averaged evaporation flux modelling based on the measured width.

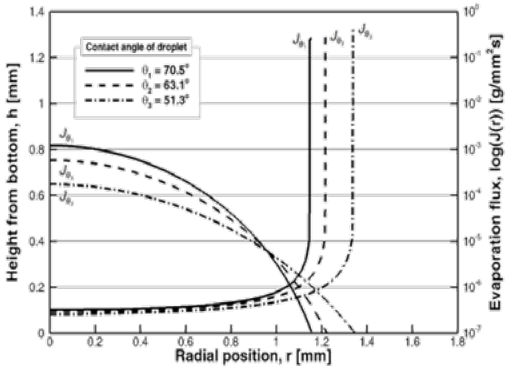
$$J_{avg} = \left(\int_{R_t - w}^{R_t} J \, dr \right) / w \tag{2}$$

where R_t is total contact radius of droplet considering ETF region, and R_a is apparent contact radius of spherical cap, w means the width of ETF, and J_{avg} denotes the AEF in the ETF which is treated as the boundary limit mathematically. For closing this equation, it is necessary to get the experimental measures of width and thickness of ETF. Those measures were obtained by the SPRIM system used in the present study.

3. Results and discussion

Figure 4 shows the measured ETF profiles. The measurements were made five times for getting the averaged values with relative errors. A convex shape was observed consistently at different droplet volumes. Indeed, the shape of ETF has been explained by the force balance along the triple lines according to Young-Laplace model and kinetic theory. As shown in Fig. 4, we can see that a slight change in liquid film thickness is observed, indicating that the shape of ETF does not change with time by interacting with the bulk droplet region.



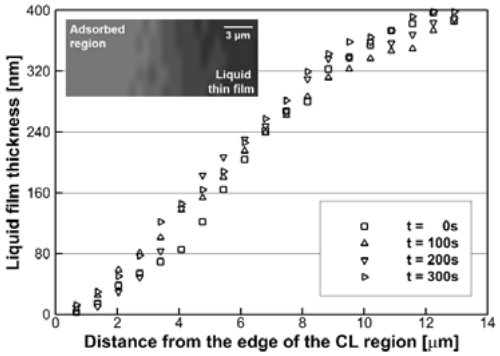


Fig. 4. The measured liquid film thickness with respect to time.

Based on this result, we can estimate the averaged evaporation flux as shown in Fig. 5. For validation, the evaporation flux at the apex of droplet showed being of the same value compared with the data from Hu and Larson [3]. The maximum evaporation flux was estimated to be 0.2547 g/mm^2·s, 0.2486 g/mm^2·s, and 0.2486 g/mm^2·s for the droplet volume of 2 μl, 4 μl, and 6 μl, respectively. It shows that the averaged evaporation flux predicted in the ETF becomes getting higher for smaller drops. That is, the smaller the droplet volume, the greater the absolute amount of evaporation flux in the ETF region. It means the portion of evaporation flux in the ETF region cannot be ignored for smaller droplet.

Fig. 5. Real-scale droplet meniscus and scaled evaporation flux considering ETF region with respect to drop volume at the initial stage.

4. Conclusions

This study reported that there exists the evaporating thin film clearly in the contact line region by the SPR imaging method. We also suggested the new approach to estimate the averaged evaporation flux. The following conclusions were drawn.

1) We observed the existence of an ETF and measured its profile in the contact line region. It indicates that the current SPR system can successfully measure the submicron liquid film thickness.
2) The present study investigated the effect of droplet volume on the ETF profile, but it was negligible. Although the droplet volume increased, the profile of ETF remains consistent shape in the contact line region because it was affected by the interfacial forces with the bulk region. Also, we estimated the averaged evaporation flux in the contact line by using the measured data. It could be used to overcome the singularity problem of the diffusion-limited model. It was shown that the contribution of ETF to evaporation was dominant as the droplet volume decreased. It is also noted that the smaller droplet was

significantly affected by the ETF which cause the higher mass transfer.

Abstract

In order to help prevent global warming, greenhouse gas emissions must be reduced. Equivalent CO_2 emissions can be reduced by using heat pump water heaters instead of conventional gas boilers or electric-resistance water heaters. We focused on the differences in annual performance of heat pump water heaters using different refrigerants, including those that contained CO_2 and R32. When assessing different refrigerants, the effect of different climates in relation to the specific application area was taken into consideration. To this end, water supply and ambient temperatures were varied according to the particular climatic conditions to calculate annual performance. As a result, the effect of different refrigerants and climates on the annual performance of heat pump water heaters was revealed.

1. Introduction

To build a sustainable society and address recent environmental problems such as increasing energy demand and global warming, it is necessary to save energy. Widely applied heat pump technologies, which include highly energy-saving refrigeration, air-conditioning, and heating technologies, can contribute to energy conservation in society and alleviate environmental problems. The vapor compression heat pumps occupy an important position in energy conservation due to their energy saving performance and high versatility.

However, many refrigerants used in vapor compression heat pumps have adverse effects on the environment. In order to protect the environment, international efforts are being made to switch from conventional refrigerants with high environmental impact to refrigerants with low global warming potential (GWP). Various types of low GWP refrigerants, including mixed refrigerants, have been proposed with varying thermodynamic properties, transport properties, and environmental performance. However, the performance of a heat pump system optimized for newly developed refrigerants has not been clearly understood; thus, it is necessary to select a suitable refrigerant and to evaluate and compare the performance of each new refrigerant.

To evaluate and compare the performance of different heat pump systems, systems designed for different types of refrigerants must be considered. However, the typical drop-in test that is currently performed on new refrigerants is not sufficient to clarify the performance of the system. During drop-in tests, it is common that component specifications like dimensions of heat exchangers are not suitable for the target refrigerants. To deal with this problem, a heat pump performance simulation model, where the heat transfer performance of heat exchanger is considered by relying on the pinch temperature approach, is developed.

This study aims to establish a simulation-based performance evaluation method for vapor compression heat pumps. This method evaluates the energy consumption of heat pumps and compares their performance in various operating conditions and regions. The proposed evaluation method is developed with the aim of easily selecting suitable refrigerants and establishing system configuration guidelines.

2. Research target

This report covers heat pump water heaters using various refrigerants. A simulator was developed to evaluate the annual performance of heat pump water heaters. This simulator was built to compare the performance of different refrigerants, even when there was no actual machine designed for new refrigerants.

2.1. Heat pump water heaters

Compared to conventional electric-and gas water heaters, heat pump water heaters can release several times more heat than the input energy. An example of a widely used residential heat pump water heaters in Japan is the EcoCute. The EcoCute uses a supercritical CO_2cycle, enabling a highly efficient hot water supply under specific operating conditions. The CO_2 refrigerant has the advantages of a low GWP and high safety. However, there are disadvantages such as special measures being required for the refrigerant circuit due to high operating pressure and decreasing performance under conditions of higher inlet water temperature.

The performance of a heat pump varies in relation to the climatic conditions such as the ambient air temperature and the inlet water temperature. Accordingly, the beneficial effect of implementing a heat pump water heater can be expected to vary depending on the region. In addition, as suggested by the example of the EcoCute, the most suitable refrigerant for residential heat pump water heaters may vary depending on the region and application. Therefore, it is critical to assess the performance of residential heat pump water heaters using low GWP refrigerants in different climatic regions.

2.2. Low GWP refrigerants

In order to mitigate global warming, the production and use of refrigerants with high GWPs are limited, and the use of low GWP refrigerants is promoted. Currently, hydrofluorocarbons (HFCs) are popular refrigerants; however, they often have a high GWP. Various alternative refrigerants have been proposed to satisfy conflicting requirements, and evaluated for different application cases by simulations and experiments. [1] [2] [3]

However, the heat pump system tested with an alternative refrigerant was designed for operating with the existing refrigerant. Therefore, when a new refrigerant is proposed, the system is not operated in a state that is suitable for the specific refrigerant. Namely, performance assessments performed when other refrigerants are applied to a system designed for a different working fluid are not providing sufficient information for guiding the choice on which new refrigerant to use.

3. Method

The performance of the heat pump water heater was evaluated for various refrigerants. Hot water supply demand and climate vary depending on the region and season. To evaluate the energy saving and environmental performance of heat pump water heaters, it was necessary to evaluate the performance throughout the year.

Therefore, an annual performance simulator for heat pump water heaters was constructed, which used the annual climatic conditions and hot water demand in each region as input data. Then, the annual performance could be calculated by simply specifying the refrigerant. This feature made it easy to evaluate a variety of new refrigerants that did not have actual equipment and could serve as guidelines for refrigerant selection.

3.1. Simulator overview

In the annual performance simulator, the specifications of the water heater, the climatic conditions, the demand for hot water supply, etc. are provides as the input and the annual operating state fluctuations and the annual performance are the output. Heat pump water heaters are expected to operate throughout the year. Thus, in order to judge the applicability of low GWP refrigerants to water heaters, it is important to evaluate the performance of water heaters throughout the year. Therefore, the annual power consumption of the water heater and the annual average COP, along with the time series data of the operating state, such as compressor discharge temperature, are given as the output. Fig. 1 shows the input/output relationship of the annual performance simulator. The subscript i is used to represent certain hourly data in the time series. The annual performance simulator includes a simulator that analyzes the thermodynamic cycle.

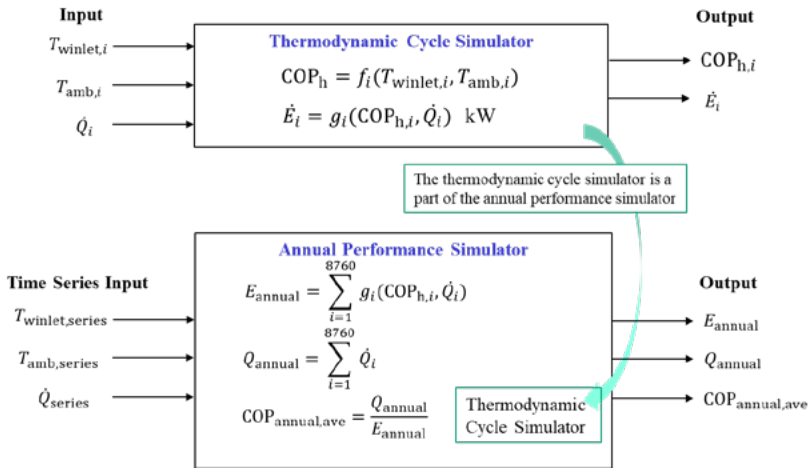

Fig. 1. Annual performance simulator overview

3.2. Thermodynamic Cycle Simulator

In order to design heat pump equipment suitable for the region and application, it is necessary to compare candidate refrigerants and select an appropriate refrigerant. To evaluate the annual performance in each region when a new refrigerant is applied to the heat pump water heater, commonly, a considerable amount of time is spent setting the design parameters for various new refrigerants and performing simulations and experiments.

Therefore, in this report, a mathematical model that emphasizes the calculation speed and ease of setting the design parameters of the equipment was developed for thermodynamic cycle analysis and incorporated into the annual performance simulator. This section describes this mathematical model.

Fig. 2 shows the flow diagram of the heat pump water heater and the corresponding Ph diagram of the heat pump cycle. The numbering of each point indicated by the arrows in Fig. 2 is used throughout this paper.

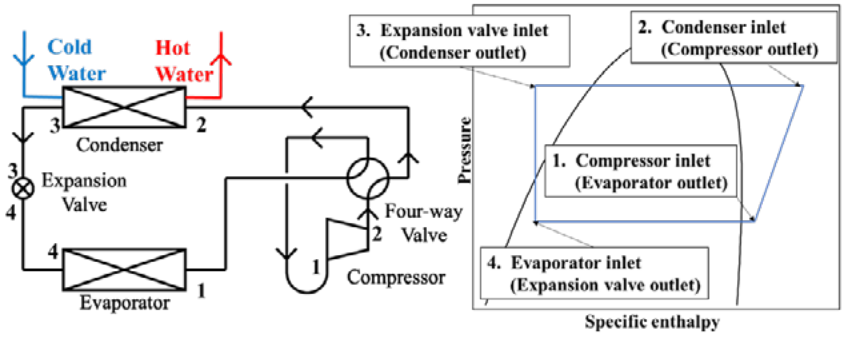

Fig. 2. Heat pump cycle flow diagram and Ph diagram

The heating coefficient of performance (COP) of the heat pump cycle is defined by the following formula.

$$\mathbf{COP_h} = \frac{\dot{\boldsymbol{Q}}_{\mathbf{con}}}{\dot{\boldsymbol{W}}_{\mathbf{comp}}} \tag{1}$$

To clarify the mass and energy balance of each component of a heat pump, the balance equations for each component are described below. The mass balance equation and energy balance equation in the compressor are

$$G_{\mathrm{R1}} = G_{\mathrm{R2}} \tag{2}$$

$$\dot{\boldsymbol{W}}_{\mathbf{comp}} = \boldsymbol{G}_{\mathbf{R2}}\boldsymbol{h}_{\mathbf{R2}} - \boldsymbol{G}_{\mathbf{R1}}\boldsymbol{h}_{\mathbf{R1}} \tag{3}$$

The compressor suction temperature and compressor suction enthalpy are given by

$$\boldsymbol{T}_{\mathbf{R1}} = \boldsymbol{T}_{\mathbf{Rvap,eva}} + \boldsymbol{\Delta T}_{\mathbf{SH}} \tag{4}$$

$$\boldsymbol{h}_{\mathbf{R1}} = \boldsymbol{h}_{\mathbf{R1}}(\boldsymbol{T}_{\mathbf{R1}}, \boldsymbol{P}_{\mathbf{eva}}) \tag{5}$$

For zeotropic refrigerants, $T_{\mathrm{Rvap,eva}}$ is given by the evaporator dew point. The compressor adiabatic efficiency is

$$\boldsymbol{\eta}_{\mathbf{comp}} = \frac{\boldsymbol{h}_{\mathbf{R1}} - \boldsymbol{h}_{\mathbf{R2,ad}}}{\boldsymbol{h}_{\mathbf{R1}} - \boldsymbol{h}_{\mathbf{R2}}} \tag{6}$$

Using equation (6), the compressor discharge enthalpy can be calculated by

$$h_{\mathrm{R2}} = h_{\mathrm{R1}} + \frac{h_{\mathrm{R2,ad}} - h_{\mathrm{R1}}}{\eta_{\mathrm{comp}}} \tag{7}$$

η_{comp} is a constant and is given to the simulator as an input. The value of η_{comp} is assumed from typical value of actual compressor adiabatic efficiency. Here, in order to calculate $h_{\mathrm{R2,ad}}$ by the equation of state, the compressor discharge entropy of the reversible process is used.

$$\boldsymbol{s}_{\mathbf{R2,ad}} = \boldsymbol{s}_{\mathbf{R1}} \tag{8}$$

$$\boldsymbol{h}_{\mathbf{R2,ad}} = \boldsymbol{h}_{\mathbf{R2,ad}}(\boldsymbol{P}_{\mathbf{con}}, \boldsymbol{s}_{\mathbf{R2,ad}}) \tag{9}$$

The same formula is used for the condenser in the subcritical cycle and the gas cooler in the transcritical cycle. As heat pump water heaters are the target of this study, a mathematical model of a counter-flow heat exchanger is constructed. The mass balance and energy balance equations of the refrigerant in the condenser

(or, gas cooler) are

$$\boldsymbol{G_{R2} = G_{R3}} \tag{10}$$

$$\boldsymbol{\dot{Q}_{con} = G_{R2}h_{R2} - G_{R3}h_{R3}} \tag{11}$$

For the water,

$$\boldsymbol{G_{W2} = G_{W3}} \tag{12}$$

$$\boldsymbol{\dot{Q}_{con} = G_{W2}c_{pW}T_{W2} - G_{W3}c_{pW}T_{W3}} \tag{13}$$

The condenser (or, gas cooler) refrigerant outlet temperature is

$$\boldsymbol{T_{R3} = T_{W3} + \Delta T_3} \tag{14}$$

The mass balance and energy balance equations for the expansion valve are as follows.

$$\boldsymbol{G_{R3} = G_{R4}} \tag{15}$$

$$\boldsymbol{G_{R3}h_{R3} = G_{R4}h_{R4}} \tag{16}$$

The mass balance and energy balance equations in the evaporator are

$$\boldsymbol{G_{R4} = G_{R1}} \tag{17}$$

$$\boldsymbol{\dot{Q}_{eva} = G_{R1}h_{R1} - G_{R4}h_{R4}} \tag{18}$$

The refrigerant dew point temperature in the evaporator is

$$\boldsymbol{T_{Rvap,eva} = T_{amb} - \Delta T_{eva}} \tag{19}$$

ΔT_{eva} is given to the simulator as a positive constant. This is used to calculate the compressor suction temperature in equation (4). The refrigerant evaporation pressure is calculated from the equation of state as follows.

$$\boldsymbol{P_{eva} = P_{eva}(T_{Rvap,eva})} \tag{20}$$

We focus on the pinch temperature in the condenser in order to build a model that determines the state of the refrigerant in the condenser from the temperature conditions of the hot water inlet and outlet. There is at least one pinch temperature in the condenser, usually two. It is impossible from the viewpoint of heat transfer to have a pinch temperature below 0 ° C. Therefore, a constraint condition that takes a positive finite value as the pinch temperature is set. K_1 and K_2 are positive constants. The inequality constraints on the condenser refrigerant outlet pinch temperature ΔT_3 and the condenser internal pinch temperature $\Delta T_{\mathrm{con,pinch}}$ (see Fig. 3) are represented by

$$\Delta T_3 \geq K_1 \tag{21}$$

$$\boldsymbol{\Delta T_{con,pinch} \geq K_2} \tag{22}$$

Here, $\Delta T_{\mathrm{con,pinch}}$ is the pinch temperature in the condenser that can exist other than ΔT_3, and is defined as follows using the temperatures $T_{\mathrm{R,con}}$ and $T_{\mathrm{W,con}}$ of the refrigerant and hot water, respectively, that exchange heat with each other. [4]

$$\boldsymbol{\Delta T_{con,pinch} = T_{R,con,pinch} - T_{W,con,pinch}} \tag{23}$$

The simulator input values of K_1, K_2 and ΔT_{eva} are assumed from typical value of domestic heat pump hot water heaters. The heat exchange and pinch temperature in the condenser will be explained using Fig. 3 with

the heat exchange on the horizontal axis and the temperature on the vertical axis.

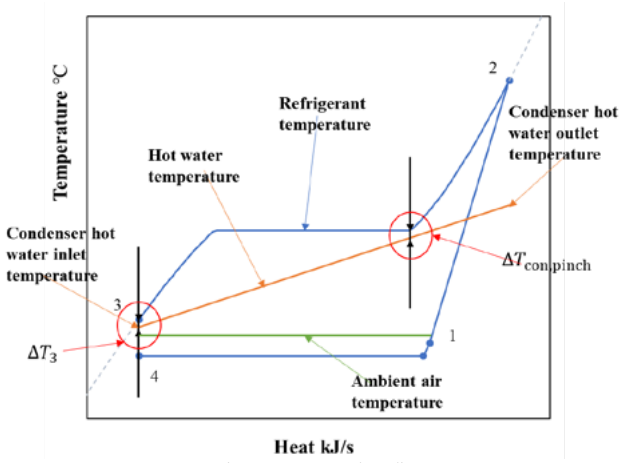

Fig. 3. Temperature heat diagram

From the mathematical model of the condenser model described above, the absolute value of exchanged heat of both fluids in the condenser is equal. Therefore, the horizontal width of the thermal composite line of water and the thermal composite line of refrigerant are equal, and the start and end points are at the same position on the horizontal axis. As the flow rates of both fluids are directly related to the heat capacity, the curves (including straight lines) representing the heat exchange process of both fluids can be scaled with respect to the horizontal axis, depending on the mass flow rate of each fluid. The relationship between heat exchange and temperature is expressed in Fig. 3.

$$\boldsymbol{T_{\mathrm{R,con,pinch}} = T_{\mathrm{R,con,pinch}}\left(P_{\mathrm{con,pinch}}, h_{\mathrm{con,pinch}}\right)} \tag{24}$$

$$\boldsymbol{T_{\mathrm{W,con}} = \frac{T_{\mathrm{W2}} - T_{\mathrm{W3}}}{G_{\mathrm{W2}} h_{\mathrm{W2}} - G_{\mathrm{W3}} h_{\mathrm{W3}}} \left(G_{\mathrm{W}} h_{\mathrm{W}} - G_{\mathrm{R}} h_{\mathrm{R}}\right) + T_{\mathrm{W3}}} \tag{25}$$

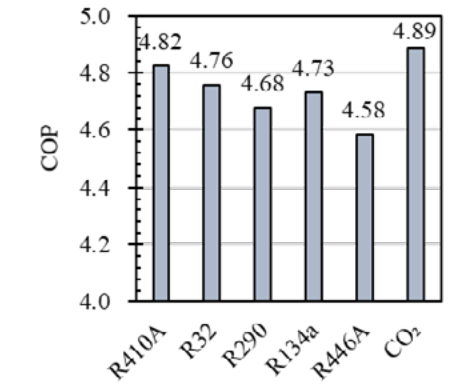
Under these conditions, the COP maximization problem, with the condenser pressure as the optimization parameter, is solved. A cycle is constructed using the solution of this maximization problem as the condenser pressure P_{con}.

4. Discussion

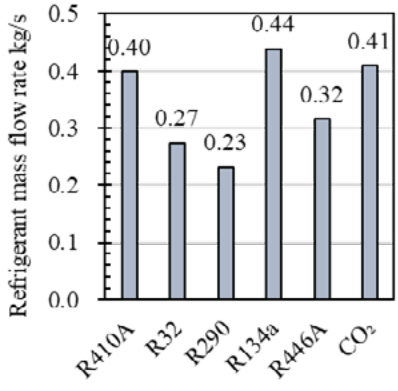
4.1. Fundamental characteristics of heat pump water heater

Several refrigerants are evaluated using the thermodynamic simulator in order to clarify similar and significantly different characteristics. As R410A refrigerant, which is currently widely used in heat pumps, has a high GWP of 1924, alternative low GWP refrigerants have been proposed. R32 and R446A are compared as substitute refrigerants for R410A. In addition, R134a and propane are also included in the comparison to understand the characteristics that differ significantly depending on the refrigerant.

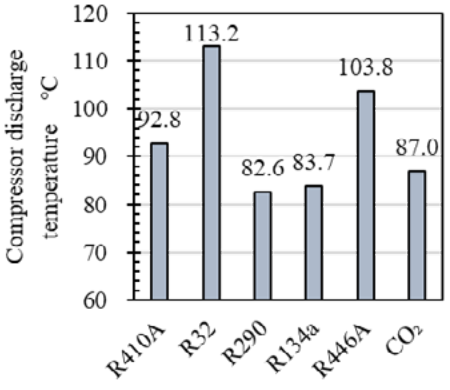
Japan's average climatic conditions are adopted as reference conditions, and the COP, compressor discharge temperature, and refrigerant mass flow of each refrigerant compared. The standard conditions are an inlet water temperature of 16.5 ° C, outlet water temperature of 65 ° C, and an ambient air temperature of 16 °C. Fig. 4 shows the results of the comparison.



The refrigerant with the highest COP (4.89) is CO_2, and the refrigerant with the lowest COP (4.58) is R446A. CO_2 refrigerant is a transcritical cycle under these operating conditions. R410A has the highest COP of the subcritical cycle refrigerants. The compressor discharge temperature is the highest for R32, at 113.2 °C. R290 is the refrigerant with the lowest discharge temperature of 82.6 °C. R134a also has a low temperature of 83.7 °C. The mass flow rate of R134a is the largest, but R410A and CO_2 feature similar values. Conversely, R290 has the smallest mass flow rate, and the value of R32 is close to it.



A parameter study is conducted for COP, compressor discharge temperature, and refrigerant flow temperature. Fig. 5 shows the results for the feed water temperature, Fig. 6 shows the results for the condenser outlet water temperature, and Fig. 7 shows the results for the ambient air temperature.



First, we focus on COP. With one exception, all refrigerants show similar trends for water supply, hot water, and ambient air temperature. Generally, the COP decreases with respect to the feed water temperature and condenser outlet water temperature and rises with respect to the ambient air temperature. In the region where the feed water temperature is low, the COP of the CO_2 refrigerant is higher than that of other refrigerants. However, when the feed water temperature exceeds 20 °C, the COP of other refrigerants may increase. The COP of the CO_2 refrigerant is the lowest at around 30 °C.

Next, we focus on the compressor discharge temperature. Although the discharge temperature values differ between refrigerants, there is no significant difference in the tendency for parameter changes except for CO_2. The compressor discharge temperature with CO_2 refrigerant rises more than other refrigerants when the feed water temperature is high and the ambient air temperature is low.

Finally, the refrigerant mass flow rate is described. Here, the CO_2 refrigerant also shows a different tendency. Compared with other refrigerants, the increase in mass flow rate is remarkable when the feed water temperature and the ambient air temperature become high.

Calculation condition (Standard condition, defined in text)	
Ambient air temperature	16 °C
Water inlet temperature	16.5 °C
Water outlet temperature	65 °C
ΔT_3	3°C
$\Delta T_{con,pinch}$	3°C

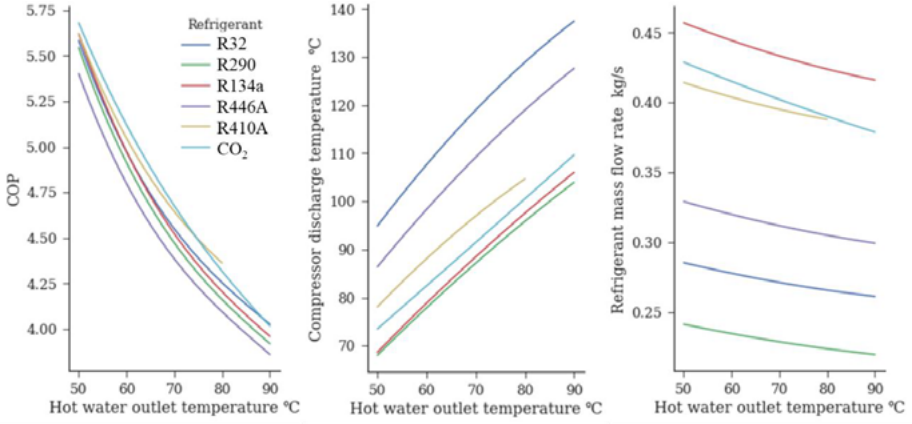

Fig. 6. Parametric study on influence of hot water outlet temperature on COP, Compressor discharge temperature, and Refrigerant mass flow rate

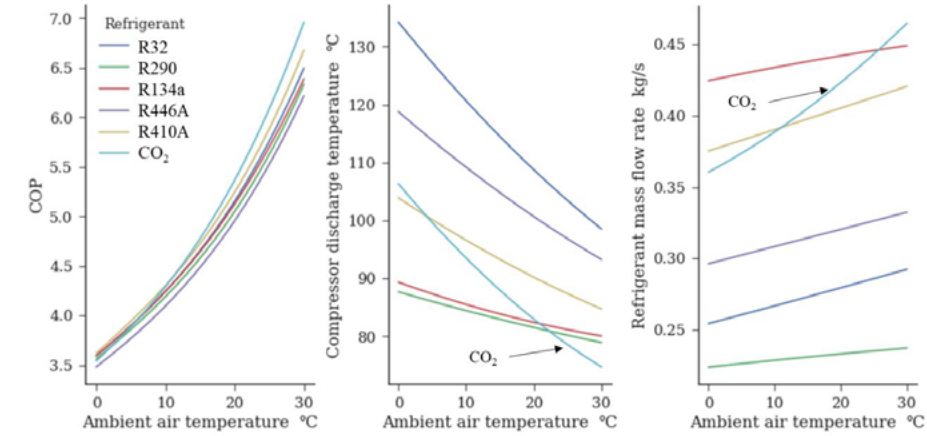

Fig. 7. Parametric study on influence of ambient air temperature on COP, Compressor discharge temperature, and Refrigerant mass flow rate

4.2. Annual performance evaluation

A simulation is conducted to investigate the effect of differences in area, climate, and refrigerant on the annual performance of heat pump water heaters. The condenser hot water outlet temperature is fixed at 65 ° C, and the ambient air temperature, water inlet temperature, and hot water demand were input in time series. In this report, the supply water temperature is given by a direct relation to the ambient temperature, and the same daily pattern is used for the hot water demand in each region. The hot water demand pattern is based on table B.6 of JIS C9220:2011 Annex B. [5]

The target refrigerants are CO_2 and R32, which have been used as refrigerants for domestic hot water heaters in Japan. Sapporo, Tokyo, and Naha are selected as three representative cities for Japan's high, middle, and low latitudes. These three cities are indicated in Fig. 8. The climatic data on the ambient air temperature are from 2018 [6]. Fig. 9 shows the ambient temperature fluctuations in these three cities. For ease of understanding, the trend of annual fluctuation in Fig. 9 uses monthly averaged data, while input data to the simulator refer to the hourly data.

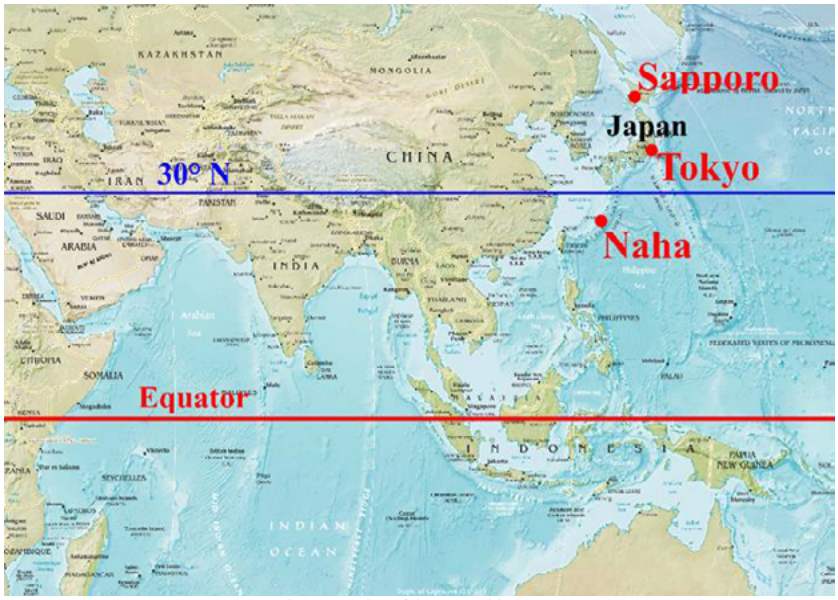

Fig. 8. Location of the target cities **[7]**

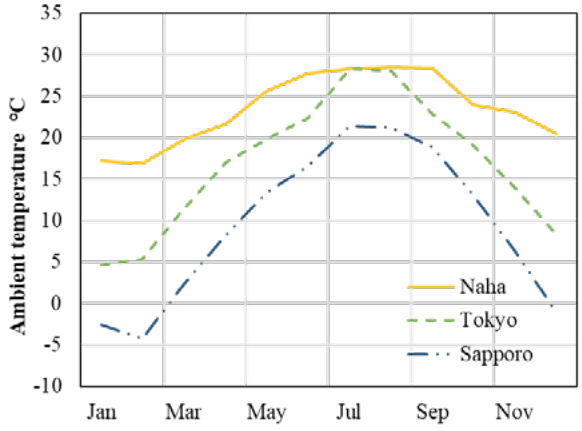

Fig. 9. Annual ambient temperature at Sapporo, Tokyo, and Naha

Fig. 10 shows the evaluation results of the annual power consumption and annual average COP of the water heater. Generally, the annual power consumption decreases and the annual average COP tends to increase as the latitude of the region decreases. When the CO_2 refrigerant is used as a reference, the annual power consumption of the R32 refrigerant increased by a maximum of 2.53%, and annual average COP decreased by 2.46%. Focusing on the regional characteristics, the annual power consumption in Sapporo was approximately twice that of Naha. This is not only because of the lower heat load due to the higher ambient temperature of Naha, but also because the COP is higher here than in Sapporo almost throughout a year, as described later.

Fig. 11 shows the annual COP change. The graph on the left is for the CO_2 refrigerant, and the right is for the R32 refrigerant. For all refrigerants, it is demonstrated that the COP is higher in summer than in winter. Naha has shown that it can operate at a high COP throughout the year and there is almost no COP difference between the two refrigerants.

To compare the trend of the COP variation for each refrigerant in detail, Fig. 12 shows the COP fluctuation for the first week of 2018 and Fig. 13 shows that of the first week of the second half of same year. Thus, the difference in COP trend for each refrigerant is not significant. According to Fig. 7, regarding the ambient air temperature, the performance difference is considered to increase in the hot season and regions. However, as shown in Fig. 5, CO_2 has a significantly larger COP drop than other refrigerants with respect to the water inlet temperature. Accordingly, the COP of CO_2 refrigerant is slightly higher in any of these three regions during winter, however, the COP of R32 refrigerant come to almost same at Tokyo and Naha in summer, as shown in Fig. 12 and Fig. 13. Therefore, it can be considered that the COP is reversed with other refrigerants in hot seasons and regions.

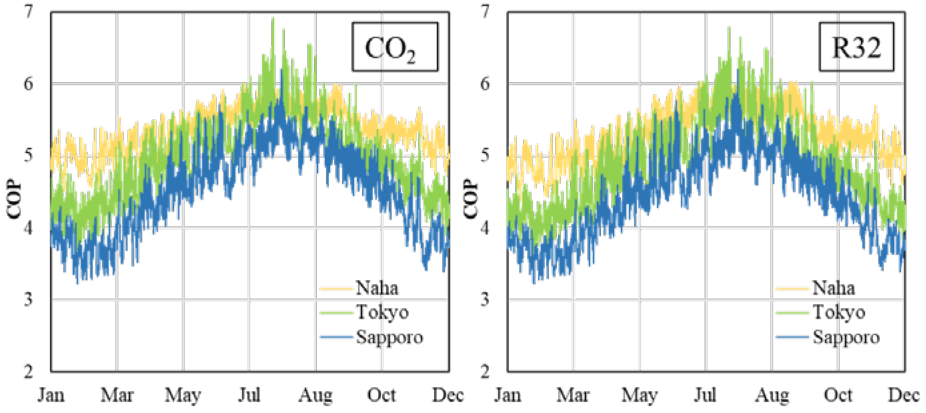

Fig. 11. Annual COP fluctuation (Left: CO_2, Right: R32)

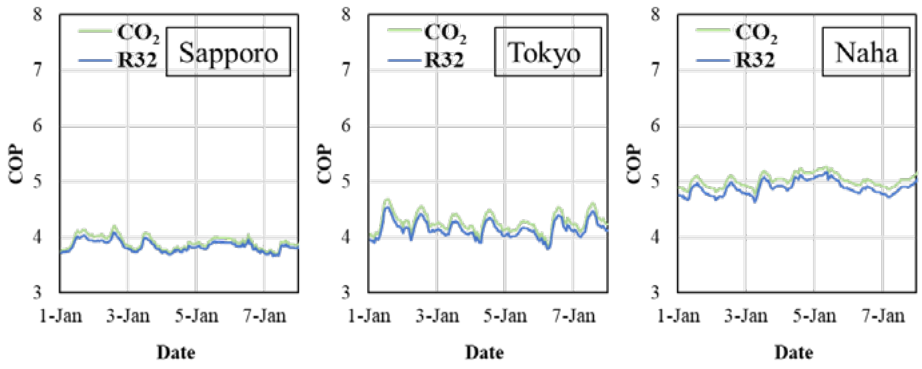

Fig. 12. Weekly COP fluctuation (Winter, Comparison by refrigerant)

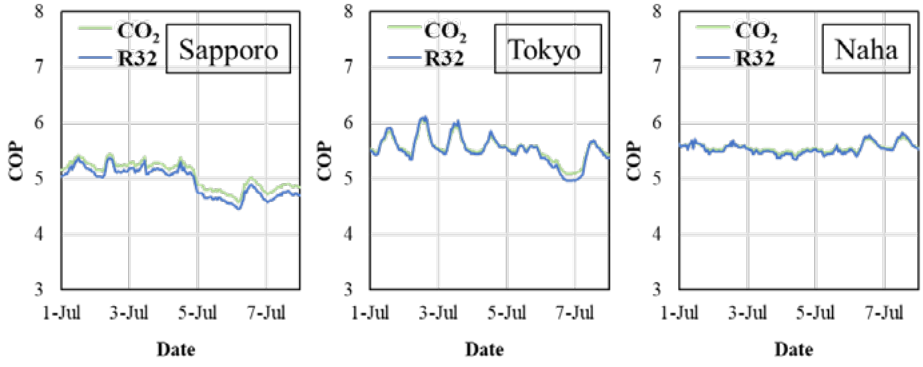

Fig. 13 Weekly COP fluctuation (Summer, Comparison by refrigerant)

5. Outlook for the future

Currently, in practice, a domestic heat pump water heater requires a water tank for the following two reasons. First of all, water usage during a shower is around 10 L/min for 10 to 20 minutes. Thus, the power output required in order to provide instant heating for a shower is about 10 to 20 kW. The higher the power output is, the more expensive the price of a heat pump is. As a result, it is impractical to use high output power heat pumps for domestic water heating. Secondly, due to the daily fluctuations of the electricity pricing in Japan, using electricity at night is cheaper and in order to lower the cost, heat pump systems are designed to operate and store hot water during that period.

This report focuses on the heat pump cycle itself rather than the water tank. However, using a water tank can result in the temperature of water supplied to condenser or gas cooler to be higher than that of the tap water. This is believed to have some influence to the system's performance. Other than that, the time of operation should also be carefully considered since factors like ambient air temperature, water supply temperature and heat loss can be different between day and night, and, thus, affect the system's efficiency. Therefore, in the future, we would like to build a model that considers the hot water storage tank and perform more accurate and versatile annual performance evaluation based on this model.

6. Conclusion

An annual performance simulator was constructed to compare the performance of various refrigerants

and heat pump water heaters in different regions. The actual climate data of different Japanese cities were inputted into the simulator to compare the heater performance in different regions and with different refrigerants.

As a result, it was confirmed that the water heater performance was higher in lower latitude areas. In addition, it was suggested that the lower the latitude, the smaller the fluctuation of the driving condition, and the more stable the operation. The comparison of R32 and CO_2 suggests that the performance of the CO_2 refrigerant is higher in all regions of Japan. However, the results of the basic performance analysis suggest that the performance can be reversed in warmer areas, and in applications where the water supply temperature is high.

Abstract

A small thermal grid for historic Almshouses 'the Schipjes' in Bruges was designed in 2016 and is nearing the final phase of construction while partly in operation. The houses' building envelopes were retrofitted with respect to the monumental character to decrease the heating demand and the required temperature levels.
The houses are connected to a low temperature thermal grid supplied by a hybrid of a ground source heat pump (GSHP), solar thermal panels (ST) and a condensing gas boiler (not installed after predesign simulation).
Domestic hot water (DHW) at higher temperature in the individual houses is provided by booster HP's, while room heating (RH) is provided by floor heating and radiators.

A limitation of thermal power creates a challenge to verify which rule based control (RBC) operates optimal for this case.

The study simulates the project using Modelica. RBC variations are simulated in which temperature levels in the system, anticipation, building integrated or central vessel storage are implemented. For each variation the resulting comfort, the share of renewable energy supply (RES) and the electrical energy use (COP) are quantified. Conclusions are a.o. that building integrated storage is needed for the load management, as well as a heating curve for the further increase of the RES system performance. The individual variations lead to a decrease of discomfort by 17%, an increase of RES by 7.4% and a decrease of electrical energy use of 25% on an annual basis.

Keywords: simulated control impact assessment, thermal grid, ground source HP, fossil free system approach, residential retrofit

1. Introduction

This paper describes a study that optimizes the operation of a residential renovation project that combines a thermal micro grid, a centralized ground source heat pump, centralized thermal solar collectors and booster heat pumps in each of the houses for domestic hot water. The concept decisions, design and sizing phases were supported by dynamic system simulations, aiming at a balanced performance increase by system approach and building retrofit. The overall aim was to realize a future oriented integrated solution towards zero fossil fuel concepts in historical city centres, which could have a large replication factor throughout Europe and beyond. The project is partly in operation, and the handover is approaching, so this study aims to define the Rule-based Control (RBC) to be programmed in order to provide thermal comfort with minimal environmental impact of the system.

2. Context

The Almshouses ‘the Schipjes’ is a social housing neighbourhood in Bruges, Belgium (Fig 1). It was built in the beginning of the 20th century (1907, arch René Cauwe). Today it is the property of Mintus, the social welfare organization of the city of Bruges, and houses 12 small households. In 1999 a limited retrofit was realized, providing a thin insulation layer in the roof, renewing the electrical installation and installing an

individual gas fired stove (with an efficiency of less than 80%) in each house, with integrated heat exchanger to distribute heat to radiators in the kitchen, bedroom and bathroom. The domestic hot water (DHW) was delivered by a direct electrical boiler. The Schipjes has been classified as heritage in 2009, Bruges is a Unesco acknowledged historical city.

Due to non-compliance with contemporary comfort expectations a deeper renovation was planned, thereby thoroughly upgrading the energetic and ecologic aspects of the houses. The research project, funded by VLAIO (Flemish Agency for Innovation and Entrepreneurship) started in 2014, by a consortium of two universities, three companies and two social organisations (Fig 2). Several configurations of thermal supply of the thermal grid and retrofit options for the houses themselves were investigated and compared. After an experience-based long list approach, four system configurations were shortlisted and simulated, and after adding investment and operational cost evaluation the results have been leading to the finally chosen concept (Aertgeerts, Boydens & Helsen, 2016). In the study phase only 11 houses were connected to the thermal grid, during execution one house was added leading to a total of 12.

Fig. 1. Almshouses the Schipjes, birdsview

Fig. 2. Almshouses the Schipjes, the consortium partners of the renovation guidance project on site

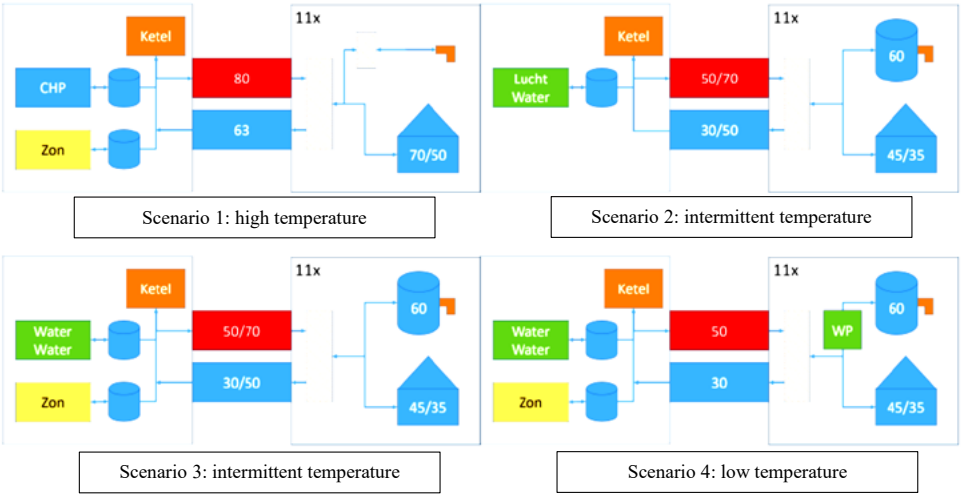

Fig. 3. Schematics of the four shortlisted system configurations

The four scenarios as illustrated in Figure 3 were selected in order:

- to assess the impact of efficiency gains and losses, among them: thermal grid operating temperatures, affecting (1) associated heat losses to the ground, (2) injection potential of the solar thermal system, (3) the COP of the heat pump;
- to compare different heat supply technologies in different configurations and operating modes with regard to their system efficiency (cogeneration (CHP), gas fired condensing boiler (GCB), air to water heat pump (AWHP), ground source heat pump (GSHP), solar thermal (ST), water to water booster heat pump (BHP)).

The gas fired CHP scenario 1 was used as a reference case, since this configuration was considered and observed the most feasible in the market for small scale collective system solutions in Belgium, around 2010-2014, by boydens engineering. Main disadvantages are the dependency on fossil fuels and the local air pollution in the city centre, as well as the maintenance cost and high system temperatures.

Scenario 2 aimed at lowering the investment cost, share of fossil fuels and system temperatures by using the AWHP as dominant supply, and applying intermittent higher system temperatures (if needed through support of a condensing gas boiler) for DHW demand, storing higher temperatures in individual storage tanks in these periods.

Scenario 3 applies the same intermittency, but using the GSHP as main thermal supply. The ST was added to temper ground source depletion, and prevent gas boiler operation for DHW in sunny periods.

Scenario 4 is implementing the same centralized supply as scenario 3 but focusses on a permanent low temperature in the thermal grid of maximum 50°C. The DHW is boosted to the required 60°C in the individual storage tanks, with decentralized BHP's in the houses.

Scenario 4 was chosen as final concept, since multiple criteria, i.e. share of renewables, solar heat supply, total primary energy demand reduction and fossil fuel reduction reached optimal levels in the system simulations, performed by The Thermal Systems Simulation research group of KU Leuven (A. Aertgeers, L. Helsen). These simulations also showed the condensing gas boiler was superfluous in this case (fig 4).

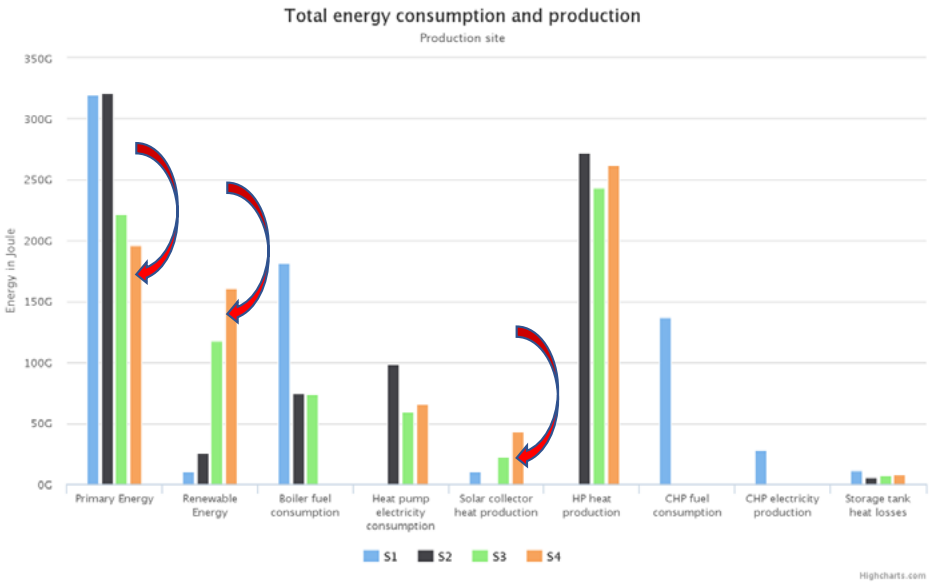

Fig. 4. Results of the first predesign simulation based comparisons, leading to the preferred scenario 4

The renovation started in 2016 and will be finalized in spring 2020. It was realized in phases, and 8 houses are already in operation since September 2019. Illustrations below show: the site plan with the thermal grid and the position of the 8 boreholes, double U, each 125 m deep (Figure 5), the supply cabin in the garden that houses the heat pump, storage tanks and pumps (Figure 6) and the booster heat pump with DHW storage mounted in the individual houses (Figure 7).

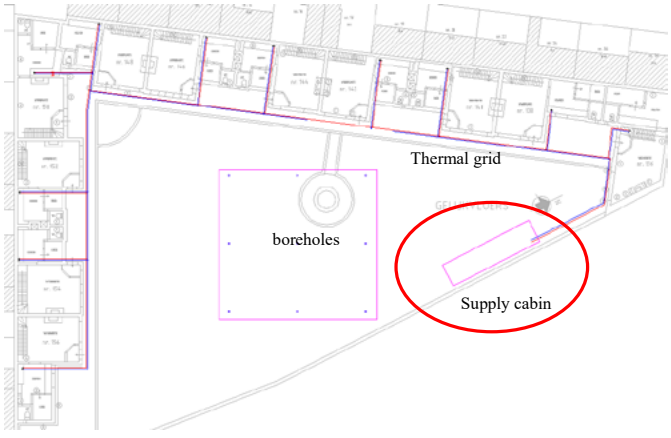

Fig. 5. The site plan with the thermal grid, and the position of the 8 boreholes, double U, each 125 m deep

Fig. 6. The supply cabin in the garden that houses the ground source heat pump, storage tanks and pumps

Fig. 7. The booster heat pump with DHW storage mounted in the individual houses

The design being consolidated and under construction, a performant RBC programming of the system is targeted and therefore this simulation based study was performed.

Furthermore, adding one house to the system in the course of the project, without changing the system sizing, raised the question whether thermal comfort would be endangered, and whether the condensing boiler would be needed anyhow. Or, in case, if a smartly implemented RBC could avoid this move back to fossil technologies.

This synthesizes the main research question: What is the impact of the control on the operation and the sizing of a heat pump based thermal grid, or alternatively stated, can we correct a given undersizing by a smarter control in a real environment?

3. Methodology

The houses and the supply, distribution and emission systems were dynamically modelled and simulated in more detail than in the predesign stage. The RBC as foreseen from designers experience was implemented in the model and the resulting thermal comfort was evaluated, together with other performance indicators, such as: share of renewable energy sources (RES) and primary energy use.

All simulations have been performed in the Modelica simulation environment using Dymola, and component models from the Modelica libraries IDEAS, Buildings and IBPSA. The explicit Euler solver was used instead of the DASSL solver (however a comparison was made in one case). For more detailed information we refer to the master thesis of Sigrid Feyaerts [1].

The hydraulic scheme of the thermal system is shown in fig 8.

Analysis of the results according to the engineered design (reference case) led to expected shortcomings, and to the creation of alternative controls. These alternative control strategies were implemented in the model and the results were compared to the reference design case.

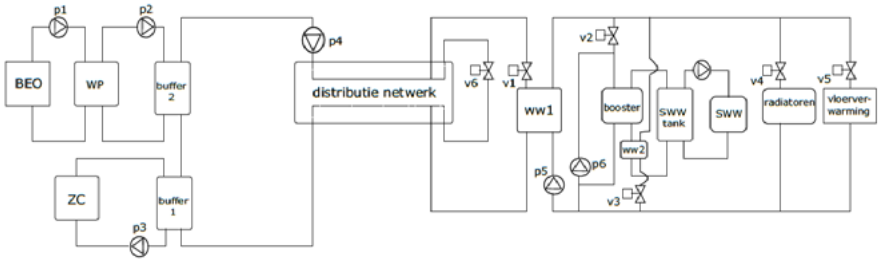

Fig. 8. Hydraulic scheme of the thermal grid, supply systems on the left side, situation in one of the twelve individual houses on the right side. BEO refers to the ground source, WP to the heat pump, ZC to the solar thermal collector, distributie netwerk to the thermal grid, ww to a heat exchanger, SWW to domestic hot water and vloerverwarming to Floor heating

The main assumptions and simplifications in the simulation model are (1) single zone modelling of the houses, (2) fixed ground source temperature of 7°C, with a COP of 3.67 (for the real installed unit) when supplying 50°C at the condenser side, (3) DHW user behaviour according to the StROBe stochastic approach [2] (however the monitored DHW use showed lower loads than the StROBe approach), (4) no internal heat gains taken into account, (5) TMY Uccle (BE) as weather data, as well as a comparison with monitored data (KU Leuven, 2017).

The reference RBC can be summarized as an on/off control of the heat pump activated by the HP buffer temperature (on if lower than 50°C-3°C for 3 min and demand in one of the houses, off if 50°C + 5°C is reached in the buffer for 5 min). ST injects if a 3°C surplus towards the solar buffer tank is noticed for 2 min, off if the ST temperature becomes lower than the buffer temperature). The secondary side of the heat exchanger of the house uses a heating curve for the radiators/floor heating (40°C, -10°C / 20°C, 20°C). Hysteresis is applied for the DHW booster HP (60/45°C) and thermostatic valves are used on the radiators.

The RBC performance for multiple scenarios (using different control strategies) is assessed using the following criteria:

1. Thermal discomfort: Kelvin-hours with temperatures below the setpoint (defined by the StROBe model).
2. Share of RES (renewable energy sources in supply):
   (solar energy supplied by ST + ground source extracted heat) / the total heat supplied
3. Total electricity demand for heating: electricity use for the GSHP and the booster HP's

4. Results and discussion

4.1 Reference RBC

Figure 9 shows how the heat supply and demand are distributed over the system components for the reference RBC. Important to stress are: (1) the centrally supplied heat to the grid (Enet) on a yearly basis , (2) the electricity supplied to the heat pumps (EhpEl, EboosEl), and (3) the dissipated heat loss in the grid (Edis). For this reference case the yearly electricity use by the heat pumps (geothermal and booster) is 154.2 GJ.

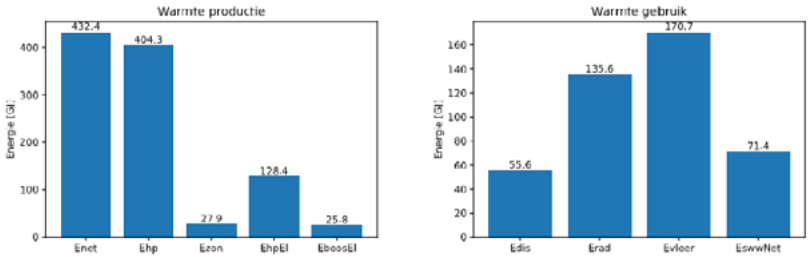

Fig. 9. Heat supply and emission per system element for the reference case

Figure 10 (left) presents the energy sources used for heat generation and (right) the distribution over the different users (grid losses, radiators, floor heating and DHW). The reference RBC results in a RES share of 66.3%, distributed as 60.2% GSHP (Egrond) and 6.1% ST (Ezon).

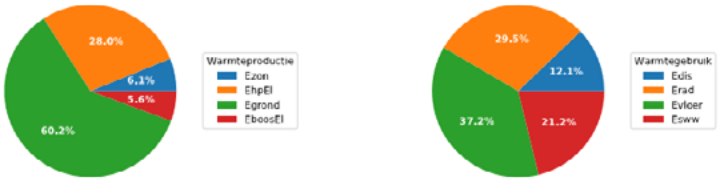

Fig 10: Heat supply and emission share for the reference case

The aggregated thermal discomfort for all houses is 17084 Kh for the full year. This result is not as such directly interpretable. However, according to ISO7730 class A buildings allow maximum 100 Kh/a outside the +/- 1°C bound thereby guaranteeing the PPD is limited to 5% [3]. Therefore, to give insight in the discomfort level, the number of Kelvin-hours that the indoor temperature set point – 1°C is not achieved is assessed, hereby not considering the first two start up hours in the morning, resulting in an average of 83 Kh/a for an individual house. Better understanding of this occurring discomfort is achieved by zooming in on a cold period in January (see Figure 11).

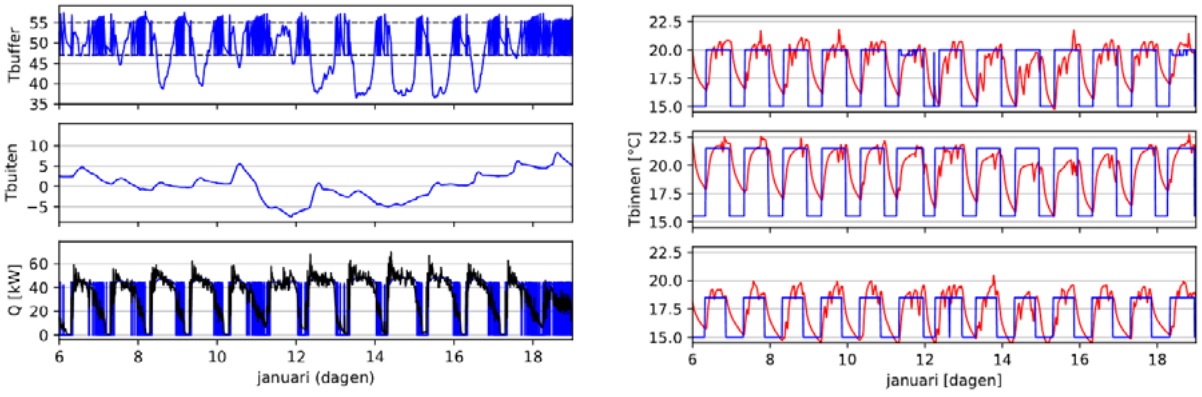

Fig. 11. Total heat (left, demand in black, supply in blue) and comfort (right, for different set points) profiles in a cold winter period for the reference RBC case

It is very clear that the night setback of the RH (room heating) creates a demand profile that varies between the peak demand (around 60 kW) and no demand over 24 hours. As the demand for DHW is prioritized in the reference RBC, and at these times the supply to the radiators and floor heating is temporarily shut off, this can affect severely the discomfort for the room heating in the morning, since the reheating of the local DHW storage takes 62 min on average. Therefore an adapted strategy for DHW reheating is an obvious goal in the advanced RBC. It is clear that simply following the peak demand would require additional thermal supply, and stepping back to adding the condensing gas boiler the most evident measure.

4.2 Alternative RBC - Adapted DHW reheating strategies:

Several variations for the DHW reheat rules have been investigated:

1. More frequent and time limited reheating of the DHW tanks can be achieved by adapting the reheat set point to 50°C instead of 45°C. Of course a higher average DHW temperature during reheat will decrease the booster HP COP. The reheating time is observed to decrease to 43 min on average. However no significant improvement is observed in the aggregated thermal discomfort.
2. Preheating DHW during night time to a higher temperature was also implemented, using a set point of 70°C. The overlap of RH and DHW demand in morning hours was as such reduced, resulting in a decrease of thermal discomfort by 10%. A decrease of the average COP of the booster HP's from 3.8 in the reference case towards 3.4 was noticed, as well as a small decrease of RES share from 66.3% to 65.9%.
3. A strategy with simultaneous RH by the radiators (only FH is off) during DHW reheating results in a lower discomfort (-17%). Especially during the day the combination of the stored heat in the FH, shut off (of FH) during DHW demand, and the available power of the radiators succeeds in maintaining indoor thermal comfort (Fig 12). In the morning hours the night setback control prevents this action.

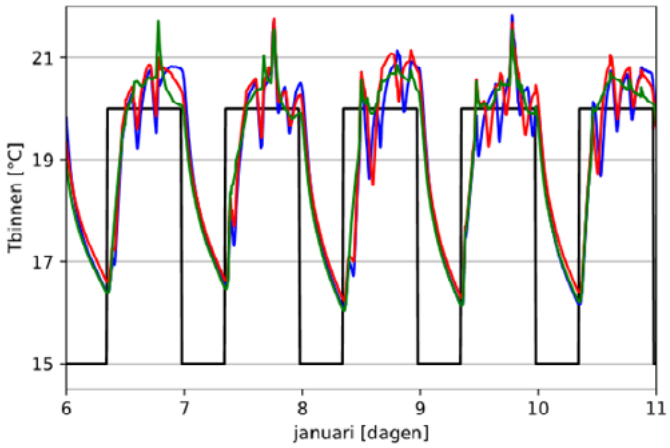

Fig. 12. Effect on indoor temperature by keeping the radiators (green line), or the floor heating (red line) activated during DHW demand (booster HP in operation), the reference RBC result is the blue profile

4.3 Alternative RBC - Anticipation:

Anticipation in cold periods of the year, where logically the limited thermal power results in more frequent discomfort hours, is a next approach. Based on the research of Basciotti and Schmidt [4] some variations have been set up. Anticipating the start-up and peaks in the morning by thermal storage in the central storage tanks at higher temperatures did not give any relevant results, due to the limited storage potential. Night storage in the houses, however, by reducing the night setback for floor heating proved to be far more effective. It decreases the required supply capacity and improves thermal comfort, with an extra electricity supply of only 1.2%. The RES share remains 66% and the total heat demand of the grid rises by only 0.3%. The higher demands during the night are largely compensated by the decrease of start-up energy use (see Figure 13), as

studied by Frederiksen and Werner [5], even in this case where the insulation level of the historic houses is rather limited.

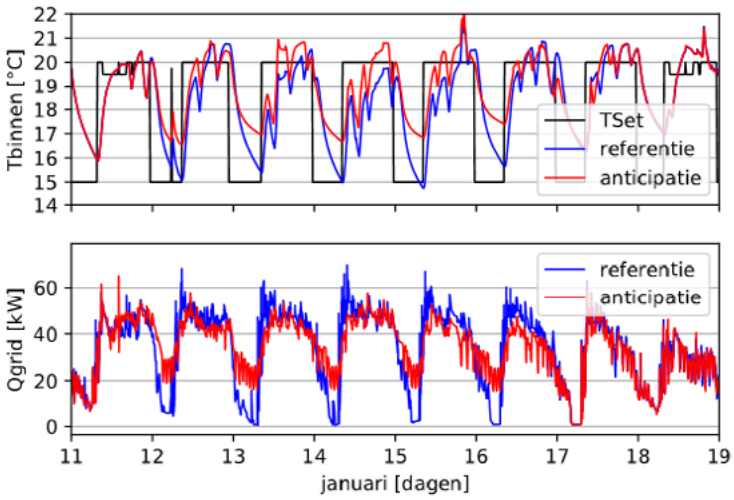

Fig. 13. The effect of reduced night setback on achieved indoor temperatures and supply peaks during cold periods

4.4. Alternative RBC - Adapted heating curves:

As a final exercise the effects of adapted heating curves are studied. Previous research of Ommen et al. [6] already resulted in optimization of supply temperatures in thermal grids with central HP supply and decentralized booster HP's. Inspired by those results, the grid is controlled by two different heating curves, selected as: (1) 50°C, -10°C / 25°C, 20°C and (2) 50°C, -10°C / 30°C, 15°C. The first led to inlet temperatures at the booster HP, which are not within the boundary constraints of the manufacturer. Both heating curves lead to a higher amount of injected solar energy and a higher COP of the GSHP. The total electricity supply decreases by 25%. The (dis)comfort however is not affected.

4.5. Summary: overview of variations investigated

An overview of the results of the described individual variations to the reference RBC is shown in Table 1. Results for the reference case applied to the measured climate data (Leuven, 2017), have been added as well. In the thermal discomfort column the improvements can be seen for the individual variations, and one should keep in mind the considerations put forward in the beginning of this section, prior to Fig 11.

Table 1 Overview of results of implemented variations to the reference RBC

RBC variation	RES share (%)	Thermal discomfort (Kh)	COP-HP	COP-booster HP	Thermal grid heat demand (GJ/a)
Reference	66.3	17.1 k	3.13	3.78	432.4
Preheating DHW	65.9	15.4 k	3.13	3.44	433.9
Simultaneous RH	66.6	14.1 k	3.14	3.78	433.8
Continuous FH	66.0	16.1 k	3.11	3.78	433.7
Heating curve (2)	73.7	16.9 k	4.37	3.54	414.3
Weather data 2017	66.4	11.9 k	3.09	3.78	360.9

5. Conclusion

The research case investigated handles individual variations in the RBC approach for the hybrid heat supply and emission systems in Almshouses 'the Schipjes' in Bruges, a practical case that is nearing completion. As the given installed power is limited and challenged towards the extension of the connected houses during construction the possible improvements by variations in the reference rule based control design were studied. Individual changes have shown that reasonable impact on the expected discomfort is possible, without decreasing, in some cases even increasing other performance criteria such as the share of RES and COP of the global system. Thus the degree of impact of the control on the required size of the supply systems, taking into account storage and dynamic effects, has been clarified for this specific case. This study moreover shows that a fully RES-based thermal network is feasible, even in historic city centres, provided that also the electricity used is based on RES technologies. Given the large amount of historic centres in Europe and beyond, the replication factor of this concept can be substantial.

Future work will consist in evaluating combined variations that improve the targeted criteria. The combination of continuous FH, adapted heating curve and simultaneous RH with radiators seems to be the best case to evaluate.

Abstract

Within the agriculture sector, drying of food and flowering products is a required production step. Most companies use hot air dryers where the heat is obtained by combustion of natural gas. This paper proposes a heat pump assisted drying system as an alternative. Flower bulb carrying boxes containing just harvested products have been approximated as packed beds filled with spherical products. A heat pump is proposed which includes a cross flow heat exchanger and allows for recirculation of the drying air while maintaining its operating temperature and humidity at optimal conditions to guarantee the required drying rate while preventing damage of the product. Simulink is used to optimize the operating conditions of the system guaranteeing both the product quality and a low energy consumption. The heat pump has been sized to dry 10 flower bulb carrying boxes of about 800 kg each in 24 hours. The performance of the heat pump (170 kWh/day renewable electricity) is compared to the performance of conventional fossil fuel based drying systems (350 kWh/day fossil fuel). Understanding heat and mass transfer mechanisms during drying allows optimization of the heat pump design.

Keywords: heat pump, drying of horticulture products, moisture removal, experimental drying rates;

1. Introduction

1.1. Energy needs in field horticulture

Drying is an energy intensive process. It accounts for 10 to 20% of the total consumption of energy by industry in most developed countries [7]. Drying of agricultural products is commonly accomplished using hot air convective drying, where air is preheated by a gas burner or indirectly by a gas boiler. The Paris agreement from 2015 imposes the banning of fossil fuels as heat sources for drying processes. Heat pumps are currently the most appropriate technique to replace gas boilers. Heat pumps can both be used for heating and dehumidification purposes making its users less dependent on weather conditions, lowering the energy consumption and guaranteeing a constant high product quality. When renewable electricity is used to drive the heat pumps, its operation is fully independent of fossil fuels.

The agricultural sector can be divided in field horticulture (production and processing of food and flowers), greenhouse horticulture, animal farms, wood processing and fishing. These sectors, in the Netherlands, consume 140 PJ of primary energy corresponding to CO_2 emissions of 7.3 Mton. The strategy of the Dutch government [4] to fulfill to the Paris agreement by 2030 imposes a CO_2 emission reduction of 40% for the agricultural sector. According to Wildschut [18] the field production and processing of flowers and flower bulbs is responsible for about 5 PJ of primary energy. It is also expected that this sub-sector contributes to the CO_2 emission reduction with 40% . The sector has signed an agreement with the government that by 2023 16% of the energy use will come from renewable sources [18]. Implementation of heat pumps for drying needs in the sector making use of renewable energy will give significant contributions to these goals.

1.2. Flower bulb processing

This study focus on flower bulbs. Flower bulbs generate heat by metabolism, absorb water and attract diseases when wet. After harvesting the flower bulbs need to be quickly dried to prevent that germs and fungi develop. Flower bulbs need to be conserved at specific temperature, water content and water activity. The water activity, a_w, gives the ratio between partial and saturated water vapor pressure at the surface of a product and is influenced by the temperature and humidity of the surrounding air. Also the concentration of CO_2 and ethylene around the flower bulbs need to be controlled to prevent health issues and contamination with external viruses. According to Wildschut et al. [19], a small amount of ventilation is, however, sufficient to prevent harmful concentrations. According to Rockland & Beuchat [14] a high water activity supports the growth of microorganisms, germination of spores and participation in several types of chemical reactions. Bacteria usually require at least a water activity of 0.91 and fungi of 0.60. So a flower bulb drying system should bring and maintain the water activity close to values just below 0.60. Every 1% of prevented product loss due to better conditioning of the drying and storage conditions results in savings of about € 16500. per year for the average farmer.

The transportation and storage of flower bulbs is usually realized in large cubic boxes of 0.8 to 1.2 m^3. These can be easily transported using forklift trucks. These boxes have a perforated bottom through which drying air can be circulated. Fig. 1 illustrates how the drying air flow from a central air treatment system can be distributed to a large number of these cubic boxes.

At the end boxes the forklift openings are blocked with foam creating a pressure rise which forces the air through the flower bulbs in the boxes. The return air is discarded or dehydrated and heated before being recirculated. The air temperature is maintained in the range 20 to 25 °C, depending on the cultivar. The average drying time of one batch is 24 to 36 hours and the amount of water that needs to be removed is around 50 kg per box [5].

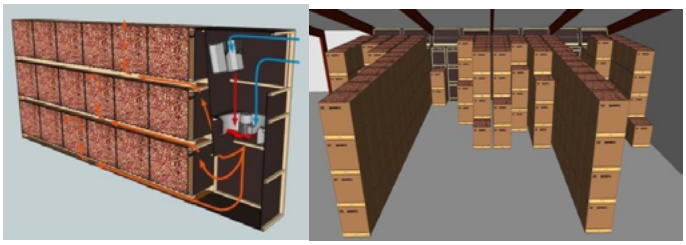

Fig. 1. Drying distribution arrangement for multiple flower bulb boxes.

1.3. Modeling of drying processes of agricultural products

Tzempelikos et al. [15] and Agrawal and Methekar [1] modeled the heat and mass transfer processes during drying of quince slices and pumpkin, respectively. Alnaimat et al. [2] and Li et al. [8] studied the heat and mass transfer processes in a structured packed bed column to determine temperature and humidity of air as it rises in countercurrent flow to cooled water. Minea [11] has reviewed the advances in heat pump drying technologies and its modeling approaches. Although these studies concern different drying processes, they have been used as the basis for the development of the flower bulb drying model introduced in this paper.

2. Drying of flower bulbs

The drying process starts by conditioning the air that is circulated along the bulbs to the required conditions (20 to 25 ºC; low humidity < 5 g/kg_{dry_air}). If possible heat recovery should be used. Then heat is transferred from the drying air to the surface of the bulbs while at the same time water evaporates from the surface of the bulb into the drying air flow. In this evaporation process surface water, or bounded water inside the product which has diffused into the surface, is removed from the bulb surface into the drying air flow. The resulting colder, humid air flows back into the conditioning system and is brought back to feed conditions. Mujumbar [12] distinguishes two drying rate regimes. In the begin of the process unbounded water is evaporated from the surface at a constant rate. When bounded water from the core of the bulb starts to be removed, at a critical moisture content of the bulb, the drying rate starts to decrease. This rate will then generally linearly decrease with the moisture content of the bulb until equilibrium is attained and the drying process stops.

2.1. Flower bulb properties

Bulbs are structured in multiple layers and have a strong solid surface which protects them against damage and diseases. Their structure is similar to the structure of onions and garlic which have been more frequently investigated. The effective moisture diffusivity of the flower bulbs, D, expressed in m^2/s has been assumed to be identical to the moisture diffusivity in onions as reported by Mujumbar [12] and is given in eq. 1 where the moisture content per kg bulb, x, is expressed in kg_{H2O}/kg_{bulb} and T, is the bulb temperature, in K.

$$D = \frac{1}{1+x} \cdot 1.45E-08 \cdot e^{\left[-\frac{70.2}{8314}\left(\frac{1}{T}-\frac{1}{333.15}\right)\right]} \quad (1)$$

Density, specific heat and thermal conductivity of onions reported by van Hiele et al. [16] have been assumed to apply for flower bulbs. Moisture content dependent values have been adopted from Kalbasi [6]. Its values are given in Table 1.

Table 1. Density, ρ, specific heat, c_p and thermal conductivity, λ of flower bulbs. x in kg_{H2O}/kg_{bulb} and T in K.

Properties of flower bulbs based on properties onions	$\rho_{product}$ (kgm^{-3})	$c_{p_product}$ ($kJkg^{-1}K^{-1}$)	$\lambda_{product}$ ($Wm^{-1}K^{-1}$)	ρ_{bulk} (kgm^{-3})	c_{p_bulk} ($kJkg^{-1}K^{-1}$)	λ_{bulk} ($Wm^{-1}K^{-1}$)
Van Hiele et al. [16]	882	3.77	0.48	575	3.77	0.35
Kalbasi [6]		1.84+2.34*x	0.445+0.309*x-0.005*T			

In this study the water activity is obtained making use of the Chung-Pfost equation with the coefficients proposed for garlic bulbs by Madamba et al. [9]. The water activity is obtained using eq. 2 in which T is expressed in ºC.

$$a_w = e^{\left[-\frac{203.4}{T+76.5}\cdot e^{(-0.072\cdot x)}\right]} \tag{2}$$

The equilibrium moisture content of the bulbs can be related to the water activity. The Guggenheim-Anderson-de Boer equation predicts this relation over a wide range of water activity. For onions, Mujumbar [12] proposed eq. 3 with the parameters given in Table 2.

$$x_{eq} = \frac{b_0 \cdot b_1 \cdot b_2 \cdot a_w}{(1-b_1 \cdot a_w)\cdot(1-b_1 \cdot a_w + b_1 \cdot b_2 \cdot a_w)} \tag{3}$$

Table 2. Parameters proposed by Mujumbar [12] for the equilibrium moisture of onions in the Guggenheim-Anderson-de Boer equation. R in kJkmol^{-1}K^{-1} and T in K.

b_0	b_1	b_2	$b_{10}*10^5$	b_{11}	b_{20}	b_{21}
20.2	$b_{10}\cdot e^{\frac{b_{11}}{RT}}$	$b_{20}\cdot e^{\frac{b_{21}}{RT}}$	2.3	32.5	5.79	6.43

2.2. Modeling of drying process

The model has been developed for a single flower bulb carrying box. Fig. 2 illustrates how the box with coordinates x, y and z has been considered. The properties of flower bulbs and air flow are only changing in z-direction so that a control volume considers the whole x-y cross section of the box. The model is transient considering an one-dimensional step Δz in space and a time step Δt. The flow passage area of the box is constant along the height of the box and results in $z/\Delta z$ control volumes. Each control volume contains a volume fraction of flower bulbs, liquid and air. Multiplying each volume fraction with the corresponding material density results in the total mass in the control volume.

Fick's law allows for the determination of the mass transfer over the height of each control volume. This rate of mass transfer can be converted into the rate of humidity ratio change per control volume [17] as given in eq. 4.

$$\frac{d\omega}{dz} = \frac{k_G A_w}{G_a}\cdot\frac{M_v}{R}\left[\frac{p_v^{sat}(T_{\text{int}})}{T_{\text{int}}} - \frac{\omega}{0.622+\omega}\cdot\frac{p}{T_G}\right] \tag{4}$$

In this equation M_v is the molecular weight of the water vapor, R the universal gas constant, T_G (K) the air temperature, T_{int} (K) is the interface temperature (the flower bulb surface temperature), k_G (m/s) is the mass transfer coefficient, A_w (m^2/m^3) is the wetted effective surface area per unit volume. G_a is the mass flux of air through the cross flow area of the box, A_c, and p is the total system pressure.

The change in air temperature is obtained from the energy balance [17] and is given in eq. 5.

$$\frac{dT_a}{dz} = \frac{\frac{d\dot{m}_v}{dz}\cdot\Delta h_{fg} - \alpha\cdot(T_G - T_L)\cdot A_w\cdot A_c - \frac{d\dot{m}_v}{dz}\cdot(2501.1+1.8135\cdot T_{a_in})}{\dot{m}_a\cdot c_{p_a} + 1.8135\cdot\dot{m}_v + 1.8135\cdot\frac{d\dot{m}_v}{dz}} \tag{5}$$

where

$$\frac{d\dot{m}_v}{dz} = \frac{d\omega}{dz}\cdot\dot{m}_a \tag{6}$$

and T_L is the flower bulb surface temperature. The heat transfer coefficient between flower bulb surface and air, α, has been obtained from the correlation proposed in Mills [10] for spherical shaped packed beds.

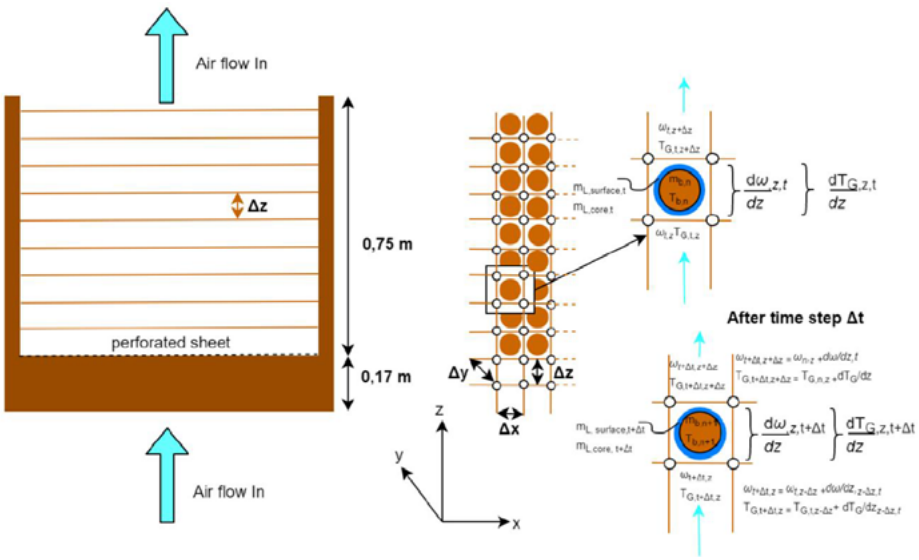

Fig. 2. Discretization of the flower bulb box considering it as a packed bed of flower bulbs.

$$\alpha = \frac{\lambda_a}{L_{char}} \cdot Nu = \frac{\lambda_a}{L_{char}} \cdot (0.5 \cdot \mathrm{Re}^{0.5} + 0.2 \cdot \mathrm{Re}^{0.67}) \cdot \mathrm{Pr}_a^{0.33} \tag{7}$$

With the characteristic length L_{char} obtained from eq. 8.

$$L_{char} = d_{bulb} \cdot \frac{\varepsilon}{1-\varepsilon} \tag{8}$$

With ε the void fraction of the packed flower bulb bed which was initially assumed to be 0.26 [3]. The Reynolds of the flow is calculated using eq. 9:

$$\mathrm{Re} = \frac{G_a \cdot L_{char}}{\mu_a} \tag{9}$$

The mass transfer coefficient is obtained making use of the Chilton-Colburn analogy.

$$k_G = \frac{\alpha}{\rho_a \cdot c_{p_a}} \cdot \left(\frac{\mathrm{Pr}}{Sc}\right)^{0.67} \tag{10}$$

The wetted effective surface area per unit volume is obtained considering that the flower bulbs are spheres and taking the void fraction into account.

$$A_w = \frac{6}{d_{bulb}} \cdot (1-\varepsilon) \tag{11}$$

The pressure drop through the packed flower bulb bed has been predicted making use of the Ergun equation for packed beds, as proposed by Mills [10].

$$\frac{dp}{dz} = \frac{150 \cdot \mu_a \cdot u_{char}}{L_{char}^2} + \frac{1.75 \cdot \rho_a \cdot u_{char}^2}{L_{char}} \tag{12}$$

With the characteristic velocity obtained from eq. 13.

$$u_{char} = \frac{G_a}{\rho_a \cdot \varepsilon} \tag{13}$$

During the second drying regime mainly internal diffusion dominates the process. To take this into account the volume of the flower bulb has been discretized into several nodes between which diffusion is calculated. Details of the approach have been reported in Wagenaar [17].

3. Experimental data

During the summer of 2018 experimental data of the drying period have been collected at two different companies: Niels Kreuk BV and Gebr. Boon Hem BV. Data have been collected of temperature, relative humidity, total mass and pressure drop for batches of flower bulb boxes. Here only the data obtained at Niels Kreuk BV is discussed.

A schematic of the drying chamber and drying arrangement is shown in Fig. 3. This company makes use of a heat pump to dry its flower bulbs. In this arrangement dry air enters the flower bulb boxes from the top and the humid air leaves at the bottom. The air is then dried and heated by a heat pump. The figure shows the position of the boxes which have been measured.

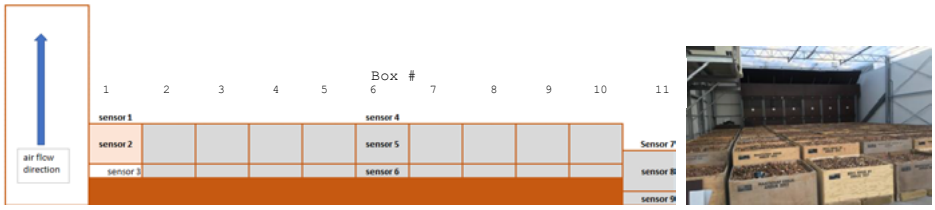

Fig. 3. Schematic of the heat pump based drying chamber of Niels Kreuk BV.

Table 3 shows the mass reduction of the different flower bulb boxes after 15 h and after 62 h of operation. The initial mass is the mass of the boxes just arriving from the field and before starting the drying operation.

Table 3. Mass reduction during the drying period of flower bulb boxes at Niels Kreuk BV. Data collected in July 2018.

	Initial mass [kg]	Mass after 15 h [kg]	Reduction [kg]	Reduction [%]	Mass after 62 h [kg]	Reduction [kg]	Total Reduction [%]	Total mass removed [kg]
Box 1	830	804	26	3.1	794	10	4.3	36
Box 6	790	772	18	2.3	762	10	3.5	28
Box 11	816	799	17	2.1	788	11	3.4	28

The table makes clear that the amount of moisture (and probably remaining soil) in each box is different so that in average the drying percentage is 4.1% but that the contents of some boxes dry 3.4% while of others dry up to 4.3%. The temperature and relative humidity have been measured by installing Lascar EL-USB-2 temperature and humidity data loggers in the different boxes. The temperature is measured with an accuracy of ± 0.5 K and the relative humidity with an accuracy of ± 2%. Fig. 3 shows that for some boxes the temperature and humidity change of the air flow as it passes the boxes have been measured. Fig. 4 illustrates how temperature and humidity change with time at inlet, halfway and at outlet of box 11. The air volume flow rate has been measured making use of an anemometer from Testo-air and mounting a plate with anemometer size perforations above the boxes. The measuring probe of Testo-air 435 has an accuracy of ± 0.1 m/s. The air volume flow through the boxes varies linearly with the position with the largest flow through box 1 (1600 m^3/h) and the lowest through box 11 (1200 m^3/h).

Fig. 4 makes clear that the control of the air inlet temperature and humidity was not able to maintain the air inlet conditions during the experimental period. In the first hour of operation, the air leaving the first half of the box was already saturated with water so that the relative humidity halfway the box is already identical to the relative humidity at the outlet of the box. It is only after about 20 minutes that the orange line starts decreasing. During some periods it is clear that the air inlet and outlet humidity did not change indicating that there was no humidity removal during these periods.

The pressure drop across the flower bulb box was 220 Pa for a volume flow rate of 1417 m^3/h and, respectively, 180 Pa and 100 Pa for volume flow rates of 1259 m^3/h and 917 m^3/h. These data have been used to calibrate the value of the void fraction. This was done by adjusting the value of the void fraction in eq. 13 until the result of eq. 12 corresponded with the experimental data. A value of 0.196 was derived for the void fraction which is slightly lower than the value proposed by Conway & Sloan [3] which was 0.26. A void fraction of 0.196 has been further used in the model.

The experimental wetted effective surface area per unit volume taking the eventual dirt in the void between the flower bulbs into account has also been derived from the experimental data. Since the rate of mass transfer is constant during the first hour of operation, A_w can be derived from eq. 4 when it is assumed that the bulb surface is at wet bulb conditions. From the experimental data, a value of 0.198 is calculated for A_w. This corresponds to assuming an average flower bulb diameter of 4.1 cm in eq. 11, what is quite reasonable.

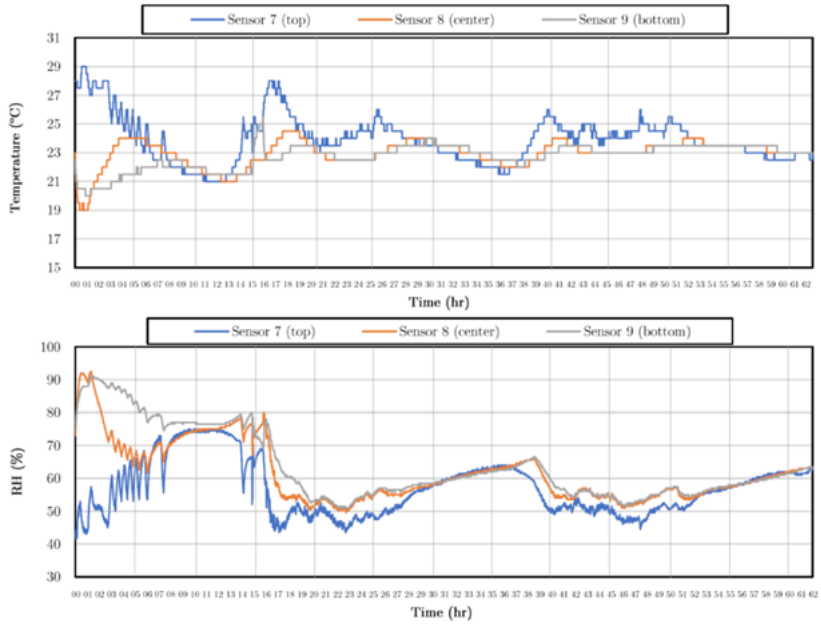

Fig. 4. Temperature (top) and relative humidity (bottom) of the air flow through the flower bulb box 11. Blue is inlet, orange halfway and grey is outlet. The time scale goes from 0 (start time) to 63 h (end of drying process).

4. Model validation

In Fig. 5 (left) the prediction of the model (light blue line) for the air outlet temperature is compared to the experimental outlet temperature (green line). The experimental inlet temperature (red line) is used as input for the model. The agreement is quite good. In Fig. 5 (right) the prediction of the model (light blue line) for the absolute humidity of the air at the outlet is compared to the experimental outlet absolute humidity (green line). The experimental inlet absolute humidity (red line) is used as input for the model. In the center the comparison of the relative humidity. The agreement is quite good.

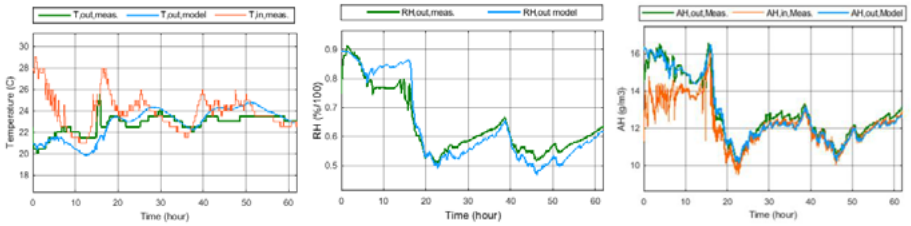

Fig. 5. Temperature (left) and absolute humidity (right) of the air flow through the flower bulb box 11. Red is inlet (experimental and also used as model input), light blue the outlet condition predicted by the model and green is experimental outlet. The time scale goes from 0 (start time) to 60 h (drying period).

Fig. 6 compares the progress of the drying process with the experimental data. The orange line gives the experimental data, the blue line gives the model prediction taking the flower bulb discretization into account and the purple line gives the model prediction based on the absolute humidity change and the air volume flow rate.

Using the flower bulb discretization to take the internal diffusion into account clearly improves the accuracy of the prediction. The model has been validated making use of the root mean square error method. Details of the validation have been reported by Wagenaar [17].

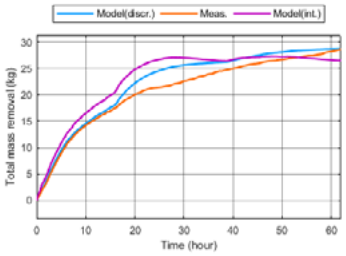

Fig. 6. Mass removed from box 11 as a function of time. The orange line shows the experimental data while the other two lines give the model prediction calculated in two different ways.

5. Heat pump dryer design

The flower bulb heat pump dryer proposed in this study is a typical vapor compression cycle assisted with a cross flow heat exchanger (CFHE). Its schematic and operating conditions are illustrated in Fig. 7. The system has been designed to remove the surface water of 10 flower bulb boxes in 8 h. Depending on the return temperature and humidity of the air after removing moisture from the boxes (state 1 in Fig. 7) the required evaporator capacity will vary from 40 to 60 kW. The heat pump should be able to remove 30 kg/h of water.

The heat pump has been modelled using simplified models for each component. Propane (R290) has been selected as the working fluid as it, as a natural refrigerant, has low environmental impact. A pressure ratio dependent isentropic efficiency has been adopted for the compressor, leading to efficiencies in the range 0.70 to 0.72 for the studied conditions. The evaporator and condenser dimensions and capacities have first been determined using the NTU-method. UA values of 3.55 and 3.20 kW/K have been obtained respectively for the evaporator and for the condenser. The heat exchanger effectiveness has then been used to predict the evaporating and condensing temperatures for different operating conditions, assuming these processes have infinite heat capacity. This is illustrated for the evaporator in eq. 14.

$$T_{evap} = \frac{T_{a_out} - T_{a_in} \cdot e^{-NTU}}{1 - e^{-NTU}} \tag{14}$$

The CFHE has also been modelled using the NTU-method as proposed by Ogulata & Doba [13] and its effectiveness is given in eq. 15.

$$\varepsilon_{CFHE} = 1 - 0.447 \cdot NTU^{-0.4} \tag{15}$$

The output temperature is then obtained from eq. 16 in which the indexes refer to states in Fig. 7.

$$T_2 = T_1 - 0.8 \cdot \varepsilon_{CFHE} \cdot (T_1 - T_3) \tag{16}$$

The 0.8 correction factor has been proposed by the CFHE manufacturer to take into account the condensation that takes place as the air passes the cold surface.

The heat pump dryer model has been implemented in Simulink. The schematic of the model is given in Fig. 8 and illustrates the links between the different components and the air flow conditions.

6. Heat pump dryer performance prediction

To prevent the air temperature to attain values above 35 ºC, what may damage the flower bulbs, the heat pump dryer is modelled with a constant air volume flow of 10000 m^3/h (1000 m^3/h per flower bulb box). Assuming that the air leaving the flower bulb boxes is almost saturated (95% relative humidity), the corresponding temperature and enthalpy at the evaporator outlet can be obtained. Then the required cooling

capacity can be determined and with it the required mass flow of refrigerant. The rotational speed of the compressor can then be adjusted to deliver the required cooling capacity.

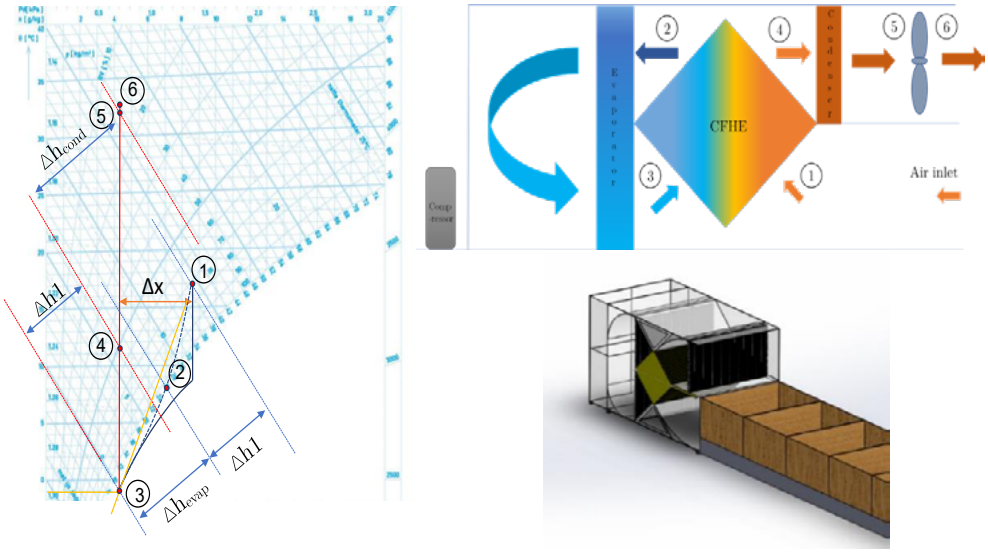

Fig. 7. The drying process in a Mollier diagram and schematic of the heat pump dryer. Between states 2 and 3 the air flow passes the evaporator of the heat pump and between 4 and 5 passes its condenser. State 1 is the return condition after removing moisture from the product. State 6 is the air condition as it enters the flower bulb boxes.

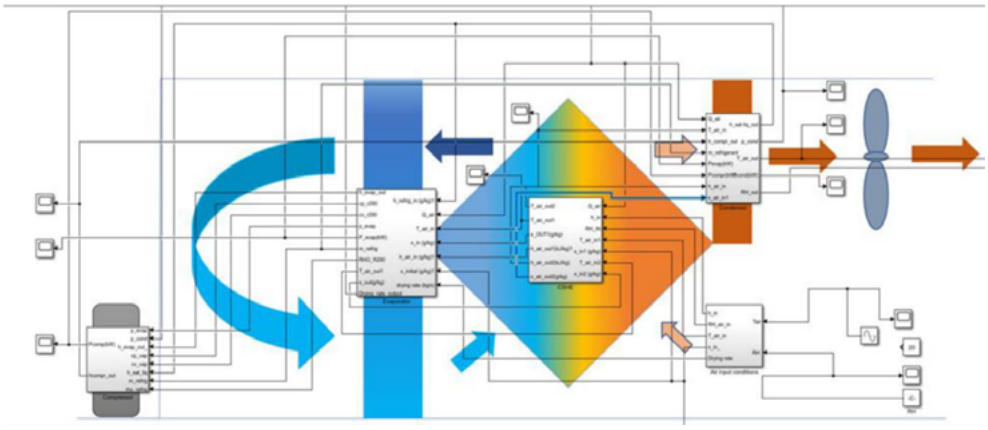

Fig. 8. Simulink model of the heat pump dryer showing the interaction between the different components of the system.

Fig. 9 shows, in the center, the predicted temperatures in the different positions of the heat pump system (the states are indicated in Fig. 7). The left hand side gives the temperature and relative humidity at the inlet and outlet of the heat pump dryer. The conditions of the air stream leaving the flower bulb carrying box (Fig. 5) are used as input for the heat pump dryer model. In the final stages of drying the humidity ratio remains practically unchanged between in- and outlet. Air enters at high temperature and low relative humidity and leaves at lower temperature and higher relative humidity. The right hand side of Fig. 9 gives the condensation and evaporation temperatures of the heat pump as predicted by the model. The evaporating temperature never goes below 0 ºC so that frost formation and associated problems are prevented. The condensation temperature reaches up to 40 ºC, a temperature about 7 K higher than the air outlet temperature and 15 K higher than the

air inlet temperature. The condensation temperature could be lowered by implementing a larger / external condenser to remove excess heat and with it the COP of the system would be improved.

The heat loads of the different components as predicted by the model and the corresponding coefficient of performance (*COP*) are given in Fig. 10 with left the heat loads, in the center the *COP* and the specific moisture extraction rate (*SMER*) expressed in kg/kWh and right the required mass flow of refrigerant. The refrigerant mass flow variation with time indicates that the compressor needs to operate between full-load and about 60% part-load. A range with very acceptable part-load performance.

Typical drying walls just increase the moisture removal capacity by preheating the drying air making use of hot water heat exchangers. The temperature of the drying air is conventionally increased with 4 K as the air passes these heat exchangers. Taking a boiler efficiency of 90% into account, heating 10000 m^3/h air requires a fuel heating power of 14.6 kW. This corresponds to a fossil fuel based energy consumption of 352 kWh per day. The left end side of Fig. 10 shows that during the first 24 hours the compressor of the heat pump (light blue line) consumes approximately 170 kWh renewable electricity. This is an energy consumption reduction of 57%. A CO_2 emission reduction will only be attained if the compressor is driven by renewable electricity. With an average energy conversion efficiency of 0.42 in the Dutch fossil fuel driven power stations, using electricity generated by these power stations will result in approximately the same CO_2 emissions.

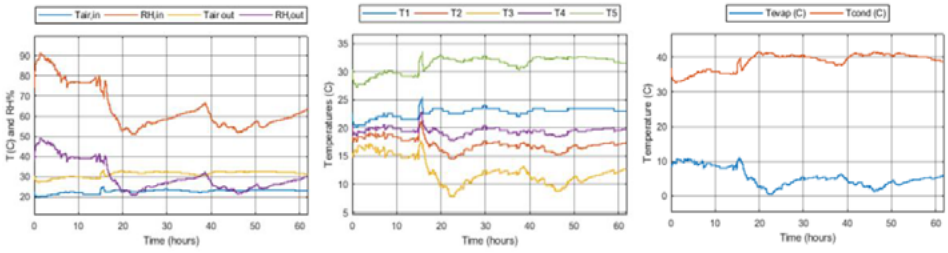

Fig. 9. Simulation results of heat pump performance. Left the air temperature and relative humidity at inlet and outlet of the heat pump dryer. In the center the air temperature changes along the different components (see Fig. 7 for positions). Right the condensation and evaporation temperatures of the heat pump.

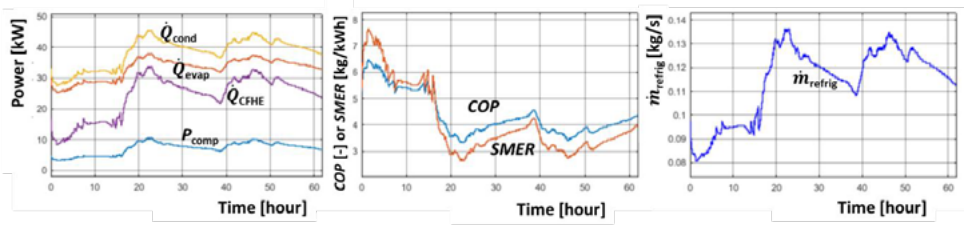

Fig. 10. Simulation results of heat pump performance. Left the heat exchanged in the different components. In the center the *COP* and *SMER* of the system. Right the required mass flow of refrigerant as a function of time.

7. Conclusions

In this study a Simulink model has been developed for the drying process of flower bulbs which includes a vapor compression heat pump assisted with a cross flow heat exchanger for heat recovery. The model results have been validated making use of experimental data collected at a flower bulb company. The main conclusions of this study are as follows:

- The drying process of the flower bulbs distinguishes two regimes: first the unbounded water is evaporated from the surface of the bulbs at a constant rate after which the water from the core of the bulbs starts to be removed and the moisture removal rate linearly decreases until an equilibrium is attained.
- Approaching the flower bulb boxes as packed beds of spherical shaped bulbs with void fraction of 19.6% and average diameter of 4.1 cm gives results comparable to the experimental values for what concerns the drying rate.

- To prevent too high temperatures of the air entering the flow bulb boxes, compressor speed control is required. The expected load conditions are in the range 60 to 100%.
- In the first 15 hours of operation the *COP* of the heat pump reaches values in the range of 6. However, improvement of the design of the condenser and evaporator is possible since, in the present design, the temperature driving forces across these heat exchangers are quite large.
- During the first 15 hours of operation the heat pump removes around 25 kg of moisture per flower bulb box. This is around 3% of the total weight per box.
- During the first 15 hours of operation the heat pump extracts 6 kg of moisture per kWh of energy consumed.
- While a conventional fossil fuel driven drying system consumes 350 kWh per day, the proposed heat pump dryer consumes 170 kWh renewable electricity per day.
- Implementation of heat pumps for drying purposes in the agriculture sector results in energy savings combined with improved product quality while burning of fossil fuels is prevented.

Abstract

Buildings consume 40% of the total global energy and contribute to over 30% of all CO_2 emissions. Space heating forms a significant part of energy consumption in buildings. A possible solution is to recover waste heat from sewage and to upgrade its exergy using a heat pump. Polymers reduce cost and energy required for manufacturing the heat exchangers. The impact of sewage flow and temperature, heat exchanger dimensions and thermal enhancement of polymers on heat recovery is studied using a Matlab model. The model integrates a sewage heat exchanger with a heat pump and optimizes heat recovery from sewage. A heat pump is used to obtain hot water at 55°C for space heating. Heat recovered from sewage and overall COP are quantified. In case of HPDE with graphite filler, increase in filler content from 0% to 30% increases thermal conductivity from 0.46 to 1.89 $Wm^{-1}K^{-1}$ increasing the heat recovery with 34%. The heat transfer coefficient becomes twice as large when polymer with no filler is enhanced with 30% filler content. Large heat exchange area and variability of sewage level limit the recovered heat.

Keywords: enhanced polymer; sewage heat recovery; heat pump; building heating.

1. Introduction

Buildings consume about 40 % of the total global energy and contribute to over 30 % of all CO_2 emissions [17]. Space heating and cooling and domestic hot water supply form the largest part of the energy consumed in residential buildings [2]. Use of fossil fuels to cope with heating and air-conditioning demands of buildings leads to a series of critical problems such as pollution, climate change and energy shortage [9]. Next to this, the Dutch government has set goals to phase out the use of natural gas and wants to be free from natural gas in 2050. The city of Rotterdam has set a sub target for 2030: 49% CO_2 reduction. Thus, it is vital to develop sustainable technology that can assist in reducing this energy consumption.

A possible route to reduce the energy consumption from buildings is to recover heat from sewage (waste) water. Water that has been affected in quality due to anthropogenic influence is called waste water. According to Hepbasli et al. [5] more than 15% of the thermal energy supplied to buildings is lost through the sewer system. Waste water can be used as a heat source for heat pumps to fulfill the heating and cooling requirements of buildings. These streams are suitable heat sources because, as reported by Frijns et al. [3], in the Netherlands, these flows reach to 1928 Mm^3 per year so that by cooling the flow with 5 K 40.4 PJ heat can be extracted from the flow. Additionally its temperature is higher than ambient in the winter and lower in the summer and daily temperature changes are small.

Currently, mainly in Europe, about 500 Waste Water Source Heat Pumps (WWSHP) are estimated to be in operation with thermal rating in the range of 10 - 20,000 kW. Installation of WWSHP systems can be either in the sewer system or after the waste water treatment plant (WWTP).

Although recovering heat after WWTP would eliminate the risk of bio-film growth in the heat exchanger, the maximal temperature of waste water is usually at the initial stages of the sewer system. Moreover, heat recovery location in the sewer is closer to the consumers than waste water treatment plants [16].

A WWSHP consists of three components (i) Waste Water Heat Exchanger - Heat is recovered from waste water (ii) Heat pump - The heat recovered is upgraded to be used in the heating system of buildings (iii) Distribution system of heating and cooling in buildings.

Waste water can lead to the fouling of the waste water heat exchanger. Fouling occurs when fluid degrades near heat transfer surface or solids deposit on surface. Sometimes, microorganisms create bio-film matrices on heat exchange surface which will also result in reduced heat transfer performance of the heat exchanger [2]. Liu et al. [9] have reported that the convective heat transfer and fouling resistances on the sewage side of the waste water heat exchanger accounted for 80% of the total thermal resistance of their system.

In this paper, sustainable and economic system design is considered to recover waste heat from sewage for heating / cooling of buildings to reduce their carbon footprint. The ”Doelen” case in Rotterdam is considered to illustrate the benefits of heat recovery in terms of renewable energy, economics and sustainability of installing such systems in sewers. The Doelen is a concert venue and convention center in Rotterdam, Netherlands. The heat recovered from sewage will contribute to the heating requirements of ’Doelen’. Furthermore, polymer sewage heat exchangers are considered for heat recovery due to their advantages such as low cost, lesser weight, lower fouling and higher corrosion resistance. It is estimated that the energy required to produce a unit mass of polymers is two times lower than of common metals, which makes polymer heat exchangers environmentally friendly [1].

The objective of this study is to develop technology that provides a strong basis for scaling up sewage waste heat recovery systems for large urban areas. The scope includes designing, modeling and validation of the most suitable polymer heat exchangers for heat recovery from sewage systems.

2. State-of-the-art

2.1. Sewage heat recovery potential

About 70% of the total drinking water produced in the Netherlands is used for domestic purposes [6, 15] and contributes most to the temperature of the sewage flow. Roest et al. [12] report that drinking water enter the sewage at around 27 ºC and the water from bathing and showers at 38 to 40 ºC. Tap water and water from the dish washer and washing machine enter the sewage at approximately 40 ºC. According to Hofman et al. [6] these flows correspond to 40 % of the total energy losses from modern Dutch dwellings. The temperature of the effluent leaving the WWTP was found to be roughly 15 ºC. Cooling the total effluent flow (1928 Mm^3/year, [3]) with 5 K ΔT from 15 ºC to 10 ºC delivers 40.4 PJ low temperature energy available as heat source for heat pumps. With a COP of 4 these heat pumps could deliver 53.9 PJ of heat at 55 ºC at national level and 1.6 PJ for a town with 500,000 inhabitants. This is sufficient to cover 12% of the heating requirements of the built environment (448 PJ in 2015).

2.2. Possible sewage heat recovery locations

Heat recovery from sewage can be done in three locations of the sewage network [2]. Heat can be recovered at the source of sewage (buildings), or in the sewage line or after the treatment of sewage.

Waste water temperature affects the water treatment process. Nitrification, one of the steps of water treatment, is a temperature dependent process. Growth of nitrifying bacteria is impeded at lower waste water temperatures [16].

Looking at the pros and cons of each location, recovering heat from the sewage network is more advantageous since waste water flow is higher and continuous in comparison to the decentralized domestic sewage system. The problem with recovering heat after treatment is that the WWTPs are located far away from residential buildings, implying additional investment on pipelines and insulation.

2.3. Waste Water Heat Exchangers

Liu et al. [9] report the COP of a WWSHP system designed for the (partial) heating supply of a residential building with 10,000 occupants in Dalian, China. The system can be used for heating and cooling. Heat recovery is of the indirect type so that the waste water exchanges heat with a secondary flow in a heat exchanger, after which it is sent back to the municipal sewage pipeline. This system uses a shell and tube heat exchanger.

Spriet and Hendrick [14] developed a simulation to evaluate the potential of heat recovery from waste water. The model has been validated using experimental data of an installation located in Myrtes (Brussels), Belgium. The sewage heat exchanger is installed in the sewer while the heat pump is placed in a machine room. The recovered heat is used for heating of a conditioned space. The waste water heat exchanger is of the multi-row tube type. HDPE tubes are connected in series in multiple tube rows. A solution of glycol in water (MEG 33 %) is used as the heat transfer medium inside the tubes to recover heat from waste water.

Among the two WWSHP systems described, the first one used a metallic shell and tube heat exchanger for heat recovery from waste water. The use of shell and tube was only possible because the sewage was cleaned off of the fouling elements using complex anti-clogging equipment. The anti-clogging system requires regular maintenance and adds to the overall cost of the system. Thus, considering the overall system complexity, space requirements and the cost of metallic heat exchangers, the system used in Myrtes was selected for further investigation in this study. Experimental data and simulation results of the Myrtes site can then be used for validation purposes.

2.4. Polymer materials

Different polymers have been compared based on the values of three of the most important features : thermal conductivity, λ, yield strength (YTS) and cost of raw materials. The four polymers with the highest thermal conductivity are listed in Table 1. PS is included because it is commonly used in heat exchangers.

The fillers used in polymer composites are particles, fibers, flakes and laminas. Chen et al. [1] provide a list of some composites with their matrix material, filler material, filler volume and the resulting thermal conductivity values. For instance, the thermal conductivity of PS (0.14 $Wm^{-1}K^{-1}$) rises to 0.25 $Wm^{-1}K^{-1}$ when 10 % graphite is added as filler to the material and to 0.90 $Wm^{-1}K^{-1}$ when 30% graphite is added.

Table 1. Commonly used polymers with highest thermal conductivity. Please consult the list of abbreviations in the nomenclature for the polymer specifications. The thermal conductivity of copper, a frequently used material in heat exchangers, is 401 $Wm^{-1}K^{-1}$ and copper costs around 5.54 €/kg.

Polymer	λ_t [$Wm^{-1}K^{-1}$]	YTS [MPa]	Cost [€kg^{-1}]
HDPE	0.46	25.9	0.54
LDPE	0.30	10.8	0.57
PPS	0.30	68.9	1.10
PC	0.20	62.0	1.10
PS	0.14	43.9	0.90

The advantage of having high YTS is that the thickness required to withstand pressure can be lower. Low thickness leads to higher *U*-values. When compared to metals, the benefit of low cost of polymers far outweighs that of high thermal conductivity of metals. Among the remaining options, HDPE shows the highest λ value and a relatively high YTS. For this reason, HDPE has been selected for application in the sewage heat exchanger.

3. System model

3.1. Local characteristics of sewage network

The model concerns a specific sewage channel in the center of Rotterdam. The data required for modeling of the sewage heat recovery system such as sewage channel dimensions, sewage temperature and sewage flow has been provided by the Municipality of Rotterdam.

The dimensions of the sewage channel considered for the installation of waste water heat exchanger are as shown in Fig. 1. The sewage channel is located in the center of Rotterdam near the 'Doelen'. The sewage channel is approximately oval shaped with the flow passage area spanning 1.5 m in width and 1.44 m in height.

Number of tubes of heat exchanger actually submerged in sewage flow, hydraulic diameter of the channel, flow cross-sectional area and sewage flow velocity are all dependent on the sewage level. These parameters are dynamically evaluated for each sewage level. The angle between the horizontal and l_2 is 30°. When the sewage level is higher than l_4, the flow area is divided into a trapezium with sides l_1; l_2; l_5; l_3 and a rectangle with area l_5 x l_6. In that case, the length of the sides l_6=l_7 is calculated as the difference in sewage level and l_4. For sewage level lower than l_4, the flow area is just a trapezium and length of sides l_6=l_7 is 0. From a measurement in 2018, the highest sewage level that can be attained is 0.5 m. Thus, the maximum possible value for l_4 + l_6 is 0.5 m. Dimensions of the sewage channel calculated for the sewage level of 0.5 m are provided in Table 2.

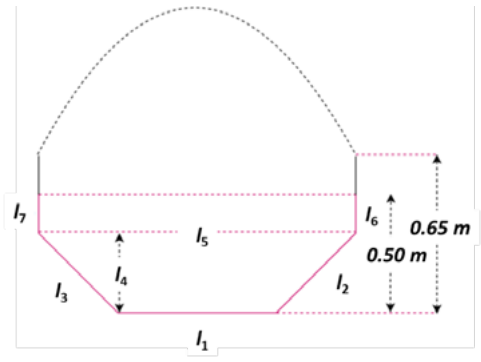

Fig. 1. Schematic of the cross section of the sewage channel.

Table 2. Dimensions of the sewage channel for a sewage level of 0.5 m.

l_1 [m]	l_2 [m]	l_3 [m]	l_4 [m]	l_5 [m]	l_6 [m]	l_7 [m]	$P_{tot,ch}$ [m]	P_{ch} [m]	$d_{hyd,ch}$ [m]	$r_{hyd,ch}$ [m]	$A_{c,ch}$ [m^2]
0.50	0.58	0.58	0.29	1.50	0.21	0.21	3.58	2.08	0.68	0.17	0.61

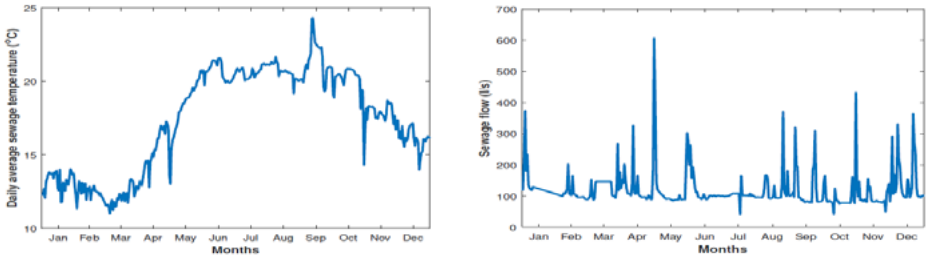

Fig. 2. Daily averaged temperature (left) and volumetric flow rate (right) of the sewage flow in 2018.

Sewage temperature values were available in intervals of 5 minutes for each day of the year 2018. Since the daily variation of sewage temperature was not significant, daily average was calculated for each day of the year and was considered to be the sewage temperature for that day. Variation of daily average sewage temperatures throughout the year is plotted in Fig. 2 (left). Sewage temperature was found to vary between a maximum of 24.3 ºC to a minimum of 11 ºC. It can be seen that sewage temperatures are higher in the summer (June, July and August) and lower in the winter.

The volume flow rate is given in Fig. 2 (right) and, in 2018, varied between a maximum of 606.8 l/s to a minimum of 41.5 l/s. Sewage flow velocity and level were calculated based on flow data and channel dimensions. From the known data that the highest sewage level in 2018 was 0.5 m, sewage levels for all other flow rates were interpolated linearly with sewage flow. The sewage level variation is plotted in Fig. 3 (left). Velocity of sewage flow was estimated from sewage flow rate, sewage level and the corresponding channel dimensions. Flow area is dependent on the sewage level and sewage level is dependent on flow. Fig. 3 (right) shows the variation of sewage velocity along the year. It can be observed that on the day of the highest sewage level, flow velocity is the lowest. Sewage velocity varied between a minimum of 1 m/s to a maximum of 2.17 m/s. The corresponding Reynolds number varied between 15000 and 76000, indicating turbulent flow.

The mass flow rate of sewage can be obtained from its velocity using eq. (1).

$$\dot{m}_{ww} = \rho_{ww} \cdot A_{c,ch} \cdot v_{ww} \tag{1}$$

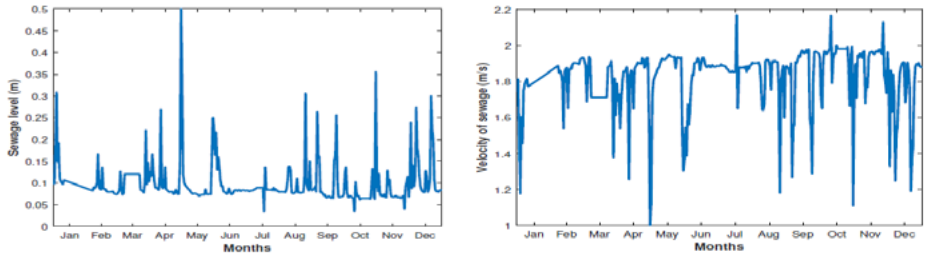

Fig. 3. Daily averaged sewage level (left) and velocity (right) of the sewage flow in 2018.

3.2. Waste water source heat pump (WWSHP) system

The waste water source heat pump systems considered in this work are schematically illustrated in Fig. 4. In the winter, heat is recovered from the sewage and in the summer rejected to the sewage. For this reason a reversible heat pump is used. Polymer waste water heat exchangers (WWHEX) are used to transfer heat with the sewage. Four heat exchangers are installed in parallel inside the sewage channel as illustrated in Fig.4.

Secondary water (a solution of glycol in water) is used as an intermediate fluid between the heat pump and the WWHEXs.

During the winter secondary water transfers the heat recovered from the sewage to the refrigerant in the evaporator of the heat pump. In the evaporator, the hot secondary water is cooled to a temperature 2 K higher than the evaporation temperature. The heat required by 'Doelen' is supplied by the condenser of the heat pump. The condensation temperature is set at 55 °C. The water used for heating in the 'Doelen' is heated from 25 °C to about 53 °C in the condenser and then supplied to the heating network of the 'Doelen'. In the summer, the heat pump is operated in reverse. Chilled water from the cooling network of 'Doelen' is cooled from 14 °C to 10 °C in the evaporator of the heat pump which operates at 8 °C. The condensation temperature of the heat pump is varied such that the secondary water inlet temperature to the waste water heat exchanger is higher than the sewage temperature.

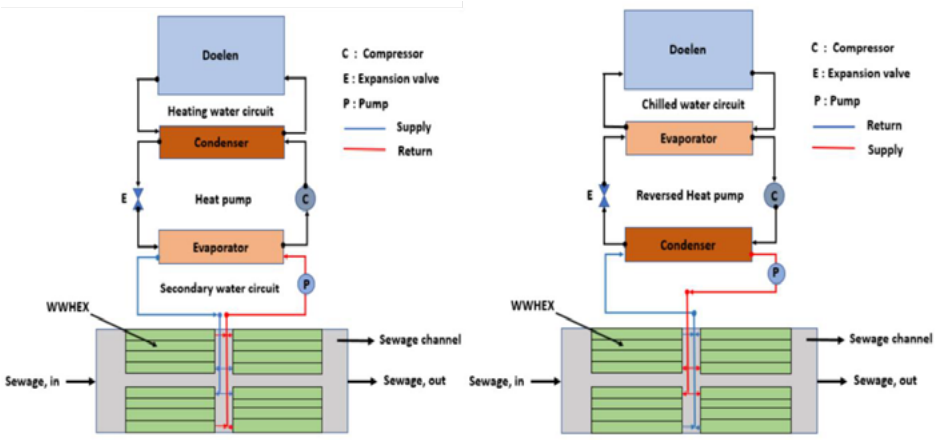

Fig. 4. WWSHP system as connected during the winter season (left) and summer season (right).

Winter and summer situations are simulated separately due to the differences in operation. For each combination of tube length and diameter of the waste water heat exchanger, the winter model is simulated on a daily basis for nine months of winter. In the heat recovery system, the sewage and heat pump condensation temperature are the only known values while all other temperatures are unknown. Based on the sewage temperature, the secondary water outlet temperature ($T_{sw,out}$) is set. The secondary water inlet temperature ($T_{sw,in}$) is varied from 0 °C to a temperature 2 K lower than $T_{sw,out}$. The evaporation temperature of the heat pump is set 2 K lower than $T_{sw,in}$. For each of the 9 months, a primary inner loop was run for the number of days of that month while a secondary inner loop ran over all combinations of temperatures until the increase in *COP* of the system was less than 5% (convergence criterion). Once the combination of temperatures with the optimized *COP* is found, the secondary inner loop is terminated and the calculations for the next day start. After the winter model has been simulated for 9 months, the total heat recovered, heat supplied, required pump and compressor power and seasonal *COP* are calculated. After that, the same calculations were repeated for the next combination of tube dimensions. At the end, all the seasonal performance parameters are compared to find the most optimal heat exchanger tube dimensions.

The same set of optimized tube dimensions are used for the summer model since the waste water heat exchanger installation is the same in the summer. In the summer, the secondary water rejects heat to the sewage, thus its temperature is set higher than the sewage temperature. The increase in secondary water temperature ($T_{sw,in} + \Delta T$) at the inlet of waste water heat exchanger over $T_{ww,in}$ is varied from 10 K to 50 K to study the effect on system performance. Thus, the summer model was simulated for different secondary water inlet ($T_{sw,in}$) temperatures. For each $T_{sw,in}+ \Delta T$, a primary inner loop iterated over the summer months. A secondary inner loop iterated over all the days of the summer where the condensation temperature was set to be equal to $T_{sw,in}$ + 2 K and the secondary water outlet temperature ($T_{sw,out}$) is set 2 K higher than the daily average sewage temperature. Similar to the winter model, all the seasonal values of the system performance indicators are calculated to find the most optimum value for $T_{sw,in}$.

3.3. Waste water heat exchanger

The WWHEX has sewage on the hot side and secondary water on the cold side in the winter and vice-versa in the summer. Multi-row polymer tube heat exchanger is selected as the WWHEX type. The polymer tubes are arranged in series. To reduce the pressure drop, the total secondary water flow required is distributed among 4 parallel heat exchangers which have tubes arranged in series. All the tube rows are installed against the surface of the sewage channel, so that the sewage flows directly over the polymer tubes. From initial analysis, it was concluded that, due to low thermal conductivity of the polymer tubes, a large number of tubes is required. For this reason the tubes are closely packed. Fig. 5 illustrates the cross sectional view of an indicative tube arrangement to assist the understanding of modeling of the heat exchanger. All the dimensions in the diagram are in mm. Fig. 5 indicates the tube arrangement for a sewage level of 0.5 m and depicts two heat exchangers placed symmetrically. In each heat exchanger, the tubes are connected in series. One heat exchanger is on the RHS and another on the LHS. A small separation between the two can be seen on the bottom side. Two more heat exchangers are placed along the channel adjacent to these two heat exchangers. A common header was used to carry the total secondary water flow, which was split into the 4 heat exchangers.

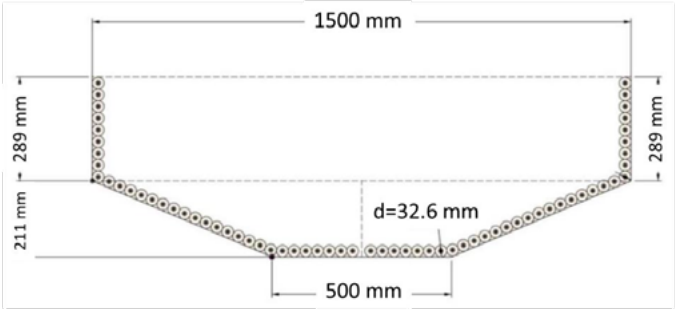

Fig. 5. Cross section of the sewage channel showing the arrangement of the polymer tubes along the surface of the channel. Fig. 3 shows that the liquid level is generally lower so that preferably only the trapezium part of the channel should be covered with tubes.

3.4. Design duty for WWHEX

The WWHEX has been designed to exchange (recover/reject) 180 kW from the sewage. It should recover 180 kW during the day with the lowest temperature in the winter and to reject 180 kW to the sewage during the hottest day in the summer. The months of September to May are the months requiring heating (winter). The rest of the months, June to August are the months requiring cooling (summer). The required heat duty of the waste water heat exchanger was considered to scale linearly with the ambient temperature. Thus, 180 kW should be recovered from sewage during the day with the lowest outside temperature while no heat should be recovered ($\dot{Q}_{ww} = 0$ kW) when the ambient temperature is above 20 ºC in the winter. In the summer, 180 kW should be rejected to the sewage on the hottest day and cooling is not required on those days when ambient temperature is lower than 20 ºC. Heat recovered from the sewage was considered to be equal to the capacity of the evaporator in the winter and the heat rejected to sewage to be equal to condenser capacity in the summer. Fig. 6 (left) depicts the variation of ambient temperature in 2018 and the required heat exchange with sewage in the winter and Fig. 6 (right) indicates the heat to be rejected to the sewage in the summer. A horizontal line marking 20 ºC is shown in both plots. It can be seen that in the winter when the ambient temperature crosses the 20 ºC line, the heat duty goes to zero and in the summer, the heat duty goes to zero when the ambient temperature is below the 20 ºC.

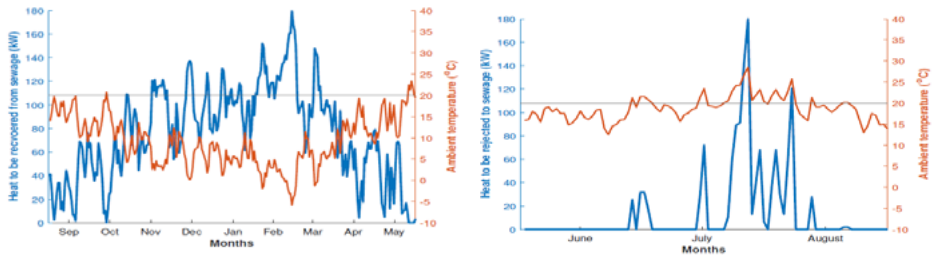

Fig. 6. Heat to be extracted from the sewage in the winter season (left) and rejected to the sewage in the summer season (right).

Due to the large sewage flow, reduction in sewage temperature was negligible after heat extraction. Thus, the physical properties of sewage at inlet and outlet of waste water heat exchangers were considered to be the same. Due to the fact that exact data indicating the quantitative and qualitative analysis of the sediments in the sewage of Rotterdam was not available, properties of water were considered for sewage water calculations. Measurements by the Municipality indicated that the sediments were low in the sewage channel considered. Properties of water have been evaluated as a function of the sewage temperature.

Flow of sewage in the sewage channel was approximated to flow through tubes. Hydraulic diameter of the channel based on the sewage level was considered to be the diameter of the channel for Nusselt number calculation. Thus, the convective heat transfer coefficient on the sewage side (α_{ww}) was calculated based on sewage flow velocity (v_{ww}) and hydraulic diameter of the channel ($d_{hyd,ch}$). Properties of sewage such as λ_{ww}, μ_{ww}, ρ_{ww} and $c_{p,ww}$ required for the calculation of (α_{ww}) were calculated at the sewage temperature.

The secondary fluid was a mixture of water and mono-ethylene glycol with a concentration leading to a freezing point of -20 ºC. The properties of this mixture have been obtained from Melinder [10]. The mass flow of secondary water has been obtained with eq. (2) where the heat duty is obtained from Fig. 6 and ΔT_{sw} is the temperature change of the secondary water as it passes the heat exchanger.

$$\dot{m}_{sw} = \frac{\dot{Q}_{ww}}{c_{p,sw} \cdot \Delta T_{sw}} \tag{2}$$

The velocity of the secondary water through the heat exchanger tubes follows from the cross section of the flow, the density and the number of heat exchangers in parallel (4). The convective heat transfer coefficient on the secondary water side α_{sw} was calculated using the same correlations as for the sewage side [11]. A fouling resistance of 0.00067 m^2KW^{-1} [9] has been assumed on the sewage side and of 0.0002 m^2KW^{-1} [13] on the secondary water side. These extra resistances have been included in the calculation of the overall heat transfer coefficient based on the external area of the tubes, U_o.

Based on the value of U_o, LMTD and the heat duty per heat exchanger, the external surface area of the tubes ($A_{tot,t}$) required per heat exchanger was obtained from eq (3).

$$A_{tot,t} = \frac{\dot{Q}_{ww,req,1}}{U_o \cdot LMTD} \tag{3}$$

This allowed for the calculation of the required number of tubes. The number of tubes must be even to ensure that the return line can be connected from the same side as that of the supply line. The number of tubes required per heat exchanger was compared with the total number of tubes that were submerged in sewage at any given time ($N_{t,sub}$) to see if it was feasible. $N_{t,sub}$ depends on sewage level with corresponding wetted perimeter, tube diameter and tube pitch. The actual heat recovered from the sewage per heat exchanger is then obtained from eq. (4).

$$\dot{Q}_{ww,act,1} = U_o \cdot \frac{N_{t,sub}}{2} \cdot A_{s,t} \cdot LMTD \tag{4}$$

With $A_{s,t}$ the surface area of a single tube. The pressure drop on the secondary flow side was obtained from the number of tubes and connecting elbows, length of the tubes, connecting header and mass flow through the

heat exchanger. This pressure drop allowed for calculation of the power consumption of the pump. For the heating period, the instantaneous COP was then obtained from eq. (5).

$$COP = \frac{\dot{Q}_{cond}}{\dot{W}_{sw,pump} + \dot{W}_{comp}} \quad (5)$$

The working fluid of the heat pump was propane (R290). In the winter season the condensation temperature of the cycle was maintained at 55 ºC. The temperature of the refrigerant at the outlet of the compressor was then around 64 ºC. In the condenser, the refrigerant was cooled from 64 ºC to a sub-cooled temperature of 30 ºC. Water from the 'Doelen' heating system was heated from 25 ºC to 53 ºC with a pinch of 5 K in the condenser. The secondary water temperature $T_{sw,in}$ at the outlet of the evaporator was the limiting factor for the evaporation temperature. The evaporation temperature of the heat pump was set 2 K lower than $T_{sw,in}$ to prevent temperature cross-over. $\dot{Q}_{cond}$ and $\dot{W}_{comp}$ were obtained from the heat pump model making use of Refprop [8] for the propane properties.

4. Model results

4.1. Validation

The data reported by Spriet and Hendrick [14] collected in Myrtes has been used for validation purposes. This test plant makes use of 30 HPDE tubes of 6 m long with internal diameter of 32 mm and a wall thickness of 2.13 mm. The recovered heat is upgraded making use of a R410A heat pump. During the experiments, the sewage flow varied between 5 and 60 m^3/h and its temperature from 6 to 18 ºC. The secondary water (MEG) was pumped over 230 m. Table 3 compares the reported experimental data with the results of the model proposed in this work.

Table 3. Comparison of the experimental data of the Myrtes plant and the proposed model.

Parameter	Myrtes plant data	Present model
Heat recovered from sewage [kW]	2.5 – 5.5	1.2 – 5.5
Heat delivered by heat pump [kW]	3.2 – 7.0	2.7 – 7.4
COP	3.7 – 5.0	3.9

In general the model predicts reasonably well the peak values recovered and delivered by the system. The lower values of the recovered heat and delivered heat are lower in the present model. The reason for this deviation is that the sewage design of Rotterdam was assumed to apply for Myrtes since its real geometry was not reported by the Spriet and Hendrick [14].

4.2. Tube dimensions of waste water heat exchanger

The winter model was run for 6 combinations of tube lengths and diameters. Standard HDPE tube lengths of 12 m and 30 m and tube inner diameters of 17 mm, 29 mm and 58 mm were selected for these simulations. The lowest COP value was observed for the combination of l_t = 30 m and $d_{i,t}$ = 17 mm while the highest COP was observed for $d_{i,t}$ = 58 mm options. Smaller tube diameters resulted in more heat recovery due to higher secondary water velocity (hence higher U_o). The highest amount of heat recovered from the sewage was for l_t = 30 m and $d_{i,t}$ = 17 mm. The lowest amount of heat recovered was for the l_t = 12 m and $d_{i,t}$ = 58 mm combination. Table 4 provides the seasonal values of COP, heat recovered from sewage, total electrical energy required to run the pump and the compressor along with a cost comparison. The cost column includes the cost of the waste water heat exchanger and the cost of electricity. The cost of heat exchanger is based on the weight of material used in the heat exchanger and the specific price of the material. It is assumed equal to three times the material cost. The cost of electricity was considered to be 50.7 €/MWh [4]. The system performance was quantified as the amount of heat delivered to 'Doelen', Q_{cond}, per unit cost (kWh/€).

Table 4. Optimization of tube dimensions for the waste water heat exchanger.

Dimensions		Q_{cond}	Q_{ww}	W_{elec}	N_t	Cost [€]			kWh/€	*COP*
l_t [m]	$d_{i,t}$ [mm]	[MWh]	[MWh]	[MWh]		WWHEX	W_{elec}	Total		
	17	236	181	66	200	396	3346	3742	63	3.6
12	29	131	103	30	128	415	1521	1936	**68**	**4.5**
	58	43	34	9	64	403	456	859	50	4.6
	17	535	405	331	200	989	16782	17771	30	1.6
30	29	486	374	126	128	1037	6388	7425	**65**	**3.9**
	58	188	148	41	64	1007	2079	3085	61	4.6

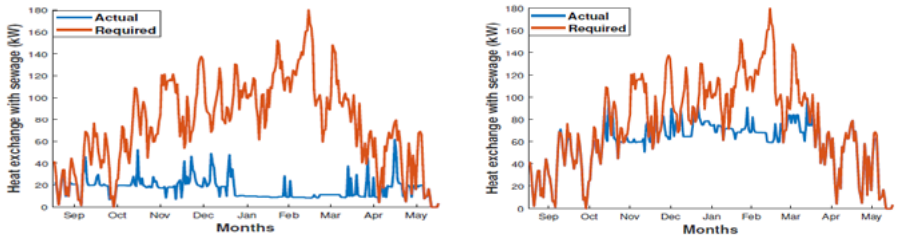

Fig. 7. Difference between the required (red) and recovered (blue) heat from the sewage for the 29 mm tube. Left for tubes of 12 m; right for tubes with 30 m.

The best two options were $d_{i,t}$ = 29 mm, l_t = 12 m and $d_{i,t}$ = 29 mm, l_t = 30 m. The 12 m option delivered 68 kWh/€, while the 30 m option delivered 65 kWh/€ which is only 4.6% lower. Thus, to make a choice between l_t = 12 m and l_t = 30 m, a comparison between the actual heat recovered and the required heat exchange with the sewage was compared as shown in Fig. 7. The heat recovered in the case of l_t = 12 m option was much lower than what was necessary (Fig. 7 left), while it was much better in the case of l_t = 30 m (Fig. 7 right). Thus, making use of just one heat exchanger with l_t = 12 m was not sufficient to recover the required amount of heat. Thus, l_t = 30 m and $d_{i,t}$ = 29 mm were chosen as the optimized tube dimensions.

Based on the time dependent sewage temperature values, secondary water inlet and outlet temperatures were determined. Based on secondary water inlet (to waste water heat exchanger) temperature, the heat pump evaporation temperature was determined (2 K lower). Condensation and evaporation temperature of the heat pump, sewage inlet and outlet temperatures and secondary water temperatures for the winter season are plotted in Fig. 8 left. The optimum COP of the system was obtained when the temperature of the secondary water increased by 10 K. Fig. 8 right shows how the COP of the system changes during the heating season.

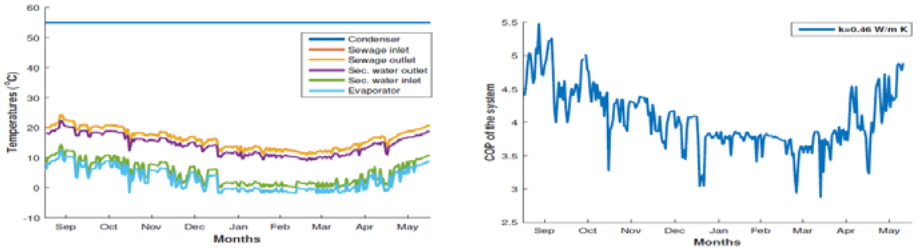

Fig. 8. Change of the operating temperatures during the heating season (left). Notice that in and outlet of sewage are the same. Right: the change of system COP during the heating season.

4.3. Effect of using enhanced polymers

Table 5 shows a comparison of WWSHP system performance in the winter and summer. Increase in thermal conductivity of the polymer tubes from 0.46 to 1.89 $Wm^{-1}K^{-1}$ enhances heat recovery in the winter much more

than in the summer. The electrical energy consumption was higher in the winter due to longer period of operation (9 months) and more heat recovery. Seasonal COP value of summer was higher than winter for both the cases (of thermal conductivity). The increased U_o in both the cases was almost two times the initial value.

Table 5. Optimization of tube dimensions for the waste water heat exchanger.

Season	λ_t	U_o	Q_{cond}	Q_{evap}	W_{elec}	Cost [€]			kWh/€	COP
	[$Wm^{-1}K^{-1}$]	[$Wm^{-2}K^{-1}$]	[MWh]	[MWh]	[MWh]	WWHEX	W_{elec}	Total		
Heating	0.46	149	486	374	126	1037	6388	7425	65.5	3.9
Cooling		143	26	23	3		152	1189	19.3	7.3
Heating	1.89	296	650	495	211		10698	11735	55.4	3.1
Cooling		290	30	27	4		203	1240	21.8	6.9

5. Conclusions

The feasibility of using locally the sewage network to deliver heat to buildings in the center of Rotterdam has been investigated. Polymer heat exchangers to be submerged along the sides and bottom of the sewage channel have been proposed in combination with a heat pump delivering heat at 55 °C. The following has been concluded:

- Using HDPE tubes 8.1 MWh/m_{sewage} heat at 55 °C can be delivered yearly. The system yearly averaged COP is then 3.9. To deliver 1 PJ of heat 34.3 km of sewage need to be equipped with such heat exchangers.
- Using thermally enhanced HDPE tubes 10.8 MWh/m_{sewage} heat at 55 °C can be delivered yearly. The system yearly averaged COP is then 3.1. To deliver 1 PJ of heat 25.7 km of sewage need to be equipped with such heat exchangers.
- The heat exchangers can be designed to deliver local heating requirements during the whole heating season.

Abstract

Seasonal thermal energy storage (STES) systems in combination with heat pumps can significantly reduce the impact of peak loads in large scale district heating systems and allow for the application of renewable heat sources in these networks. This paper investigates technologies with the highest potential for implementation in large scale district heating networks and identifies high temperature aquifer thermal energy storage (HT-ATES) as the most suitable technology. The HT-ATES has been applied at the primary side of the network (90 to 110 ºC) and at the secondary side (72 to 92 ºC). Suitable locations for the STES have then been identified. A control volume approach is used in Matlab to predict heat transfer and pressure drop in the HT-ATES wells considering porosity, permeability, grain size and geometry of the aquifer. The temperature distribution and extraction temperature are predicted as function of time. The yearly heating demand of a network has been used in combination with different operating modes to identify the required size of the HT-ATES. The simulations indicate that it will take 5 years to reach steady temperature supply.

Keywords: heat pump; high temperature aquifer energy storage; district heating.

1. Introduction

In the Netherlands, the built environment creates about 20% of the entire national energy demand. The heat consumption of the sector amounted 574 PJ in 2015 [12] and the majority of this heat is produced by gas-fired boilers. The national and international climate agreements together with policies concerning gas production in Groningen (the Netherlands) require substantial changes in the thermal energy supply of the built environment. A significant increase of the use of district heating networks (DHN) is one of the measures proposed to move away from gas-fired heating systems. Several studies predict that by 2050 a large share of the heating supply in the built environment will make use of DHNs. Hoogervorst [8] predicts a share of 57%, Roelofsen et al. [15] of 27% and Wielders et al. [27] of 61%.

Currently, most of the heat delivered by DHNs does not originate from renewable sources. Although DHNs are suitable to transport renewable energy, the thermal energy is currently mostly produced by fossil-fueled plants such as combined heat and power plants (CHP) and backup boilers (BUB). According to Schoots et al. [18], 75% of the thermal energy supplied by large scale DHNs in the Netherlands is based on fossil fuels. Renewable heat production units, such as solar heat, industrial waste and geothermal energy plants, need to be added to the thermal energy supply. The increasing variety of heat production units causes a decrease in flexibility of the heat supply. Waste heat from industrial processes does not fluctuate over the seasons but is determined by industrial activity. Solar thermal energy and energy from geothermal plants are determined by the amount of sun hours and limitation in pumping rates. For all heat sources, long operating times have a strong impact on the levelized cost of energy (LCOE). LCOE quantifies the cost of unit energy produced including the investment and operational costs of the system.

Seasonal thermal energy storage systems (STES) are able to store surplus heat. In winter, when the demand is higher than the supply, STES can function as an extra heat source. STES allows DHNs to operate in a sustainable and efficient way. In order to balance the heat demand and renewable heat supply at all times, thermal energy storage systems in DHNs seem inevitable. Fig. 1 shows the heat demand of the DHN of Utrecht in 2017 and 2018. The blue area shows the effect of STES on the required thermal energy production. In the summer the heat supply can be increased and the surplus heat (above the thermal energy demand curve) is stored.

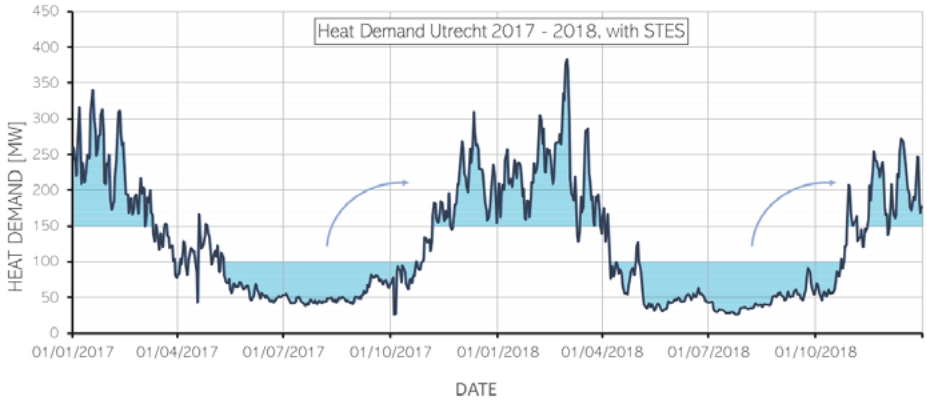

Fig. 1. Daily heat demand of the DHN of Utrecht in 2017 and 2018. The blue filled areas indicate the effect of STES on the installed capacity. In summer the heat production is increased so that the surplus can be stored to be used during winter as an extra heat source.

The transformation of a large scale mainly fossil-fueled DHN into a mainly renewable heat based system will generally reduce the flexibility of the DHN. Optimally sized STES can balance demand and supply of heat and to a certain extent provide flexibility to the DHN. The renewable heat sources can then always operate at optimal conditions while the surplus heat can be stored for later use.

The supply temperatures of most of the existing DHNs in the Netherlands is between 70 and 90 °C [27]. Low temperature DHNs, with supply temperatures <70 °C, perform thermally better since heat losses are lower [2]. While more heat sources become available when the DHN makes use of low temperatures, in the current built environment infrastructure high temperature DHNs can have a better economic performance. The existing infrastructure has been designed to deliver heat at high temperature and does not require end-user investments. Also, the high temperature DHN requires smaller distribution pipes leading to lower costs [26]. This study focuses on large scale (>2,000 consumers) high temperature supply (>70 °C) DHNs similar to the DHN of Utrecht.

The DHN of Utrecht is the third largest in the Netherlands [8]. It supplies thermal energy to more than 40,000 users. Presently the network is entirely supplied by fossil-fueled heat sources and needs to transition to renewable energy sources in the coming years. Internal scenarios from the owner, Eneco, indicate that seasonal storage is required from an economic perspective. The district heating network of Utrecht can be divided into two networks: the transport network and the distribution network. The transport network carries hot water generated at the heat source to the heat transfer station (HTS). The heat source and the HTS both have heat exchangers to transfer the heat from and towards the transport network. At the HTS the hot supply water transfers thermal energy to the distribution network. The colder water leaving the HTS is sent back to the heat source to be reheated. The supply temperature of the water is determined by the maximum thermal energy demand of the day [6]. This ensures a constant daily supply with an average lower supply temperature. As the heat demand is higher in the winter than in the summer, the temperature of the water in the transport network is higher in the winter to provide enough thermal energy. The DHN always needs to deliver safe and sufficient heat to the end-users. Safe means that the water temperature should always be high enough to prevent legionella to develop. These two characteristics determine the supply temperature of the DHN. The daily set-point is determined by a dedicated prediction software [5]. The BUBs can supply extra heat to the distribution network if the power from the source is insufficient. In the HTS the heat is transferred to the distribution network making use of heat exchangers. The distribution network's supply temperature is determined by the ambient temperature. The hot water exchanges heat at the end-user before it returns to the HTS. Fig. 2 shows left the relation between the delivered thermal power and the supply temperature in the transport network and right the relation between environmental temperature and supply temperature of the distribution network. The major heat sources are located in the transport network and consist of two CHP plants of 180 MW each and a BUB of 105 MW. Additionally a few BUBs are installed in the distribution network with capacities in the range 58 to 90 MW. Goal is to substitute these fossil-fuel driven heat sources by renewable heat sources. In the first phase mainly bio heat and green gas combustion systems will be implemented. In the second phase renewable heat sources without combustion will be implemented.

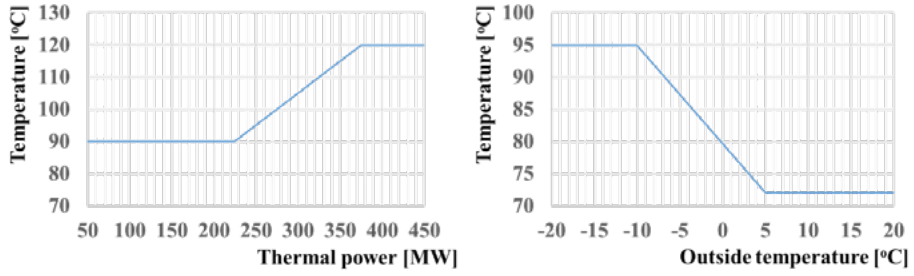

Fig. 2. Temperature levels of the supply water in the network: left in the transport network as a function of thermal power requirement and right in the distribution network as a function of the environmental temperature.

The International Energy Agency (IEA) gives an overview of previous high temperature storage systems [16]. Existing high temperature storage systems connected to district heating are predominantly located in the north of Europe. Wolfgramm [28] reports that in Neubrandenburg (Germany) a geothermal installation has been converted to a 4 MW high temperature aquifer thermal energy storage (HT-ATES) system. In the winter the system supplies heat to a low temperature district heating network. In the district heating of Braedstrup (Denmark) several pit thermal energy storage (PTES) and tank thermal energy storage (TTES) have been successfully implemented [20-21]. Several caverns are under construction to store 120 MW of hot water of the DH of Helsinki [23]. The Drake Landing project (Canada) provides almost the entire heat demand of a district by combining solar thermal heat with thermal storage [19]. The European project HeatStore plans to demonstrate underground thermal energy storage in five different countries [10].

The objective of this paper is to investigate the technical feasibility of the implementation of a seasonal heat storage system in an existing large scale DHN. The approach followed is schematically illustrated in Fig. 3. First the most suitable technology is identified, then suitable geographical locations are determined. A model for an HT-ATES system combined with a heat pump to load and unload the storage is developed in Matlab. The performance of the storage system in combination with the load profile of the DHN of Utrecht is then predicted and analysed.

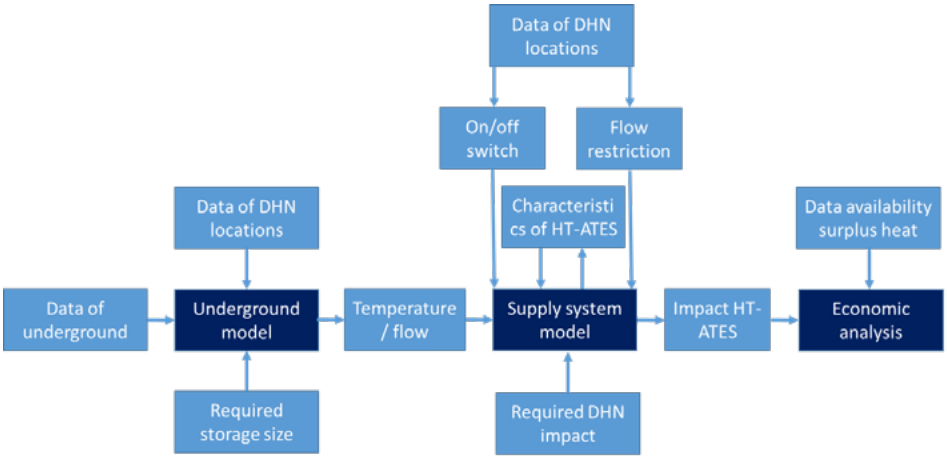

Fig. 3. Schematic of the approach used. A model was first developed for an HT-ATES taking the underground data for the different possible locations and the required storage size into account. This model allows for the prediction of inlet or outlet well temperatures and flow as a function of time. Then a supply system model including a heat exchanger and a heat pump was developed which is coupled to the HT-ATES model and allows for the prediction of the storage conditions as a function of time. Finally these results were used to estimate the economic performance of the storage facility.

2. Seasonal thermal energy storage (STES) systems

Three different groups of storage can be adopted for thermal energy storage (TES): sensible heat storage, latent heat storage and thermochemical heat storage. Fig. 4 (left) illustrates the three groups with corresponding storage capacities and temperature range [17].

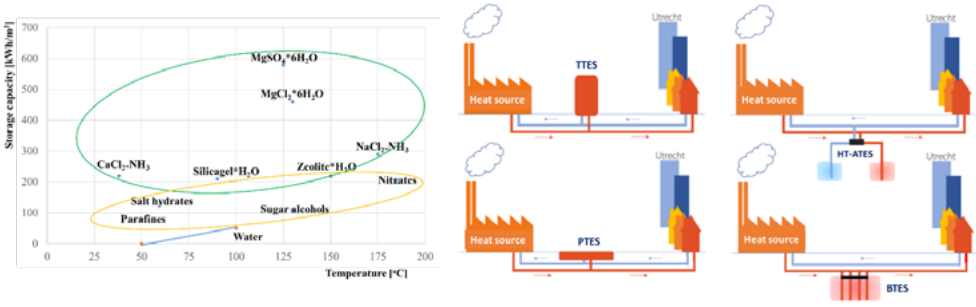

Fig. 4. Left the three groups of TES with sensible heat in blue, latent heat in yellow and thermochemical in green showing that latent heat storage can be twice compacter and thermochemical heat storage up to 7 times compacter. Right the four promising STES systems for district heating integration.

Sensible heat storage is the simplest to apply. The stored amount of energy is obtained with eq. (1).

$$Q = m \cdot c_p \cdot \Delta T \tag{1}$$

Where m is the mass of storage medium (frequently water), c_p its specific heat and ΔT the temperature difference between initial and final temperature of the storage medium. The most frequently used methods of storage of sensible heat are illustrated in Fig. 4 (right): tank thermal energy storage (TTES), pit thermal energy storage (PTES), high temperature aquifer thermal energy storage (HT-ATES) and borehole thermal energy storage (BTES). The optimal STES system stores heat at low cost and high efficiency and can be implemented in dense urban areas without too many constraints.

The bigger the storage volume, the smaller the relative area through which heat losses can take place. Increasing the size generally increases the construction costs. Especially for TTES and PTES the costs increase significantly. The increasing costs for HT-ATES are however smaller as the subsurface itself functions as the insulating material. Fig. 5 shows that the costs reduce with increasing storage volume [11].

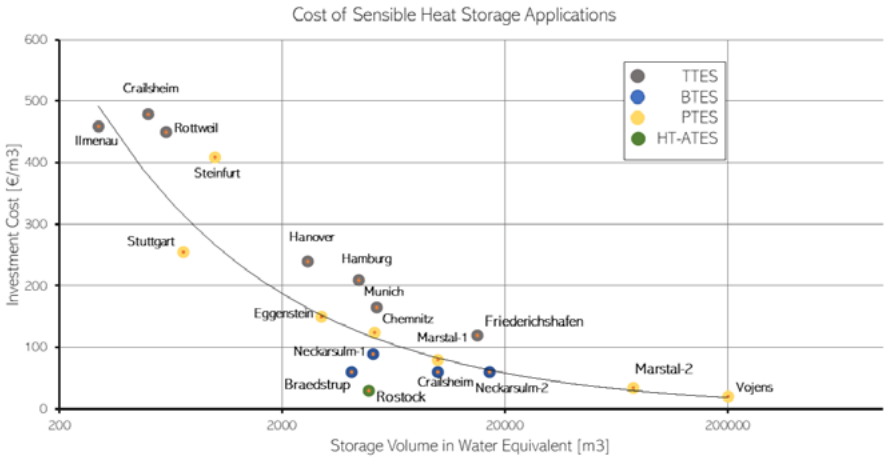

Fig. 5. Relation between specific investment costs and volume of TES based on existing plants in Denmark and Germany [11].

The largest TES, the PTES of Vojens, has a volume of 200,000 m^3 and supplies heat to 2,000 consumers [24]. According to the Danish Energy Agency [3] the costs of this plant are 113 €/GJ. The larger the STES systems, the more economic attractive the systems become. According to de Wit-Blok [7] TTES is expected to have the highest large scale investment costs (139 €/GJ) while HT-ATES is expected to have the lowest costs (14 €/GJ).

Latent heat storage uses the phase change energy of a material to store heat. The melting enthalpy is significantly larger than the sensible change of enthalpy so that the same amount of energy can be stored in a much smaller volume, see Fig. 4 (left). Additional advantage is that the phase change takes place at almost isothermal conditions which depend on the material and can be selected in the temperature range of the DHN (50 ºC to 150 ºC). The most important drawback of latent heat storage is its costs which are currently significantly higher than for sensible heat storage. According to the IEA [9] the costs are 2,778 €/GJ and need to reduce significantly before latent heat storage becomes competitive. A reduction of at least 50% is required for applications in DHNs [22].

Thermochemical energy storage uses chemical energy preserved in the bonds of molecules to store heat [13]. The energy added to the system is used to dissociate a material into other components [1]. Thermochemical storage systems have very high energy densities, see Fig. 4 (left), and are optimal for dense urban areas. Yu et al. [29] claim that storage volumes can be up to 30 times smaller than for sensible heat storage systems and the IEA [9] claims that theoretically storage efficiencies of 100% can be attained. The challenges of applying this storage system for large DHNs are the low technical readiness level and the system costs. The lowest reported potential cost is 2,222 €/GJ [9]. Remmelts [14] has compared the largest PTES storage in Vojens (200,000 m^3) assuming a storage efficiency of 60% for the sensible PTES and a storage efficiency of 100% for the thermochemical storage. The storage costs for Vojens are 113 €/GJ while the costs for the thermochemical storage are 2,222 €/GJ or 1,111 €/GJ, assuming a 50% cost reduction. As the cost of heat increases, a storage technique with a higher storage efficiency (thermochemical) will have a faster increasing economic potential. However, assuming a relatively high cost of heat (the current consumer market price of 24 €/GJ), the total yearly costs of the thermochemical storage are still 2.3 and 1.4 times higher than for the PTES.

From the previous discussion it becomes clear that presently sensible heat storage seems to be the most competitive STES and, taking into account the required size of the DHN storage, the HT-ATES solution seems the most appropriate. It occupies the least surface area of all the sensible heat storage solutions. Presently, in

the Netherlands, subsurface regulations only allow pilot high temperature storage projects and allowance for commercial projects is being investigated.

The HT-ATES can be installed in the transport network (centralized) or at several locations of the distribution network. This is illustrated in Fig. 6. The largest difference between the two locations is that the centralized location affects all distribution networks while the decentralized affects only the respective distribution network. The centralized location requires higher supply temperatures then the decentralized locations.

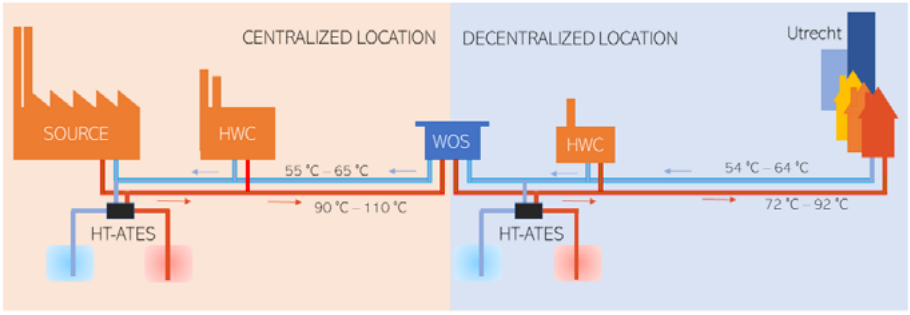

Fig. 6. Possible locations for the HT-ATES STES. At the surface, heat pumps bring the guarantee that heat can be delivered to the network (discharging phase) or to the heat storage (charging phase).

ATES system should not interfere with drinking water or other protected sub-ground areas so that those areas are excluded as possible HT-ATES locations. To prevent conflicts with protected areas the usable aquifers are more than 150 m below the surface. Below 500 m under the surface the mining law applies and the installation costs of the wells increase so that the usable aquifers must be above this level. HT-ATES systems consist of at least three layers: two confining impermeable layers and a permeable aquifer. The confining layers function as an insulator for the stored heat. The heat is stored in the aquifer layer which consist of water and sand. In the subsurface of Utrecht the impermeable and aquifer layers are stacked alternatively.

Remmelts [14] has identified suitable underground layers. These aquifers have suitable permeabilities in the range 5 m/day and 20 m/day [4]. The ground water flow is 3.5 m/year so that it will hardly affect the heat recovery of the storage.

3. Modelling of STES system

3.1. Underground thermal performance model

The thermal performance of an aquifer can be evaluated by determining its thermal recovery efficiency. This efficiency gives the ratio of extracted and injected thermal energy, see eq. (2). The non-recovered heat is the heat loss of the aquifer. This heat loss results in a higher efficiency for the next cycle.

$$\eta_{th} = \frac{T_{out,ave} \cdot V_{out}}{T_{in,ave} \cdot V_{in}} \tag{2}$$

Where T_{ave} is the average temperature during the charging or discharging period. The thermal recovery depends on the heat transport phenomena in the aquifer and impermeable layers (aquitards). Fig. 7 (left) illustrates the forms of heat transfer that have been taken into account.

The right hand side of Fig. 7 shows how the energy conservation equations have been locally used to determine the temperature. Further details of the underground model can be found in Remmelts [14]. Fig. 8 illustrates the results obtained with the underground model.

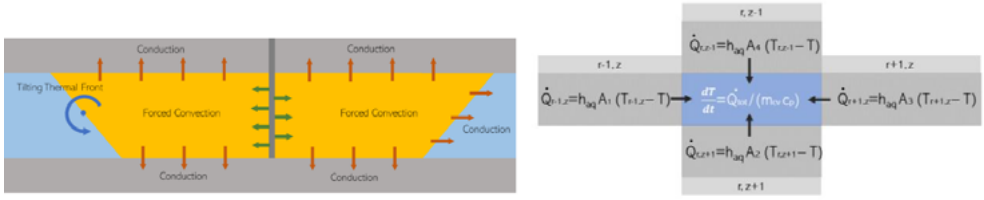

Fig. 7. Heat transfer phenomena considered in the modelling of the aquifer: convection, conduction and tilting of the thermal front. The vertical line indicates the position of the well while the yellow area represents the hot water stored in the aquifer. Right the control volume approach to determine the local temperatures in the aquifer.

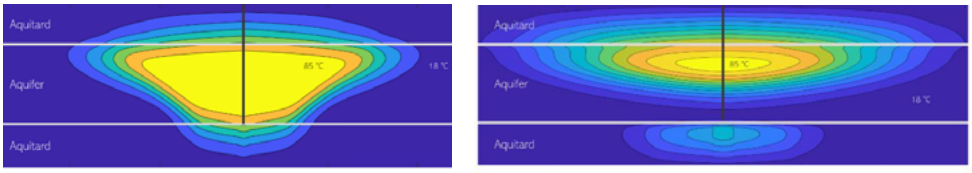

Fig. 8. Typical temperature profiles predicted by the underground model. Left at the end of the injection stage (charging) and right at the end of the extraction stage (discharging). An aquitard is an impermeable layer.

3.2. HT-ATES size

The heat available for storage originates from heat that otherwise would be wasted and from heat produced by increasing the base load of the heat sources of the DHN during the summer. Goal is to size the HT-ATES to deliver 400,000 GJ/year. The HT-ATES should be able to deliver heat for a period of 120 days with a maximum power output of 50 MW and an average of 38 MW. It is expected that there will be approximately 185 days charging time, 30 days buffer time, 120 days extraction time and again 30 days buffer time, depending on the thermal energy demand. The desired size of the HT-ATES is given by eq. (3).

$$V_{sto} = \frac{E}{\rho_w \cdot c_p \cdot (T_{well,hot} - T_{well,cold})} \approx \frac{400{,}000{,}000{,}000}{983 \cdot 4.185 \cdot (73 - 18)} = 1{,}767{,}862 m^3 \quad (3)$$

The hot well is charged with water at 85 °C but its temperature drops to 55 °C during the discharging period. The HT-ATES has been designed with a storage volume of 1,300,000 m^3 since the compressor of the heat pump delivers part of the required heating capacity. The volume extracted from the hot well should be equal to the injected volume. Otherwise the recovery efficiency for the next cycle will be lower. Also the discharging must be limited to a maximum of 180 days so that there is enough time left to recharge the HT-ATES.

The maximum allowable flow velocity in an aquifer so that the well filter does not get blocked determines its total capacity [25]. This implies that several wells are required for the required size of the storage.

3.3. Connection to DHN

The water from the HT-ATES system cannot be directly used in the DHN. It has a different chemistry than the DHN water and it must be pumped back into the same ground layer. In order to transfer the heat from the HT-ATES to the DHN a heat exchanger and a heat pump are used. Due to the large temperature difference between cold and hot wells, a heat exchanger is not sufficient. To return the flow at the desired temperature a heat pump must be used. For each doublet (pair of cold and hot wells) a pump is required to overcome the pressure difference between both wells. Fig. 9 illustrates the system connections for a decentralized supply system.

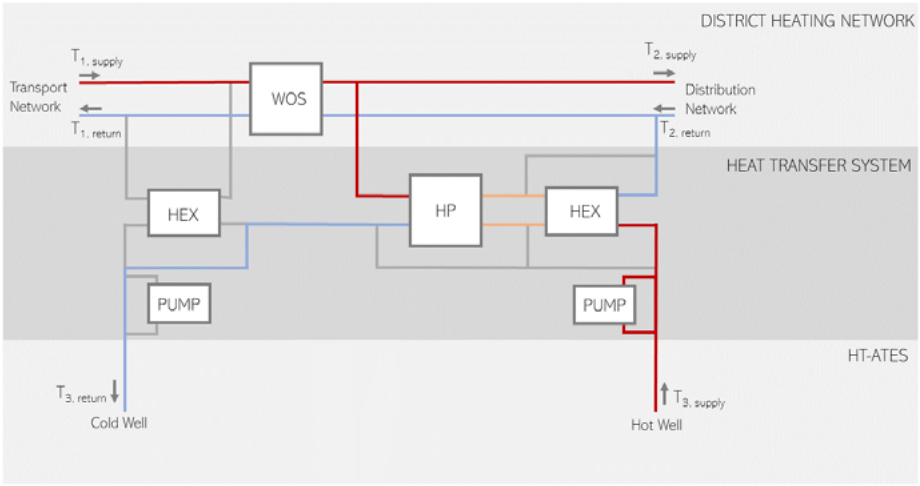

Fig. 9. Schematic of decentralized heat transfer system. The HT-ATES is operating in the beginning of the winter so that both heat exchanger (HEX) and heat pump (HP) are in operation. In red the hot water streams, in blue the cold water streams and in grey the inactive lines.

The electrical power consumed by the well pump is obtained from the extraction volume flow rate and the total pressure difference that the pump has to overcome. This pressure drop consists of the pressure drop in HEX and HP, the pressure drop between the doublet, the pressure drop in the vertical wells and the pressure drop in the transportation lines. A pump efficiency of 74% and an electric efficiency of the electric motor drive of 88% are further assumed. For the heat exchangers, the minimum temperature difference between the hot inlet and the outlet is assumed to be 5 K. If the temperature of the extracted flow becomes too low for the heat exchanger, the flow is guided through a by-pass directly to the heat pump.

Butane (R600) has been selected as the working fluid of the heat pump. An isentropic efficiency of 70% has been assumed for the compressor of the heat pump. The heat rejection from the heat pump takes place in three steps: de-superheating, condensation and sub-cooling. The condensation takes place at a 3 K higher temperature than the supply temperature to the DHN. Also at the sub-cooling side, the condenser outlet temperature is 3 K higher than the water returning from the DHN. Table 1 gives the design conditions of the heat pump and its corresponding COP.

Table 1. Design operating temperatures of heat exchanger and heat pump.

	$T_{source,out}$ [°C]	$T_{source,in}$ [°C]	$T_{sink,in}$ [°C]	$T_{sink,out}$ [°C]	$T_{condensation}$ [°C]	$T_{evaporation}$ [°C]	*COP*
Decentralized	18	60	60	76	75	15	3.99
Centralized	18	60	62	105	98	15	3.27

3.4. Heat load in DHN

The daily thermal energy demand data of the DHN and the corresponding supply and return temperatures have been linked to the thermal model of HT-ATES side of the system. The switching point for the discharging of the HT-ATES follows from the required thermal energy of the DHN. The ATES model predicts the time dependent extraction temperature. As discussed in section 1, the supply temperature of the DHN follows from its operating conditions so that the temperature delivered by the heat pump is also time dependent. The injection temperature into the cold well is fixed at 18 °C so that the evaporating temperature of the heat pump is also fixed. The extraction temperature and the temperature of the return flow from the DHN determine if the bypass of the heat exchanger is activated.

4. Results

4.1. Performance of ATES

The properties of aquifers at different locations in the area covered by the DHN of Utrecht have been used to determine the corresponding recovery efficiency. Charging and discharging cycles as discussed in section 3.2 have been applied for a total of 15 cycles for each of the possible locations. The most promise ATES in a decentralized network area had a recovery efficiency of 80% at the end of the 15th cycle and in the centralized area of 77%.

During the first years of operation the aquifers have a lower recovery efficiency because the soil needs to heat up. Fig. 10 shows the temperature of the water injected into the hot well / extracted from the hot well as a function of time for a period of 15 years. The extracted temperature at the end of the discharging period increases every year. The constant parts of the temperature line correspond to the injection period at constant temperature (85 ºC).

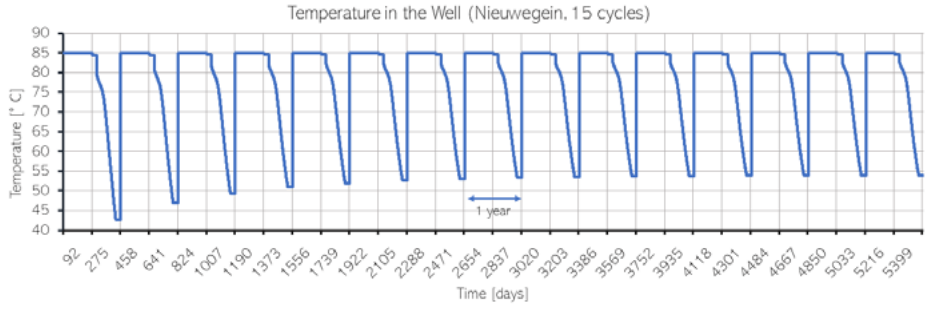

Fig. 10. Change of the extraction temperature from the HT-ATES during a period of 15 years.

4.2. Performance of STES in combination with the DHN

The locations with best performing aquifers have been tested to determine its potential for three different operating strategies:

- "Peak shaving" where the peak thermal energy demand during the winter is supplied from the HT-ATES;
- "Winter base load" where a constant base load is delivered by the HT-ATES during the winter season;
- "Total winter coverage" where the entire winter thermal energy demand is supplied by the HT-ATES.

Fig. 11 (top) shows the results of the three operating strategies for a decentralized district of the DHN with local thermal energy demand that is close to the size of the HT-ATES (1,300,000 m^3 storage). It is clear that the "total winter coverage" can nicely fit the demand of this district. Part of the storage capacity would remain unused if the "peak shaving" and "winter base load" strategies would be applied. Fig. 11 (bottom) shows that for the transport network side (centralized) of the DHN the "total winter coverage" strategy would lead to a very short operating period. Both the "peak shaving" and "winter base load" strategies could be applied at central level. However the "peak shaving" option leads to very high mass flow fluctuations in both HT-ATES and DHN sides. Such operation may lead to problems in the wells and should be prevented. For this reason the "winter base load" strategy would be the preferred one for the centralized storage. In both applications, at the end of the discharging period, the mass flow from the HT-ATES increases to provide the desired thermal power as the temperature of the extracted water decreases.

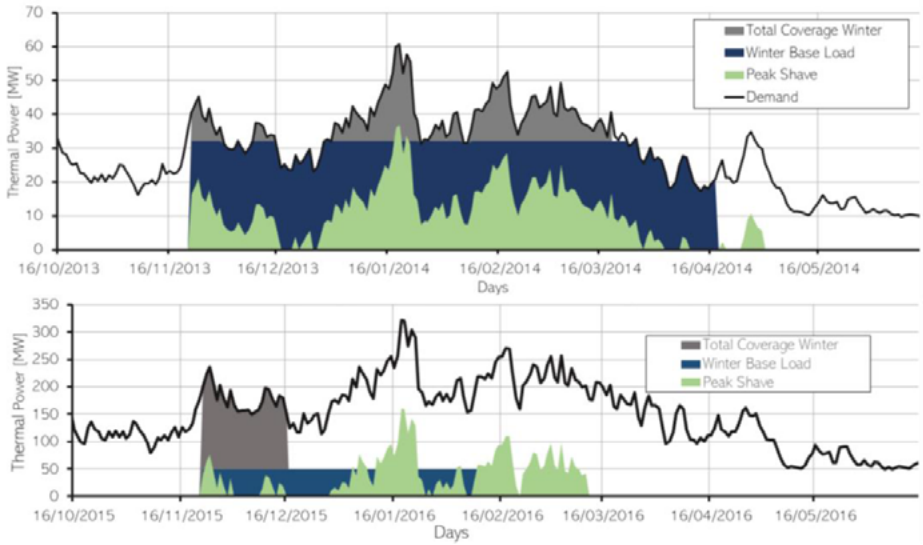

Fig. 11. Supplied thermal energy during the winter of 2015-2016 making use of an HT-ATES with 1,300,000 m^3 storage volume making use of different strategies: "peak shaving" (green), "winter base load" (blue) and "total winter coverage" (grey). Top: decentral location; Bottom: central location.

Fig. 12 shows the contribution of the heat exchanger (blue) and of the heat pump (green) during the discharging period of the winter of 2013 – 2014. Left the results for the decentral application and right for the central application. Due to the higher temperature required at the transport side, the contribution of the heat exchanger is smaller for the centralized solution. The heat exchanger can only deliver a small share of the total delivered heat. Without a heat pump the system would not be feasible.

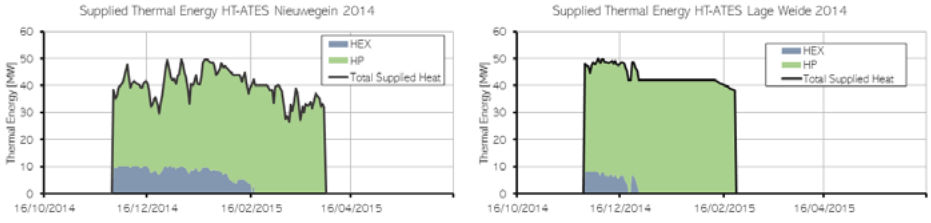

Fig. 12. Contribution of heat pump and heat exchanger to the total supplied heat to the DHN. Left: decentral location; Right: central location.

5. Conclusions

This study confirms that it is technically feasible to implement a seasonal thermal energy storage system in an existing large scale district heating network. Both application at the transport side (centralized) and distribution side (decentralized) result in solutions with comparable advantages for the whole DHN.

- The storage volume of the HT-ATES should be selected taking the local energy demand and the availability of surplus heat into account.
- The maximum thermal power should be selected in agreement with the storage volume available.
- The heat pump plays a major role in the feasibility of the concept. Just using a heat exchanger would significantly limit the energy that can be recovered from the storage.

Abstract

A comparative study for a representative case district in the Netherlands with around 2500 dwellings has been executed with the purpose of identifying the best solution for a Low Temperature District Heating (LTDH) with Low Temperature Geothermal Heat (LTGH) as the main heat source. The district is presently connected to the Dutch gas network. Its heat demand and building typologies are used as departing points. The comparison is based on 3 key performances indicators (KPI's): CO_2 emissions, levelized costs of energy (LCOE) and peak electricity use. The following LTDH designs have been considered: Central heat pump and collective peak supply at 70 ºC / 50 ºC; Central heat pump and decentral peak supply at 70 ºC / 50 ºC; Decentralized heat pumps using 30 ºC supply temperature. Individual air source heat pumps for space heating and electric boilers for domestic hot water purposes are taken as reference. The LTDH concept with decentralized heat pumps saves 19.5 %, 16.8 % and 36 % on the CO_2 emission, LCOE, and electricity use in peak load hours compared to the reference concept.

Keywords: heat pump; low temperature district heating;low temperature geothermal heat source;

1. Introduction

In 2015, 34% of the total energy use in the Netherlands originated from the built environment. 70% of the energy use in this sector was for heating dwellings, cooking food and the preparation of hot water, while the remaining was for electricity use [15]. With the current climate developments, earthquakes as a result of natural gas extraction in the northern parts of the Netherlands and a transition in public thinking towards making the world more sustainable, an investigation of alternative ways of supplying heat to Dutch dwellings has become increasingly relevant.

According to Kremer et al. [15], in 2015, 78% of the total heating requirement originated from natural gas combustion. In Dutch households, 219 PJ of natural gas was used for heating homes, 60 PJ was used for domestic hot water supply, and 6 PJ for cooking. The Dutch government aims to disconnect Dutch houses from the existing gas distribution network by 2050, and wants to stop natural gas extraction in Groningen by 2022. New solutions are required on short term to deliver the heating requirements. District heating systems, together with heat pumps, are the most commonly suggested solution for replacing the natural gas distribution network in the densely populated urban areas of the Netherlands. Low Temperature District Heating (LTDH) is one of the proposed solutions which is claimed to have high efficiency and to be easy to connect to sustainable heating sources [18].

Several researchers have investigated the feasibility of the implementation of LTDH in the Netherlands [25, 30, 31]. The results seem promising but the proposed solutions are not capable of delivering the peak duty during cold periods. European studies [18, 21, 23] have however concluded that LTDH would provide a sustainable way of supplying heat to dwellings. Most houses in the Netherlands are equipped with radiators designed for high temperature heat delivery which limit the use of low temperature heating systems. According to Østergaard [20], in Denmark, such radiators are oversized and can still be used in LTDH. This, however, still needs to be confirmed to apply for the Dutch situation.

This study investigates how a low temperature (30 ºC) geothermal source (originating from aquifers in the drilling range between 500 to 1250 m below ground level) can best be used for heating purposes in urban areas by considering a specific area in the Netherlands. The use of such geothermal heat sources for heating of greenhouses has recently been reported by Schepers et al. [25].

Geothermal installations consist of two wells, a production well and an injection well. Hot water is extracted from an aquifer at elevated temperature by the production well. The hot water is pumped from the production well to a heat exchanger (HEX), which may be part of a heat pump, at surface level. The HEX, eventually after temperature upgrading by a heat pump, transfers the heat to a secondary water network. The cooled production water is pumped back into the aquifer via the injection well. The amount of heat, which is extracted by the installation, depends on the mass flow of the ground water and the temperature difference across the HEX. The temperature of the water extracted depends on the depth of the aquifer. Water with a higher temperature is extracted at deeper reservoirs [2]. The mass flow through the HEX is determined by the pump in the production well. An important part of the geothermal installation are the filters in the geothermal reservoirs. The filters remove solids out of the water in order to protect the heat exchanger and the wells of the geothermal plant. The well pump must run between a minimal flow and maximum flow. If the flow rate is too low, the reservoir becomes clogged. If the flow rate is too high, the filter installation will be damaged [13]. The heat production from geothermal sources is therefore poorly adjustable and cannot be adjusted to large fluctuations of the heat demand. For this reason, geothermal systems cover generally a base load and the peak demands need to be supplied by other sources [10].

District heating systems (DHS) are networks which collect heat from producers and provide heat for the collective heating demand of buildings and industry. DHS can be divided in High Temperature (HT), with supply temperature > 70 , Medium Temperature (MT, [45 - 70 ºC]) and Low Temperature (LT), with supply temperature below 45 ºC, networks [17, 21].

A distinction is made between space heating demand and domestic hot water heating (DHW) demand. Heat gains and losses inside a building depend on transmission, ventilation & infiltration, internal gains and solar gains [29]. DHW is needed for the bathroom and for cooking purposes. The sum of these two demands for the whole neighborhood is the heat demand of the district.

Lundström & Wallin [19] have shown that the peak heat demand of a district is mainly caused by the space heat demand in the winter, provided that a boiler is used for DHW storage and peak shaving. In the summer,

the peak heat demand is caused by the DHW use. In 2016, the Biesdonk district of Breda (the Netherlands), with 1650 homes, consumed 14813 MWh for heating purposes and 3451 MWh for DHW [31]. When designing a DHS making use of data for a single dwelling, the heat demand of the DHS can be estimated by multiplying these data with the number of dwellings in a district making use of the corresponding simultaneity factor. The heat demand determines the type and size of the pipes [19]. Because LTDH use low supply temperature, the temperature difference between the supply and return pipe is small. To supply the same amount of heat through an LTDH instead of a HTDH, the diameters should be larger. If the peak heat requirement is supplied through the pipe network, the diameters of the pipes need to take the peak load conditions into account. If only the basis heating demand goes through the pipe network and the peak heat demand is produced near the dwellings, the diameters of the pipes can become smaller [19]. Another limitation is the supply of DHW. In the Netherlands DHW should be delivered at least at 60 °C, otherwise legionella can possibly develop in the water. For LTDH this is difficult to realize, so a need for post-heating is required. Post-heating can be done with a Booster Heat Pump (BHP) or an electric heating element. If the DHS water enters the house with 60 °C or higher, only a heat exchanger (HEX) is needed.

The heating needs differ on daily base and on seasonal base. Peak demands occur in the morning and evening on a daily base. Residents wake up in the morning and prepare to start their day. During the day, fewer people are present in a neighborhood, resulting in a lower heat demand. Most of the residents come back to their homes in the evening increasing the heat use. On a daily base, the peaks depend mainly on when the residents are at home. Occupancy level of people can be estimated using Ahmed et al. [3]. Seasonal peaks are different. These are based on the weather. In the winter, when the temperature is lower, heat demand is higher than in the summer.

According to Rezaie & Rosen [22], an DHS can be divided into three subsystems: heat production, heat transportation and heat consumption. The heating system for a neighborhood can be done collectively or decentralized [22]. The difference is the location of the heat source. In a collective heating system, the heat is produced far from the location of the end-users and it produces heat for the whole district and distributes the heat via a large distribution network. A decentral heating system produces heat close to the end-user and has a smaller or no distribution network. The same applies for storage methods. Collective storage is located far from the end-user and decentral storage is located close to the end-user. Collective storage depends on the seasonal heat demand and decentral storage depends on hourly demand [4]. In general, it can be said that decentral heating systems become more relevant for low density neighborhoods and collective heating is relevant for high density neighborhoods.

According to Alva et al. [4] and Lund et al. [18], the aquifer thermal energy storage (ATES) and hot water tank storage are currently the most suitable storage methods for an LTDH, because these systems have low installation costs and are more frequently applied than other technologies. ATES is a technology which is used for seasonal storage. Heat is extracted from the ATES during the winter and heat is injected during the summer. ATES works as follows. An ATES consists of two wells (a doublet) or multiple doublets. Groundwater from the cold well is injected at increased temperature in the warm well, when there is an excess heat production from the LTGH. In winter, when the warm well is charged, heat from the warm well is transferred to the grid and cooled groundwater is injected in the cold well. The recovery efficiency of an ATES is defined as the amount of injected thermal energy that is recovered after the injected volume has been extracted [5]. The recovery efficiency increases when the storage temperatures of the DHS decrease. The heat loss that occurs is due to displacement by groundwater flow and by dispersion and conduction.

To investigate which LTDH design can supply the peak demand most efficiently and sustainably, the following KPIs have been considered.

- CO_2 emission: the CO_2 emission of the system should be as low as possible.
- Levelized cost of energy (LCOE): the costs of produced kWh of heat should be as low as possible.
- Electricity use: Electricity use should be as low as possible to prevent overloading of the electricity net.
- Availability: the supply (including stored heat) should always meet the demand.

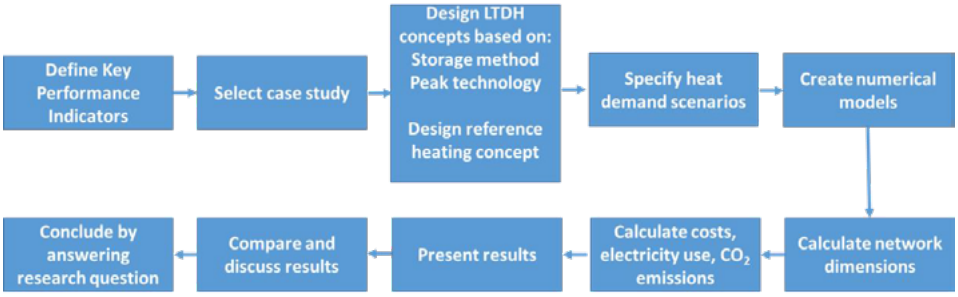

Fig. 1. Methodology used in the present study.

As illustrated in Fig. 1, this study starts with the definition of the key performance indicators (KPI) used for the evaluation of the different LTDH systems, the definition of the types of housing in the urban area considered and the quantification of the related heating requirements in these buildings. The alternative network designs considered for the LTDH network are created. The typology of the considered district allows for the determination of the required distribution line lengths and sizes. Numerical models are introduced to quantify the yearly energy requirements of the different options. Finally, the predicted electricity use, costs and CO_2 emission of the different network designs are compared to identify the most suitable solution.

2. Case study and LTDH designs

2.1. District heating location and heating requirement

Biesdonk, a district of Breda dating from the 1970's, has been selected for the present case study. In 2015, Biesdonk had 4995 residents and 2230 dwellings. The heat demands of 650 terraced houses and 1000 apartments are known. The terraced houses are low-rise buildings. Other buildings, such as shopping centers, schools, and churches are also present in the area. Heat demands for those buildings are not known and are outside the scope of this study. A map of Biesdonk and its heating demand are presented in Fig. 2. In the figure the space heating is given by the blue line and the water heating consumption by the red line.

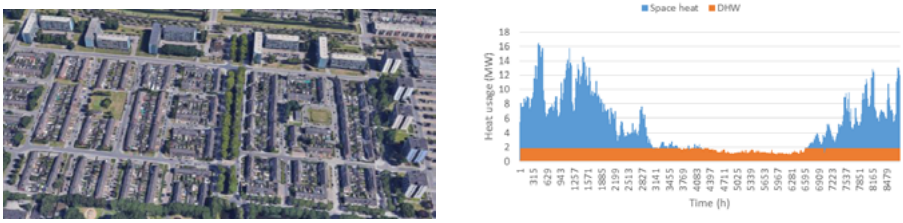

Fig. 2. District Biesdonk in Breda selected for implementation of the LTDH designs (left) and heating requirement for 650 terraced houses and 1000 apartments in 2016 (right).

2.2. Network designs

The LTGH source considered in this study is located in an aquifer 750 m below surface level and delivers 150 m^3/h (41.7 kg/s) in the heating season and 90 m^3/h in the summer of ground water with a constant temperature of 30 °C. This flow can be directly delivered to the district network making use of a heat exchanger at the well head or can be directly upgraded with a heat pump at the well head and delivered to the network at higher temperature.

Since the flow delivered by the LTGH source is continuous throughout the year, a heat storage facility is required which could be an aquifer closer to the surface maintained at the temperature level of the distribution system. This aquifer serves then the whole district and can cover the season peak needs. Alternatively, a hot water tank can be used on a decentral level to cover the daily peak heating needs. Additionally, the network

requires an auxiliary boiler to cover peak loads which cannot be covered by the storage facilities. This boiler can be installed at collective level or decentral at user level.

The return temperature for the designs which use central heat pumps is 32 ºC. Existing radiators can create a return temperature of 30 ºC, but the return water will be increased by 2 ºC due to losses in the supply set at home level [20]. If the ATES provides cold water to the return pipes, the temperature will increase as well. The return temperature for the designs without central heat pumps is 18 ºC. This can be achieved by the decentral heat pumps [30].

Table 1 gives an overview of the considered network designs.

Table 1. Evaluated designs of the network with individual air source heat pumps as alternative to the network (design 6).

Design	LTDH supply temperature	Collective storage	Decentral storage	Collective peak	Decentral Peak	DHW heating
1 – HT boiler	70 ºC	ATES	none	boiler	None	HEX
2 – HT elect.	70 ºC	ATES	water tank	none	electrical	HEX
3 – MT boiler	50 ºC	ATES	none	boiler	None	booster HP
4 – MT elec.	50 ºC	ATES	water tank	none	electrical	booster HP
5 – LT HP	30 ºC	ATES	none	none	HP	HP
6 – air HP	none	none	none	none	HP	HP

Fig. 3 gives a schematic representation of design 1 which consists of a central heat pump that upgrades the heat from the geothermal source to 70 ºC, an aquifer that collects the excess heat available from the network to deliver it when needed, a (biomass) boiler to cover the collective peak requirement and a HEX to deliver the individual DHW needs.

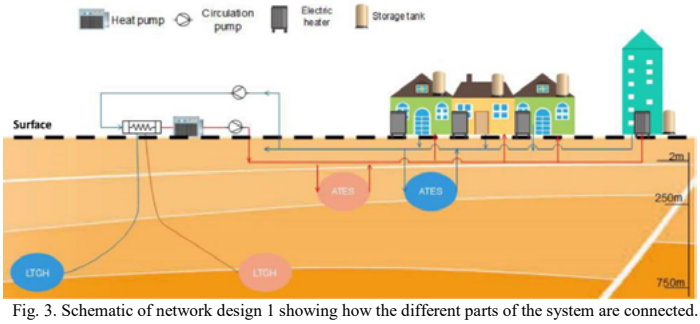

Fig. 3. Schematic of network design 1 showing how the different parts of the system are connected.

Fig. 4 is a simplified flow diagram of the network illustrating the log-mean temperature differences (LMTD) during heat exchange in the different parts of the system.

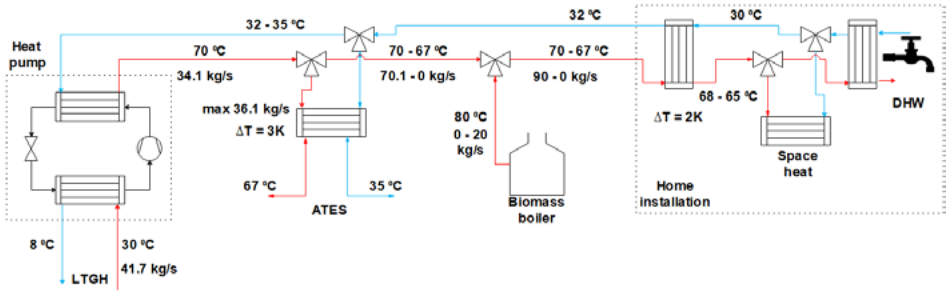

Fig. 4. Flow diagram of network design 1 showing flows and corresponding temperature levels. The supply line is given in red while the return line is printed in blue. The mass flow to / from the aquifer is limited to 130 m^3/h [9, 27].

3. Matching energy demands to energy availability

3.1. Network sizing

The heat supplied by the LTGH source can be obtained with eq. (1) where the temperature of the production well is constant at 30 °C and the injection temperature depends on the network design. The volume flow of the geothermal well is 150 m³/h (41.7 kg/s) in the heating season and 90 m³/h (25 kg/s) in the summer period.

$$\dot{Q}_{LTGH} = \dot{m}_{LTGH} \cdot c_{p_LTGH} \cdot (T_{well} - T_{injection}) \quad (1)$$

When a heat pump is used, the heat supplied to the network is enlarged as given in eq. (2) with *COP* the performance of the heat pump.

$$\dot{Q}_{LTDH_HP} = \frac{COP \cdot \dot{Q}_{LTGH}}{COP - 1} \quad (2)$$

The mass flow through the LTDH follows then from eq. (3).

$$\dot{m}_{LTDH} = \frac{\dot{Q}_{LTDH_HP}}{c_{p_LTDH} \cdot (T_{supply} - T_{return})} \quad (3)$$

The type of network material and size is determined by the heating demand per pipe line. First a network is created. The approach is based on Frederiksen & Werner [12]. The LTGH is located in the center of the district, since in this way the distances between the heat supply plant and each substation are as short as possible and therefore heat losses are smallest. For the district Biesdonk, the LTGH can be located in a small park. The network is divided into 4 sectors; A in north-west (with 360 apartments and 150 terraced houses), B in north-east (with 240 apartments and 200 terraced houses), C in south-west (with 300 terraced houses), and D in south-east (with 320 apartments and 100 terraced houses). According to Verhaegh [31], in 2016 sector A had a heating requirement of 5355 MWh, B of 6358 MWh, C of 3293 MWh and D of 4200 MWh. Pipes leaving the LTGH station are large and decrease step by step to small pipes as the network approaches the individual users. The heat transported through the pipes depends on the number of homes in a street. The heat demand is calculated for the worst case scenario. If the flow velocity exceeds 3 m/s or the pressure drop exceeds 400 Pa/m diameter adjustments need to be done. The Wanda software of Deltares [8] is then used to develop the physical infrastructure for the heat distribution network including pipe diameters and circulating pump selection. Fig. 5 illustrates the approach.

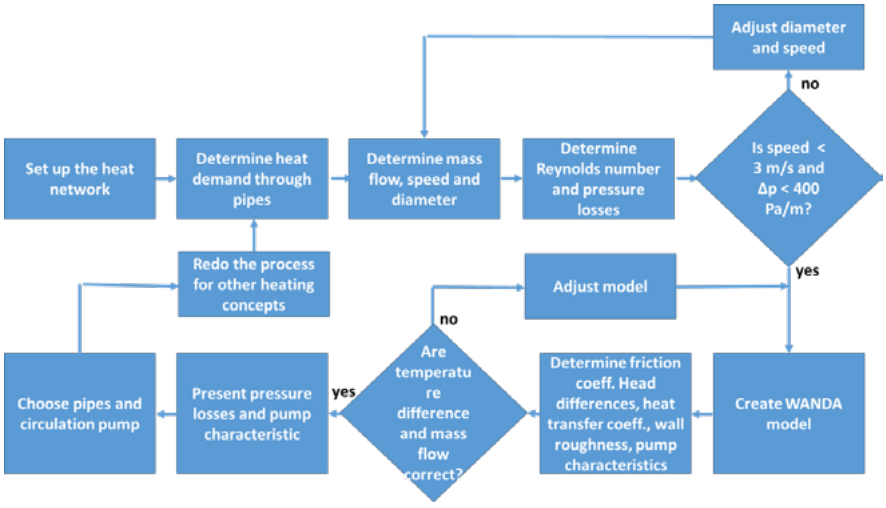

Fig. 5. Flow chart of the network sizing making use of the software Wanda of Deltares (2019).

3.2. Energy balance

Since the LTGH source delivers a fixed amount of energy, a yearly energy balance is obtained by varying the number of users connected to the network and so changing $\dot{Q}_{demand}$ in eq. (4).

$$\dot{Q}_{demand} + \dot{Q}_{loss} = \dot{Q}_{LTGH} + \dot{Q}_{peak_supply} \tag{4}$$

where the losses result from losses in the aquifers, in the network pipe lines and in the heat exchangers. The heat losses from the aquifer have been considered by assuming storage temperature dependent recovery efficiencies as proposed by de Wit-Blok [7]. The ATES at HT (67 ºC, designs 1-2) is assumed to have a heat recovery of 65%, at MT (47 ºC, design 3-4) of 75% and at LT (27 ºC, design 5) of 85%. The pipe lines losses have been adapted from Thermaflex [28], a company specialized in the manufacturing of insulated tubes for LTDH networks. The losses depend mainly on tube size and temperature level of the network and vary from a factor larger than 3 for 70 ºC in comparison to 30 ºC for the smaller inner diameters (14.4 mm) to a factor 2 for the larger tubes (138 mm). The losses from heat exchangers are generally small and have been determined by estimating its *UA* values from external surface to environment and the temperature difference to the environment. The heat exchangers are assumed to be insulated so that the *U* value is around 1.5 $Wm^{-2}K^{-1}$ and its surface is around 12 m^2. Fig. 6 in combination with eq. (5) illustrates how the capacity of the ATES storage has been determined.

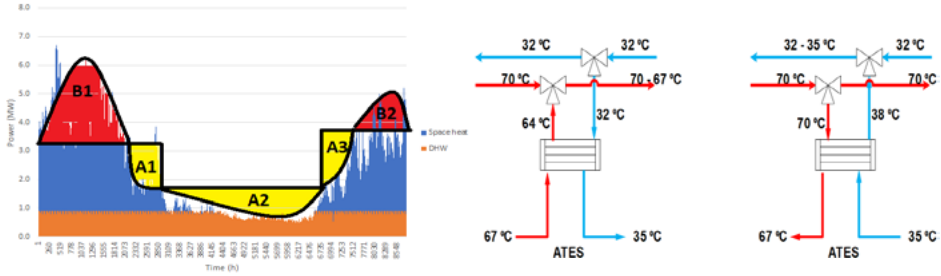

Fig. 6. Peak shaving with ATES. The extra heat delivered by the well given in yellow can be stored to be used to cover the peak loads marked in red (left). Temperatures differences in heat exchanger during discharging and charging of the ATES (right).

$$Q_{ATES} = \frac{(B_1 + B_2)}{\eta_{recovery}} = (A_1 + A_2 + A_3) \tag{5}$$

The sizing of the ATES is based on Drijver et al. [9] and Sommer [27]. The ATES is installed at 250 m depth and the maximum mass flow rate is 130 m^3/h, consistent with the geo-hydrological conditions in the Netherlands. The supplied power is calculated with eq. (6).

$$\dot{Q}_{ATES} = \dot{m}_{ATES} \cdot c_{p_{ATES}} \cdot (T_{ATES_supply} - T_{ATES_return}) \tag{6}$$

The COP of the collective heat pumps is obtained from eq. (7) with T_H the thermodynamic average temperature at the DH side and T_C the thermodynamic average temperature at the geothermal well side. The second law efficiency, η_{Carnot}, has been taken as 0.30, in agreement with de Vrieze [6]. The COP of the collective heat pumps (designs 1-4) is then 3.2 for the 70 ºC network and 3.9 for the 50 ºC network. The decentralized water-water heat pumps (network design 5) will have COPs of 4.2 and 3.6 respectively for space heating and DHW purposes.

$$COP = \eta_{Carnot} \cdot \frac{T_H}{T_H - T_C} \tag{7}$$

In network design 6, air to water heat pumps are used to deliver the heating requirement. These heat pumps extract heat from the environmental air and convert it into useful heat for a water circulation circuit. The *COP* therefore depends on the outside temperature. Table 2 presents experimental *COP* values of air – to – water heat pumps at different outside temperatures. The temperature at the inlet of the radiators is 55 ºC. At ambient temperatures below 5 ºC, frost develops on the surface of the evaporator which reduces the performance of the heat pump. The frost layer reduces the rate of heat transfer in the evaporator because it acts as a thermal insulation. Furthermore, the frost layer blocks part of the air flow passage through the evaporator which causes

a further reduction of the performance. To prevent this phenomenon, an electrical resistance is installed in the heat pump which is activated when the ambient temperature is lower than 5 ºC. The power consumed by the resistance causes a decrease of about 10% in the COP [26].

Table 2. *COP* of an air-water heat pump delivering heat at 55 ºC, adapted from Ertesvåg [11].

Ambient temperature [ºC]	-9	-7	-5	-3	-1	1	3	5	7	9	11	13
COP_{HP}	1.9	2.1	2.2	2.4	2.5	2.6	2.7	2.8	3.2	3.3	3.5	3.8

If the network has a supply temperature below 60 ºC, a booster heat pump (BHP) is required to prepare the DHW. According to Kleefkens et al. [14], when the supply temperature to the BHP is 45 ºC, the COP is 4.2. The required electricity is calculated with eq. (8), where $\dot{Q}_{HP}$ is the power delivered by the heat pump.

$$\dot{W}_{elec} = \frac{\dot{Q}_{HP}}{COP_{HP}} \tag{8}$$

The CO_2 emission considered in this study is only caused by the use of electricity and biomass. Regular geothermal sources produce extra CO_2, because natural gas is released. However, the considered LTGH source is drilled only at 750 m depth and in aquifers where no natural gas is available [25]. The emission factor of electricity and biomass in the Netherlands are currently 0.649 kg/kWh and 0.093 kg/kWh [24].

The price of electricity has been taken as 0.18 €/kWh and of biomass fuel as 0.04 €/kWh [1].

3.3. Levelized cost of energy (LCOE)

The *LCOE* calculates the costs per amount of energy delivered over a certain time. This is summarized in eq. (9).

$$LCOE = \frac{\sum_{t=0}^{t=n} \frac{I_t + M_t + F_t}{(1+r)^t}}{\sum_{t=0}^{t=n} \frac{Q_t}{(1+r)^t}} \tag{9}$$

Where *LCOE* is expressed in €/kWh, the delivered energy (Q) is the heat delivered to the users of the LTDH network. The life time (n) is the number of years the systems runs (here assumed to be 30 years). The years are expressed in (t) and run from year 0 to year 30. The interest rate (r) is assumed to be 6%, because a transformation in energy supply is a risk-full project [16]. The investment costs (I), maintenance costs (M), and fuel costs (F) are the total costs in a certain year. The costs in year 0 are the investment costs (CAPEX). During all the other years the costs consist of operational and maintenance costs (OPEX).

4. Results and discussion

4.1. Amount of auxiliary heat required

The values of all relevant variables have been calculated on an hourly basis for the whole year. As an example of the results, the difference between the power delivered by the LTGH in the two coldest weeks of the year and required by the users of the network is shown in Fig. 7 (a) for network design 1 (70 ºC). The figure makes clear that in these two weeks most of the time the power delivered by the geothermal source is not sufficient to cover the heating requirement. Some of this extra power can be delivered from the ATES as shown in Fig. 7 (b). The remaining power needs to be delivered by the auxiliary boiler. This contribution is shown in Fig. 7 (c).

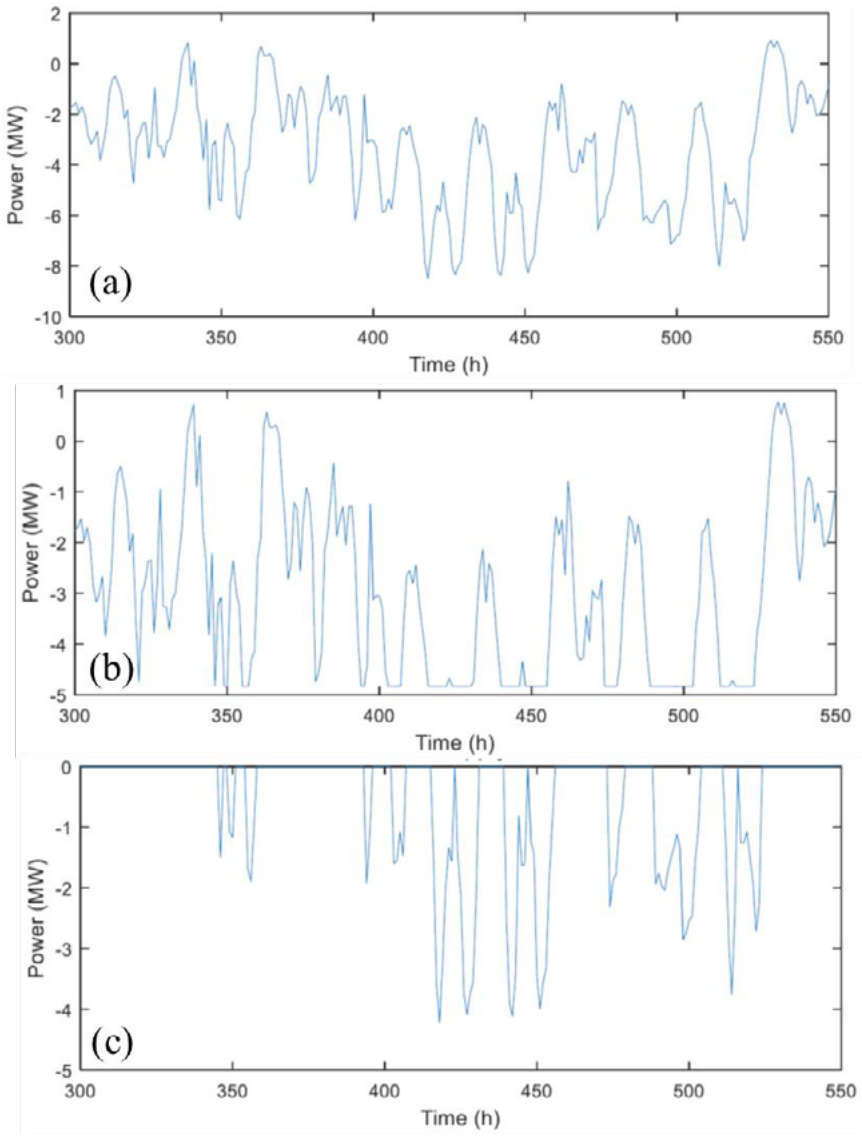

Fig. 7. Difference between available LTGH power and required thermal power by the network users during the two coldest weeks (a) for network design 1 (70 ºC). Power delivered by the ATES in these two weeks (b) and power provided by the auxiliary boiler to compensate for the shortage of power (c).

In a similar way the amount of power delivered by the auxiliary boiler has been determined for the whole year and for the different network designs.

4.2. Impact of temperature level of the network

Operating the network at a lower temperature imposes the use of larger flows and so larger tube sizes and pumps. Table 3 illustrates the impact of network design (and so its temperature level) on flows, pressure drop and tube sizes.

Table 3. Impact of network design in relevant parameters of the network. The details of the designs are listed in Table 1.

	Design 1	Design 2	Design 3	Design 4	Design 5
Flow rate [m³/h]	6 x 55.0	6 x 30.7	6 x 108.5	6 x 56.0	6 x 110.4
Largest internal tube size [mm]	102	90	138	102	138
Pressure drop [bar]	5.4	4.8	6.5	5.7	7.0
Yearly heat losses network [MWh]	3741	3346	2724	2637	1682
Peak power of LTDH [MW]	13.47	10.25	13.47	8.76	10.21

4.3. Results for KPIs

Table 4 shows the values obtained for the KPIs defined in section 1 applied for the different designs. In bold the best performing designs.

Table 4. KPIs for the different network designs. The details of the designs are listed in Table 1.

	Design 1	Design 2	Design 3	Design 4	Design 5	Design 6
CO_2 emission in 30 years [ton CO_2]	52.5	52.2	48.5	48.8	**31.8**	39.5
LCOE [€/kWh]	0.198	0.186	0.222	0.201	**0.168***	0.202*
Yearly electricity in peak [MWh]	**509**	613	528	785	527	823
Yearly heat peak source [MWh]	233	**29**	741	392		
Yearly operation peak source [h]	135	**18**	259	151		

*This assumes that the heat pump [€ 2500. (design 5) and € 7800. (design 6)] is invested twice (once in the 15 years).

Fig. 8 summarizes the performance of the different designs in comparison with the use of individual air-water heat pumps per user (design 6). The figure only considers the most relevant KPIs: CO_2 emissions and *LCOE*.

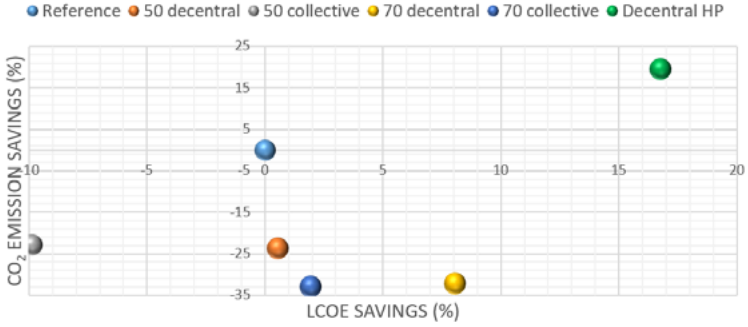

Fig. 8. Visualization of the performance of the different network designs in comparison to design 6 (no network). See Table 1 for network design details. Design 1 is indicated as 70 collective, 2 as 70 decentral, 3 as 50 collective, 4 as 50 decentral and 5 as decentral HP.

Fig. 8 shows that only design 5 (network at 30 ºC) performs better on both CO_2 emissions (19.5% less emissions then reference design) and *LCOE* (16.8% lower *LCOE* then reference design). Design 2 also leads to a significant but lower *LCOE* reduction (7.9%) but at the same time leads to a significant increase of the CO_2 emissions: +32.5%.

5. Conclusions

The supply temperature of the LTGH source has an influence on the *COP* of the heat pumps. Since the heat pumps of the LTGH use most of the total electricity, the electricity use depends a lot on the supply temperature of the LTGH source. This can be seen in the *LCOE* and CO_2 emissions as well. If the supply temperature of the LTGH source can be increased, the heat pumps require less electricity what reduces the CO_2 emission and costs for the complete system.

The best way to meet the heat demand in existing Dutch dwellings, with LTDH and an LTGH as main source is an LTGH with decentral heat pump for every single home. This LTDH concept saves 19.5 %, 16.8 %,

and 36.0 % on the CO_2 emission, *LCOE*, and electricity use in peak load hours compared to an all-electric scenario.

Abstract

This paper describes a new concept of a high temperature (HT)/low-temperature (LT) network integration by using an advanced heat pump technology able to integrate and manage various renewable and residual energy sources with different temperature levels. It is based on a vapor extraction (VE) compression cycle, which integrates two well-known cycles: a vapor compression heat pump cycle and an organic Rankine cycle (ORC). To perform a comparison with existing heat pumps, an energy/exergy analysis has been carried out by using R134a as a working fluid. Thus, for a given extraction ratio of 25%, results show that an increased heating/cooling capacity of about 30% and a high exergy efficiency of 59.7% can be achieved, compared to the 55.5% obtained for conventional compression heat pumps. A global coefficient of performance (COP) between 2.5 and 3.5 (corresponding to a vapor extraction ratio between 10% and 30%) is also obtained and compared to the 1.3-1.7 values given in the literature for existing thermally driven heat pumps (e.g. absorption heat pumps or double orc-orc heat-pump cycles) working with high temperature levels of hot sources.

Keywords: **:** *District Heating/cooling Network;, Heat pumps; Organic Rankine Cycle; Vapor compression Cycle; Thermally driven heat pump cycle; Vapor extraction compression heat pump*

1. Introduction

Heating and cooling represent around 40-50% of the total end-use energy consumption in Switzerland [1]. In their vast majorities, useful heating and hot water preparation demand in Buildings are supplied by using fossil-fuel centralized energy conversion systems like boiler or combined heat and power units (CHP) driven district heating (DH) networks [2]. These existing types of networks operate in general with relatively low thermal efficiencies related to high operating temperature levels (e.g. around 80-200°C). As an alternative or complement to pollutant control technologies to mitigate the emissions of fossil-fuel-based district heating networks, consumers, public interest groups and some local and state governments advocates a shift away from polluting energy systems to low-grade district heating/cooling systems using residual and/or renewable sources like geothermal, solar thermal, heat-pumps or waste heat [3-5].

E-mail address: malick.kane@hefr.ch.

Depending on the type of sources, such low-grade district heating/cooling networks operate at temperature levels between 10 and 35°C and use generally decentralized heat pump (HP) units to raise the temperature in buildings for heating and domestic hot water production [6-7]. These advanced networks have the advantage of being able to serve both for heating (up to 35°C in winter) and cooling (15°C in summer) if their temperature levels could be alternately adapted between seasons [9]. However, the time dependence of temperature levels of these renewable energy sources and the increasing numbers of small installations providing both heating or cooling to connected buildings will considerably affect the temperature levels of the network and therefore influence both the performance of thermal networks and decentralized heat pumps units. The high differential temperature between the DH network and the supply temperature level for heating and hot water process in the building corresponds to an important consumption of electricity in the decentralized HP units. The control of these temperature levels can be easily done in the networks by using existing HT district heating networks. Such integration of HT/LT networks can be realized by using an intermediate station unit (or Cluster). The Cluster station system could be represented by a simple heat exchanger to separate HT and LT circuits or an energy conversion system based organic Rankine cycle (ORC) cogeneration units or thermally driven heat pump (THP) cycles [10]. Figure 1 shows an application of thermally driven heat pump cycles using a HT network system (temperature between 80-280°C) to supply heat to a low-grade district heating/cooling network (20-35°C). The cold source of the THP could be renewable like solar thermal or geothermal or residual heat. A new concept of THP system able to integrate HT/LT networks with better efficiency (or COP-coefficient of performance) and can be operated with hot sources at relatively low temperature levels (even below 50°C) is the object of this paper (Figure 3).

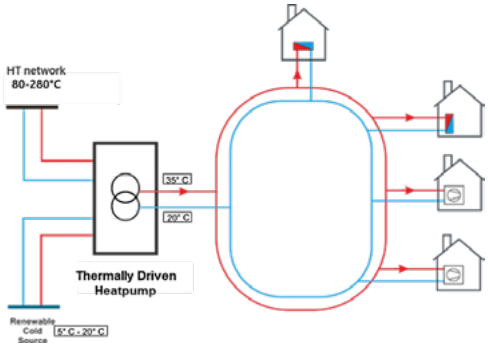

Fig. 1. An Integrated DH network application with thermally driven heat pumps

2. Existing thermally driven heat pump systems

Existing THP technologies such as absorption heat-pumps (single-effect and double-effect) [11,12], ORC driven heat pumps (ORC-ORC) [13] and ejector refrigeration technologies [14] operate in general with high temperature level are in general limited in term of capacity of heating and cooling, and efficiency (coefficient of performance). Figure 2 shows the coefficient of performance (COP) of a broad range of thermally driven heat pumps operating together in the range of hot sources with high temperature levels (between 95 and 275°C) which are more difficult to achieve using residual or renewable energy sources.

A global coefficient of performance between 1.3 and 1.7 have been demontrated for some existing commercial or experimental prototype units working with hot sources at relatively high temperature levels. We can indeed mention a) the gas fired absorption chiller units, commercialized by the company ROBUR S.A and operating at 150°C on the generator with a COP of 1.7 [15] and b) the various solar thermal prototype units based ORC driven heat pumps, demonstrated by several authors. So based on experimental studies on the ORC driven heat pumps, Prigmore and Baraber [16] showed that a COP of 1.5 can be reached with a hot source temperature of 95°C. Strong [17] worked on an ORC driven heat pump that can operates at, with a relatively high temperature level (277°C) with a COP of 1.43. He demonstrated a COP of 1.17 at 229°C. Another experimental study carried out by Biancardi et al. [18] specified a COP of 1.6 for a generator operating at 145°C. Wang et al. [13] have tested an ORC driven machine that produce a COP of 1.5 for a high temperature of 190°C.

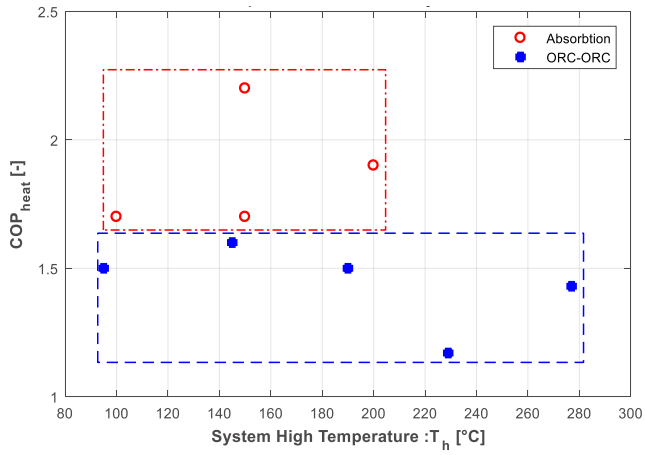

Fig. 2. Coefficient of performance of some existing and theoretical THP based absorption and orc-orc systems given in the literature

Besides those experimental investigations, some other theroretical studies have been performed mainly for absorption cycles. Grossmann [19] studied the performances of both single-effect and double-effect absorption machines for heating applications. His results showed that the single-effect absorption heat pump operating at a temperature level of 100°C can achieve a COP of 1.7 while the double-effect machine delivers a COP of 2.2 at 150°C. Critoph [20] investigated theoretically a forced convection adsorption cycle, which produced a COP of 1.9 at 200°C.

In addition to their low efficiencies and capacity for heating and cooling, such thermally driven heat pumps are limited in term of power density because of the size and the increasing number of components used in the cycle. The new ORC-ORC solution of thermally driven heat-pumps using high speed centrifugal compressor directly coupled with a radial turbine [21] are promising but needs important further developments to demonstrated efficiency, reliability and the ability to work with low temperature heat sources. Theoretical and experimental investigations have been done recently for space heating and hot water preparation in small residential building by using a gas fired boiler. A coefficient of performance of 1.3 has been demonstrated for a differential temperature of 20°C between the evaporator and the condenser and with supercritical thermodynamic cycle using R134a as a working fluid [22].

As the cost-competitiveness of existing thermally driven heat pumps is not yet feasible for applications of low temperature hot sources (below 50°C) because of the costs, efficiency and size of the units, renewable applications will shift towards increasing numbers of vapor compression heat pump technologies mainly adapted for low temperature heating and cooling [6–7]. The solution described in this paper is an original concept of "hybrid drive heat pump systems", developed by the company He-Tech. The hybrid heat pump uses both a primary heat and electricity to run a vapor compression cycle with intermediate pressure extraction for both providing heat from the condenser and recovering heat from the generator. It is based on two well-known cycles: a vapor compression heat pump cycle and an organic Rankine cycle. The system offers more flexibility to integrate and manage different renewable and residual energy sources (such as solar thermal, biomass, geothermal and waste heat) and ability to work with low-temperature heat sources (even below 50°C). One object of this present paper is to evaluate the performances (capacity for heating and cooling, coefficient of performance and exergy efficiency) of such a vapor extraction compression cycle concept and compare results to those of existing heat pump cycles.

3. Vapor-extraction heat pump cycle technology

The proposed new solution of heating/cooling is based on an innovative concept of hybrid drive heat pump technology based on a vapor compression cycle with partial flow extraction (VE heat pump cycle) that would enable to provide cost effective heating. Moreover, the system can provide significant environmental benefits by using renewable energy sources (e.g. solar thermal, geothermal and or biomass) and energy benefits by allowing the valorization of low-temperature residual heat from buildings. It is based on two well-known

thermodynamic cycles: The Organic Rankine Cycle (ORC) and the vapor compression cycle. It is able to perform energy tri-generation, which means, depending on the application, it can provide heat, cold and/or electricity. A flowsheet diagram showing the main refrigerant circuit of the proposed system is given in Figure 3.

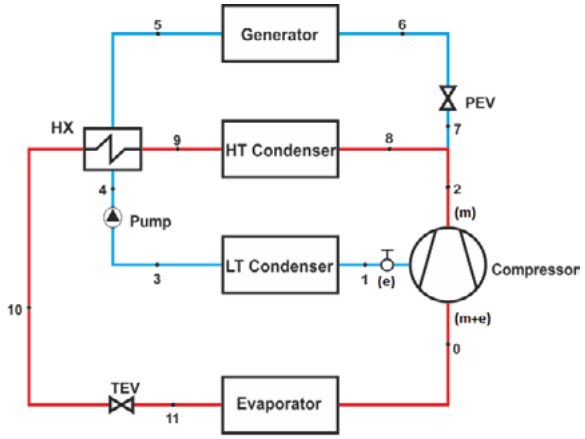

Fig. 3. Flowsheet diagram showing the main refrigerant circuit of a VE heat pump cycle

The new working fluid like R1234yf can be a good solution for such a type of advanced heat pumps. However, for the basis of this comparison with existing vapor compression heat pumps, the refrigerant R134a is considered as a working fluid for calculations. Figure 4 shows the T-s diagram of the VE heat pump cycle.

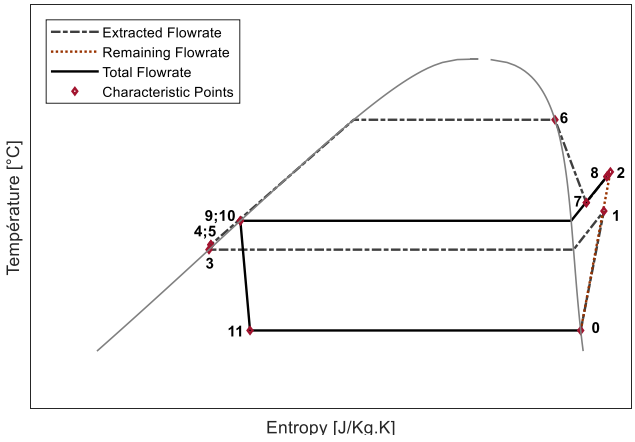

Fig. 4. T-s diagram of a VE heat pump cycle

A portion of the compressed vapor (e) is extracted from the compressor at an intermediate pressure level (fig. 3). After condensation (in the LT condenser), the liquid is pumped to feed the generator via an internal heat exchanger (HX) which acts as a preheater. The fluid vapor produced within the generator is expanded through a pressure expansion valve (PEV) controlling the outlet pressure. After mixing with the high-pressure vapor coming from the compressor (m), cooling and condensation within a heat exchanger (HT condenser), the total liquid (m+e) is cooled into the internal HX, which acts as a subcooler and then expanded through an expansion valve (TEV) into the evaporator. In order to minimize the electricity consumption, the high-pressure expansion valve (PEV) could be replaced by an expander operating at higher temperature levels compared to the PEV and able to generate a part of electricity needed for the heat pump.

To point out the contribution of the heat recovered at the generator in the overall amount of heat produced by the VE heat pump we defined a parameter named extraction ratio (ER) which represents the extracted flowrate (ė) over the compressor inlet flowrate ($\dot{m} + \dot{e}$). For a standard heat pump system, the ER is equal to zero.

$$ER\ [\%] = \frac{\dot{e}}{\dot{m} + \dot{e}} \tag{1}$$

4. Performance analysis and results

As mentioned above, a low-grad district heating (DH) network application is considered where the centralized VE heat pump is used to supply the required heat and to control the temperature of the network. Thermodynamic calculations have been made to compare the system with existing heat pumps (vapor compression standard heat pump and thermally driven heat pumps) used for the same application.

4.1. Model of the vapor extraction heat pump cycle

A simplified R134a thermodynamic model have been considered for the VE-HP. To establish such model, we made the following assumptions:

- The heat exchangers operate at the saturation level (e.g. without superheating on the evaporator and no subcooling on the LT condenser) and the system is considered in steady state;
- The expansion process through the valves TEV and PEV is considered isenthalpic;
- A global isentropic efficiency of 70% is assumed for both the pump and the compressor;
- The motor efficiency and the mechanical efficiency the pump and the compressor stages are set to 1;
- The pressure losses as well as the heat losses are ignored

The models of the VE-HP are then obtained by performing energy and mass balances on each component (Eq. 2 - 5):

$$\dot{Q}_{gen} = \dot{m} \cdot (h_{gen,out} - h_{gen,in}) \tag{2}$$

$$\dot{Q}_{evap} = (\dot{m} + \dot{e}) \cdot (h_{evap,out} - h_{evap,in}) \tag{3}$$

$$\dot{Q}_{LT_cond} = \dot{m} \cdot (h_{LT_cond,in} - h_{LT_cond,out}) \tag{4}$$

$$\dot{Q}_{HT_cond} = (\dot{m} + \dot{e}) \cdot (h_{HT_cond,in} - h_{HT_cond,out}) \tag{5}$$

where $\dot{m}$ is the mass flowrate through the generator; $h_{gen,out}$, $h_{gen,in}$, $h_{evap,out}$, $h_{evap,in}$, $h_{LT_cond,out}$, $h_{LT_cond,in}$, $h_{HT_cond,out}$ and $h_{HT_cond,in}$and h_5 are respectively the refrigerant enthalpy at the outlet and the inlet of the generator, evaporator, low temperature condenser and high temperature condenser and $\dot{e}$ is the extracted flowrate. The extracted flowrate is calculated by using the extraction ratio ER:

$$\dot{e} = \dot{m} \cdot \frac{1 - ER}{ER} \tag{6}$$

To determine the compressor total electric power, we take account of the work delivered to the fluid by the two compression stages:

$$\dot{E}_K = \dot{m} \cdot (h_{K,out,ext} - h_{K,in}) + \dot{e} \cdot (h_{K,out} - h_{K,in}) \tag{7}$$

where $h_{K,in}$, $h_{K,out,ext}$, $h_{K,out}$ are the refrigerant enthalpy at respectively the compressor inlet, extraction outlet and second stage outlet.

In the same way, the power of the pump is calculated by Eq (8):

$$\dot{E}_p = \dot{m} \cdot (h_{p,out} - h_{p,in}) \quad (8)$$

where $h_{p,out}$ and $h_{p,in}$ are the enthalpy at the pump discharge and succion.

In order to assess the contribution of the heat recovered at the generator, two definitions of coefficient of performance (COP) are considered:

- the net electric coefficient of performance (COP_{el}) given by the ratio between the output of condensers and the total electric power consumed by the system (compressor and pump)
- the hybrid (or global) coefficient of performance (COP_{gl}) taking into account both the electric power consumption and the recovered heat rate at the generator

$$COP_{el} = \frac{\dot{Q}_{LT_cond} + \dot{Q}_{HT_cond}}{\dot{E}_k + \dot{E}_p} \quad (9)$$

$$COP_{gl} = \frac{\dot{Q}_{LT_cond} + \dot{Q}_{HT_cond}}{\dot{E}_k + \dot{E}_p + \dot{Q}_{gen}} \quad (10)$$

For the classical heat pump, since the extraction ratio is zero the COP_{el} and the COP_{gl} are the same. In order to be able to compare the two technologies (standard vapor compression cycle and hybrid vapor compression cycle) with the same criterion, an exergy efficiency was defined as in equation 11. $\dot{e}_{LT_cond}$, $\dot{e}_{HT_cond}$, $\dot{e}_k$, $\dot{e}_p$, $\dot{e}_{gen}$ are respectively the heating exergy provided by the LT condenser and the HT condense, the compressor exergy consumption, the pump exergy consumption and the exergy received at the generator; T_{LT_cond}, T_{HT_cond}, T_{gen}, T_o are respectively the temperature of the LT condenser, the temperature of the HT condenser, the temperature of the hot source at the generator and the outside ambient temperature.

$$\eta_{ex} = \frac{\dot{e}_{LT_cond} + \dot{e}_{HT_cond}}{\dot{e}_k + \dot{e}_p + \dot{e}_{gen}} \quad (11)$$

$$\eta_{ex} = \frac{\dot{Q}_{LT_{cond}} \cdot \left(1 - \frac{T_o}{T_{LT_{cond}}}\right) + \dot{Q}_{HT_{cond}} \cdot \left(1 - \frac{T_o}{T_{HT_{cond}}}\right)}{\dot{E}_k + \dot{E}_p + \dot{Q}_{gen} \cdot \left(1 - \frac{T_o}{T_{gen}}\right)} \quad (12)$$

The set of equations is implemented and solved with Matlab®. At each point of the cycle, the refrigerant properties are evaluated using the thermodynamic state equations.

4.2. Performance simulation

A case study of a DH network operating at a temperature level of 35°C and with a heating nominal demand of 100% is considered for the simulation.

Table 1. An example of a table

	Pressure [bar]	Temperature [°C]
Evaporator	3.74	7
LT-condenser	8.87	38
HT-condenser	11.6	48
Generator	26.3	77

The generator of the VE heat pump is connected to the hot source with a maximum temperature of 80°C and which can come from process waste heat, solar thermal, or biomass. The VE heat pump uses the

atmosphere or a geothermal cold source for which the temperature is supposed to be constant at 10°C. Table 1 shows pressure and temperature levels of evaporation and condensation of the working fluid (R134a). The same thermodynamic cycle is used to evaluate the performance of the standard vapor compression heat pump cycle by setting the extraction ratio at 0%.

4.3. Capacity and efficiency of the VE heat pump

Figure 5 shows the variations of the VE heat pump coefficient of performance (blue curves) and exergy efficiency (red curve) in function of the extraction ratio. A net exergy efficiency of about 63% (e.g. 50% extraction ratio) can be achieved for this application. The minimum value of 55.5% corresponding to a zero extraction ratio represents the exergy efficiency of a standard vapor compression heat pump.

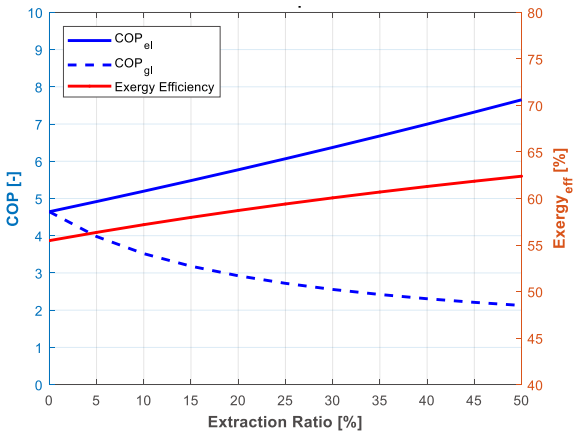

Fig. 5. Coefficient of performances and exergy efficiency of the VE heat pump cycle for various extraction ratio

Note that the global coefficient of performance decrease at high extraction ratio can be explained by the primary heat consumption, which is then too high at the generator of the cycle. As shown in figure 5 the net electric coefficient of performance increase also with the vapor extraction ratio. It can be pointed out that the compressor is used at very partial flow (operation between the LT and HT condensing pressures), requiring then less electric power consumption for the same demand or corresponding to an important gain of heating/cooling capacity when compared to the standard vapor compression cycle with same electricity consumption. Figure 6 represents the variation of heat supply vs electricity consumption with the two configurations. Results show that an increased heating/cooling capacity of about 30% is achieved for a given extraction ratio of 25% (which corresponds also to an exergy efficiency of 59.7% according to the figure 5).

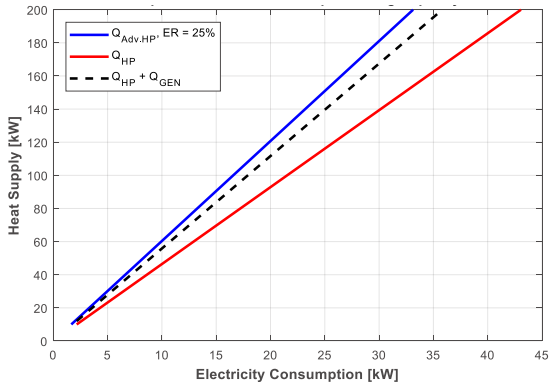

Fig. 6. Heating capacity of the VE heat pump cycle for an extraction ratio of 25% and the standard vapor compression cycle

Other sources of improvements that can influence the capacity of the VE heat pump are related to the internal heat exchanger (HX). The additional subcooling increases the evaporator cooling capacity by reducing the evaporator inlet enthalpy of the fluid. The additional condenser mass flow (**e+e**, for both the LT and HT condenser) increases also considerably the heating capacity of the installation. These added capacities are achieved with less electrical power consumption in the compressor because the amount of vapor extracted (**e**) is compressed only from the suction pressure to the intermediate pressure. Due to this increase in capacity, it could be required to specify a smaller compressor (low displacement) for a given heating and/or cooling demand. For a given extraction ratio of 25%, an increased capacity of 30% is achieved compared to a conventional vapor compression heat pump.

Fluctuations of both the amount of heat recovered at the generator, the hot source temperature and/or outside ambient temperature can be coped with the adaptation of the extraction mass flow rates of the HP working fluid. This flexibility of operation whoud allow to better integrated various sources of renewable energy such as solar thermal application.

4.4. Comparison with commons thermally driven heat pumps

A good way to analyze the performances of such technology is to compare them with those of other tri-therm machines that could be potentially used in this particular application. Figure 7 shows the coefficient of performance of the VE heat pump in function of the temperature levels at the generator compared to existing thermally driven heat pumps.

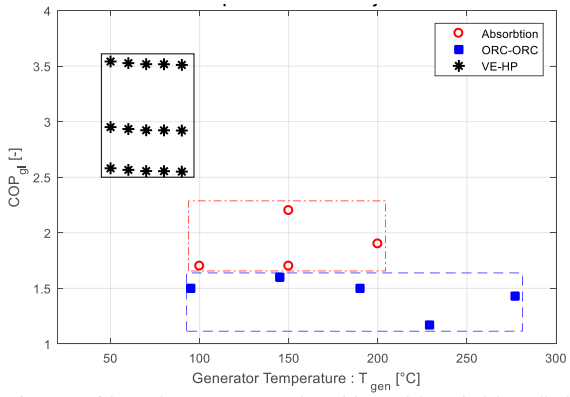

Fig. 7. Coefficient of performance of the VE-heat pump compared to exisitng and theoretical thermally driven heat pumps based absorption and orc-orc systems given in the litterature

Efficiency with vapor extraction heat pump is always higher than conventional thermally driven heat pumps (like absorption heat pump and orc-orc heat pump) when providing the same capacity for heating and cooling. Because, only the small portion (**e**) of refrigerant, extracted from the compressor (less than 30% of the main flow rate) is used to feed the generator, requiring then less heat consumption compared to other systems. A global coefficient of performance (COP) between 2.5 and 3.5 (corresponding to a vapor extraction ratio between 10 and 30%) is obtained and compared to the 1.3-1.7 of existing thermally driven heat pumps working with high temperature levels.

The results show that there is no advantage to work at relatively high temperature levels on the generator of the cycle. Such a situation corresponds in fact to a high difference of temperature between the HT condensing temperature and the generator evaporation temperature reducing then the global coeffient of performance because of losses on the pressure expansion valve (PEV). A high difference of temperature corresponds also to a high difference of pressure on the pump that is accompanied by a significant consumption of the electric power. This makes the cycles work at higher temperature on the generator, which is then detrimental for the coefficient of performance.

5. Conclusions

A new concept of hybrid drive heat pump technology based on a vapor compression heat pump cycle with partial flow extraction has been proposed and applied to control the temperature level of a low-grade district heating/cooling network **(**VE heat pump cycle**)**. The system offers more flexibility to integrate and manage different renewable and residual energy sources (such as solar thermal, biomass, geothermal and waste heat) and ability to work with low-temperature heat sources (even below 50°C). For the comparison with standard vapor compression heat pump the refrigerant R134a have been considered and a simplified thermodynamic model was performed to simulate and evaluate the performances (capacity for heating and cooling, coefficient of performance and exergy efficiency) of such a vapor extraction compression cycle concept and compare results to those of existing heat pump cycles. Results show that an increased heating/cooling capacity of about 30% and a high exergy efficiency of 59.7% (instead of 55.5%) can be achieved for a given extraction ratio of 25%, compared to the 55.5% obtained for conventional compression heat pumps. A global coefficient of performance between 2.5 and 3.5 (corresponding to a vapor extraction ratio between 10 and 30%) is also obtained and compared to the 1.3-1.7 given values in the literature for existing thermally driven heat pumps (e.g. single or double effect absorption heat pumps or double orc-orc heat-pump cycles). Future work could be devoted to experimental investigations on the VE heat pump and a comparative thermo-economical study with other solutions available for district heating/cooling application.

Evaluation of a Hybrid AC/DC Powered Residential Split-System Heat Pump Performance using a DC Nanogrid

Jonathan Ore[a,*], Fatih Meral[a], Oliver Obst[a], Orkan Kurtulus[a], Eckhard A. Groll[a]

[a]Purdue University, Ray W. Herrick Laboratories 177 S. Russell St., West Lafayette 47907, USA

Abstract

Many benefits have been observed from the employment of Direct Current (DC) distribution schemes over those of traditional Alternating Current (AC) within building architectures, ranging from enhanced system efficiency, increased reliability, reduced points of failure, and more convenient integration with renewable energy generation systems. The objective of this research is to demonstrate the emulation of a DC Nanogrid system supporting the largest categorical energy consumer in the residential building-space: the HVAC system. Through the avoidance of unnecessary energy losses due to power conversion, a DC-driven heat pump affords a significant opportunity for energy savings and overall improved efficiency. This paper presents the results from laboratory testing a hybrid AC/DC powered air-source heat pump fashioned to operate separately on either an AC or DC electrical supply. The corresponding residential DC Nanogrid system is simulated with a psychrometric chamber integrating a variable voltage DC power supply. Initial psychrometric testing of both AC and DC configurations are presented, along with corresponding thermal and electrical performance analysis. Future work will consider individual characterization of the heat pump components under DC supply, comparison of line losses between AC and DC load conditions, and additional environmental heating and cooling test cases.

Keywords: DC Power; Direct Current; Nanogrid; Heat Pump

1. Introduction

Within the U.S., the advent of ever-increasing energy demands has resulted in escalating strain on the power grid, often pressuring it to the limits of its capabilities. Modern technological innovations have fostered a greater dependency on the grid, coupling it with nearly every aspect of contemporary society. Unfortunately, the grid has not experienced a parallel rate of growth alongside technology, with some estimates reporting in the range of trillions of dollars necessary for repairs and upgrades to return to a nominal performance level. During the previous decade, the American Society of Civil Engineers scored the U.S. energy system with a grade of a "D+" for overall reliability, describing outdated distribution systems, limited system capacity, and undesirable environmental side-effects as the leading factors in their evaluation [1]. Further challenging these conditions is the increasing dependency on internet technology and cellular networks, resulting in a proportional rise in vulnerability of the electrical grid. A recent Wall Street Journal article concludes that a failure of just nine substations (via targeted attack, electrical failure, etc.) could result in a significant destabilization of the entire electrical grid [2].

These concerns have stimulated investigations into other potential solutions, including the feasibility of individual micro and nanogrids existing in both residential and commercial spaces. These grids, while still connected to the outside "main" electrical grid, possess the ability to operate autonomously and mitigate loads in an islanding-mode without relying on the external grid. Such capabilities are highly beneficial in the face of emergencies or other failures, but also offer advantages in energy costs through the employment of renewable energy sources (e.g. wind, solar, geothermal, etc.). The electrical infrastructure afforded by a micro/nanogrid is typically that of Direct Current (DC), as opposed to the traditional infrastructure of Alternating Current (AC)

currently in place. Unfortunately, nearly all appliances and devices, particularly in a residential setting, require DC power at terminal endpoints; as a result, the AC power being supplied to them must first be converted to DC, resulting in a loss of energy. This problem is further exacerbated when renewable energy is integrated, which naturally generates DC power. To provide compatibility with the existing infrastructure, energy generated from renewable resources must first undergo a conversion from DC to AC, resulting in energy loss, and then experience a second conversion from AC back to DC at the point of use, resulting in additional energy loss. Such penalties are primary drivers for interest in a DC-based micro/nanogrid solution, with some modeling estimations revealing a potential conversion loss reduction of up to 30% in a commercial building with an integrated battery [3].

The residential setting in this paper serves as the foundation for a novel type of nanogrid, which seeks to achieve a complete home conversion from AC to DC power. Nanogrid terminology is employed to differentiate the intra-building scope of the design, as opposed to a microgrid which often encapsulates multiple buildings and distributed energy generation sites and storage. The dwelling under scrutiny is a two-story 1920's era home entitled "The DC House", housing three graduate students and located in West Lafayette, IN. The DC House is situated on a 595 m^2 lot with a detached garage, and contains 208 m^2 of floor space. As part of the conversion process from AC to DC, a DC infrastructure will be designed and installed, and supplied by renewable energy sources using solar panels on the roof of the house. Modeling and simulation are planned to verify and validate the hardware solution, as has been performed in similar setups [4].

With the house serving as a "living lab", baseline AC energy consumption among the residents was evaluated for an entire year. Analysis of data collected during 2018 revealed the heat pump system to be the largest categorical energy consumer of all appliances present.

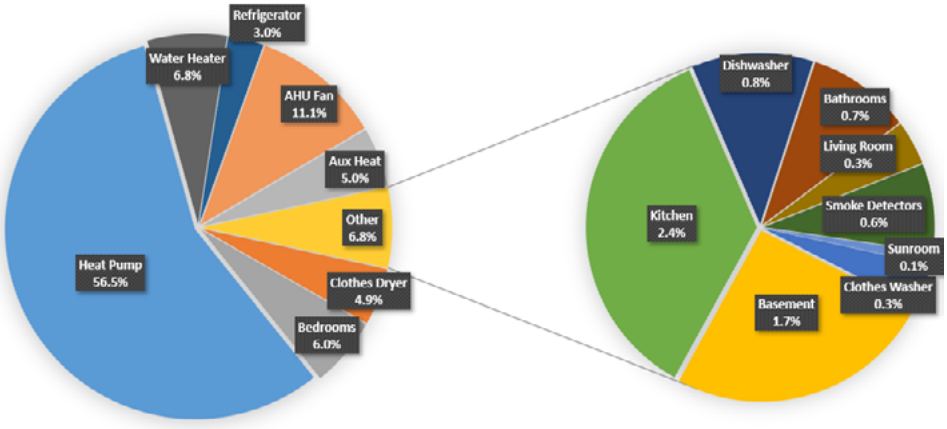

Fig. 1. DC House Categorical Comparison of Appliance Energy Consumption in 2018

A survey performed by the IEA confirms the findings in Fig. 1, estimating that space heating and air conditioning represent up to 49% of average U.S. household energy consumption [5]. As a result, electrical retrofitting of the heat pump from an AC to DC configuration affords a significant opportunity for energy savings and an increase in efficiency.

In this paper, the DC Nanogrid is simulated through the use of a variable-voltage 15 kW DC power supply. The environmental conditions inside and outside the DC House are emulated using two adjacent psychrometric chambers, capable of replicating conditions between -20 °C (-4 °F) and 55 °C (130 °F), and 15% to 100% humidity. AC and DC electrical configurations using a retrofitted hybrid heat pump are tested under a variety of cooling conditions, and compared with thermal and electrical performance metrics. Further testing conditions and topics of investigations are then considered for future study.

2. Specifications and Methods

To provide a basis for comparison across the various electrical configurations, an off-the-shelf variable speed heat pump with scroll compressor was selected and retrofitted to accept both AC and DC electrical

supply inputs. Using conventional residential AC power, the modified unit operates on a nominal split-phase 240 VAC input. Under the DC configuration, the modified unit operates on nominal bi-polar 350 VDC input, with undervoltage and overvoltage limits at 250 VDC and 400 VDC, respectively. The internal thermal configuration in the modified unit remained unchanged in order to ensure commonality. The results within this paper evaluate thermal and electrical performance with both AC and DC power conditions using the retrofitted AC/DC hybrid unit. Future investigation will then consider this data against an unmodified unit installed at the DC House operating on standard 240 VAC.

2.1. Electrical Configuration and Conversion Losses

A specific advantage of the DC-based electrical configuration arises from the difference in current consumption of the heat pump. The maximum power of the heat pump is rated at 6.96 kW, which can be used to determine the maximum current load under a 120 VAC split-phase configuration.

$$P_{AC} = I_{AC} \cdot \Delta V_{AC} \quad (1)$$

Under this relationship, the maximum current is found to be approximately 29 A. If the voltage is then increased to 350 VDC for the DC connection, the maximum current is proportionally decreased to 20 A instead. Eq. 1 can be rewritten to describe the loss of power with respect to the line resistance, as is shown in Eq. 2.

$$P_{Loss} = I^2 \cdot R \quad (2)$$

From this relationship, it is clear that the loss of power associated with resistance in the system is reduced in proportion to the squared inverse of current. As a result, halving the current requirement for a component could potentially reduce its electrical line transmission power losses by a factor of one-fourth. In the specific case of the heat pump under study in this paper, the decrease in current requirements from 29 A to 20 A affords a theoretical maximum reduction in line power loss of up to 52%, assuming equivalent resistances.

Although the line power consumption represents only a small portion of the energy consumed by the heat pump system, the savings become more significant over larger distances and across numerous appliances. These losses also reduce result in a voltage drop between supply and appliance, potentially reducing performance and introducing system instability. Additional current requirements also impose an increase in the wire gauge, resulting in higher costs and even further possible line losses. These factors will be closely analyzed in future studies to numerically quantify differences between AC and DC configurations, and their corresponding transmission losses under a variety of line lengths.

In a traditional electrical design, input three-phase AC voltage is passed through a bridge rectifier, converting it to a usable DC voltage as shown in Fig. 2.

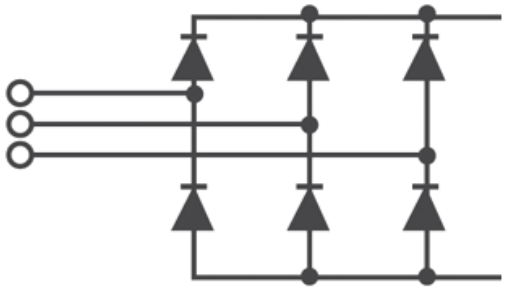

Fig. 2. Standard Three-Phase Bridge Rectifier Circuit

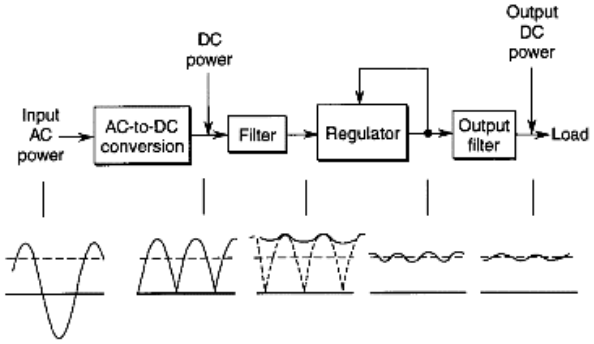

Fig. 3. Complete Power Conversion Process from AC to DC [6]

The entire conversion process can be summarized using the flow diagram in Fig. 3, with the corresponding electrical waveform shown immediately underneath. The rectification stage in Fig. 2 is represented in Fig. 3 by the "AC-to-DC conversion" block. As Fig. 3 illustrates, this first stage of rectification results in the largest source of energy lost. Through the ratcheting-effect of the diodes in the rectifier, the negative phase of the AC waveform is removed in the first step towards the DC conversion. The collective result of each stage in Fig. 3 can yield a net loss of 10% to 15% or more in energy efficiency.

The internal control mechanisms of the modified heat pump have been designed to accept both conventional AC voltage and DC input. The hybrid nature of the modified heat pump is made feasible in part by the capability of the bridge rectifier in Fig. 2 to allow DC voltage to pass through without significant impedance. In the case of a pure DC voltage, which is constant without any sinusoidal component, the diodes have no impact on the path of current outside of a small voltage drop, and therefore do not inhibit the processing of the DC input. The remaining conversion stages (filter, regulator, etc.) also have no significant impact on an input DC voltage, and thus the final output DC power shown in Fig. 3 is still achieved.

2.2. Hybrid Heat Pump Setup and Specifications

Initial experimental data for the hybrid heat pump was collected using a 230 VAC connection available within the psychrometric chambers. Within the U.S., 220 VAC to 240 VAC are generally understood as synonymous, and thus the DC House and psychrometric laboratory setting can be considered electrically equivalent for future studies. The hybrid heat pump under study is a 14.07 kW (4 ton) air-source split-system design, accepting either 240 VAC or 350 VDC as inputs. Indoor and outdoor components of the heat pump were installed separately in individual psychrometric chambers to properly emulate realistic environmental conditions at the DC House. The outdoor unit contains a compressor, condenser, outdoor fan, and a four-way valve, while the indoor unit includes the evaporator, thermostatic expansion valve (TXV), and indoor fan. The heat pump unit contains a scroll compressor, and a manufacturer Seasonal Energy Efficiency Ratio (SEER) value of 18. The nominal indoor airflow rate is 2379 m^3/h, and the hybrid system is charged with 6.1 kg of R410A. The heat pump system is composed of a variable speed compressor, an indoor fan with variable volume flow rate, and an outdoor fan with a variable speed motor. The specifications are summarized in Table 1.

Table 1. Hybrid Heat Pump Configuration Summary

Available electrical configurations	Cooling capacity	SEER rating	Refrigerant	Testing environment
240 VAC / 350 VDC	14.07 kW (4 ton)	18	R410A	Psychrometric Chambers

2.3. Equipment Setup and Data Collection

Laboratory data from the hybrid heat pump was collected using a National Instruments cRIO-2091 data acquisition system (DAQ) with a LabVIEW based visual interface for inspection and logging. Watt transducers were individually installed to monitor the AC power consumption of the indoor unit fan, and the outdoor unit fan and compressor. When employing the DC power configuration, cumulative system power was monitored

using the 15 kW MagnaPower variable-voltage DC power supply. DC power was distributed to the indoor unit using 20 m of 10 AWG wire, and to the outdoor unit using 10 m of 6 AWG wire.

Thermal data collected was evaluated using both air and refrigerant enthalpy methods to determine the cooling capacity. A schematic summarizing the psychrometric chamber layout and refrigeration loop configuration is provided in Fig. 4, with the state point descriptions given in Table 2.

Table 2. Hybrid Heat Pump State Point Definitions

State Point	Description
1	Compressor Inlet
2	Compressor Outlet
3	Condenser Inlet
4	Condenser Outlet
5	EXV Inlet
6	EXV Outlet
7	Evaporator Inlet
8	Evaporator Outlet

Thermophysical properties from the psychrometric test setup were determined through the use of the Engineering Equation Solver (EES) software [7]. In addition, state points 1 through 5 and 7 in Fig. 4 could be calculated from the measured pressure and temperature values of the refrigerant. State point 6 between TXV and the evaporator was obtained assuming both an isenthalpic expansion across the TXV device and negligible pressure drop at the outlet of the TXV and evaporator. The refrigerant mass flow was determined using a Coriolis mass flow meter configured for liquid phase between state points 4 and 5.

Cooling capacity of the hybrid heat pump could be calculated through two separate means, and then compared to determine the accuracy of the system measurements. Using a First Law energy balance and the given assumptions at each state point, the evaporator cooling capacity can be computed from Eq. 3.

$$\dot{Q}_{evap} = \dot{m}\Delta h_{evap} = \dot{m}(h_7 - h_6) \tag{3}$$

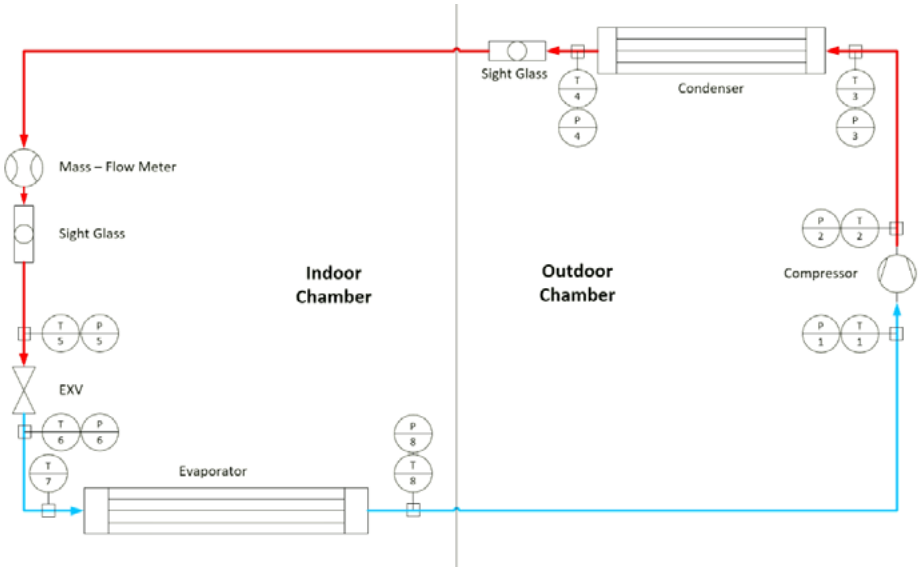

Fig. 4. Hybrid Heat Pump Cooling Configuration Schematic – Psychrometric Chamber Setup

The net capacity is then calculated by taking the difference between the cooling capacity of the evaporator from Eq. 3, and the additional heat added to the system from the indoor fan. The amount of heat was assumed approximately equivalent to the overall power consumption of the indoor unit, resulting in the relationship given by Eq. 4.

$$\dot{Q}_{delivered} = \dot{Q}_{evap} - \dot{W}_{indoor} \tag{4}$$

Alternatively, the hybrid heat pump cooling capacity could also be determined using an air-side approach. In this evaluation, the overall air-side capacity can be calculated again by considering a First Law energy balance applied to the indoor unit. Within this energy balance, the difference in enthalpy of the air flow is accounted for, along with the phase change of water condensed within the unit, yielding Eq. 5.

$$\dot{Q}_{delivered} = \dot{m}_{air}\Delta h_{evap} - \dot{m}_{water}h_{water} \tag{5}$$

In order to evaluate Eq. 5, calculation of the mass of air flow is needed. This can be determined by analyzing the volume flow rate of the nozzle box in line with the indoor unit's duct work of the indoor unit, which is designed in compliance with ASHRAE Standard 37-2009 [8]. The volumetric flow rate is calculated iteratively using Eq. 6.

$$\dot{V}_{air} = Y\sqrt{\frac{2\Delta p_{nozzle}}{\rho_{air}}}\sum_{0}^{k} C_i A_i \tag{6}$$

The expansion factor (Y) and coefficient of discharge (C_i) in Eq. 4 are defined in ASHRAE Standard 37-2009, and the area of the duct work (A_i) was specified during system installation [8]. With the volumetric flow rate obtained, the air flow mass can be solved by multiplying by the air density, and illustrated in Eq. 7.

$$\dot{m}_{air} = \dot{V}_{air}\rho_{air} \tag{7}$$

In addition to the mass of the air flow, the mass of the condensed water flow is also needed to evaluate Eq. 5. EES is used to calculate the inlet air enthalpy, outlet water enthalpy, and outlet air enthalpy, provided the necessary inputs are given. This includes the air dry-bulb temperature, which is measured with a 3x3 thermocouple grid situated between the inlet and outlet of the indoor unit, the relative humidity of inlet air using a relative humidity sensor, and the dew point of the outlet air. The dew point is determined through a periodic sampling of the air at the rate of 1 L/min, which is then processed through a chilled mirror dew point sensor. The relationship between these values calculated in EES is detailed in Eq. 8.

$$\dot{m}_{water} = \dot{m}_{air}(\omega_2 - \omega_1) \tag{8}$$

Finally, the heat pump coefficient of performance (COP) can be tabulated by dividing the system cooling capacity by its power consumption, as defined in Eq. 9.

$$\mathrm{COP} = \frac{\dot{Q}_{delivered}}{\dot{W}_{total}} \tag{9}$$

2.4. Testing Methodology

The hybrid heat pump with variable-speed components was tested in accordance with the guidelines set by AHRI. To establish common baseline testing conditions for both the AC and DC electrical configurations, psychrometric indoor and outdoor room conditions were specified from test conditions A, B, C, D, and E from Table 8 of the AHRI Standard 210/240 [9]. The compressor was operated near full speed during each test, but not explicitly controlled under either AC or DC configuration.

The test conditions performed are collected into a matrix shown in Table 3, with temperature values provided in both English and SI Units because SEER calculations require the input of temperatures in °F. Each test case was performed under both the 230 VAC and 350 DC configuration under steady state conditions, and monitored for thermal and electrical characteristics every few seconds. This data was subsequently post-processed using the EES software at the conclusion of the testing.

Table 3. Hybrid Heat Pump Psychrometric-Based Test Matrix

Test Case	Cycle Configuration	Indoor Temperature [°F/°C]	Indoor Relative Humidity [%]	Outdoor Temperature [°F/°C]	Indoor Relative Humidity [%]
1	Cooling	80/26.7	51.10	95/35	39.60
2	Cooling	80/26.7	51.10	82/27.8	39.90
3	Cooling	80/26.7	51.10	87/30.6	40.20
4	Cooling	80/26.7	51.10	82/27.8	39.90
5	Cooling	80/26.7	51.10	67/19.4	40.30

2.5. COP and EER Analysis

The test matrix described in Table *3*. Hybrid Heat Pump Psychrometric-Based Test MatrixTable 3 is also leveraged to evaluate the COP and the Energy Efficiency Ratio (EER) ratings for the hybrid heat pump system. These ratings, along with the SEER calculation, are standard methods used to rate the heating and cooling performance of U.S. heat pumps. A seasonal analysis is necessary to characterize the benefits of a variable speed system, which come in form of the ability to match part-load conditions. The COP and EER ratings are used in this study to quantify the thermal performance of each test case under the AC and DC configurations of the hybrid heat pump.

3. Results

The results of the hybrid heat pump testing under the AC and DC electrical configurations of the test matrix in Table 3 are detailed in Table 4 and Table 5.

Table 4. Hybrid Heat Pump 230 VAC Test Results

Test Case	Electrical Configuration [VAC]	Cooling Capacity [kW]	Indoor Power [kW]	Outdoor Power [kW]	Total Power [kW]	COP [-]	EER [-]
1-AC	230	12.8	0.4478	3.6204	4.0682	3.15	10.8
2-AC	230	14	0.4515	3.1088	3.5603	3.93	13.4
3-AC	230	13.6	0.3357	3.2627	3.5984	3.78	12.9
4-AC	230	14.1	0.3238	3.0835	3.4073	4.14	14.1
5-AC	230	15.4	0.3568	2.5475	2.9043	5.30	18.1

Table 5. Hybrid Heat Pump 350 VDC Test Results

Test Case	Electrical Configuration [VDC]	Cooling Capacity [kW]	Total Power [kW]	COP [-]	EER [-]
1-DC	350	13.3	3.9050	3.38	11.3
2-DC	350	14.1	3.3260	4.24	14.1
3-DC	350	13.9	3.4557	4.02	13.9
4-DC	350	14.3	3.2429	4.41	14.3
5-DC	350	15.8	2.8138	5.62	15.8

The cooling capacity, COP, and EER measured in each of the test cases was acquired using the refrigerant method calculation. Although these capacities were similar in magnitude between AC and DC configurations, the thermal state points of the refrigeration cycle maintained some significant differences, especially at the compressor suction temperature. To consider these more closely, the thermal characteristics of the first test case under both the AC and DC configurations are presented in Table 6.

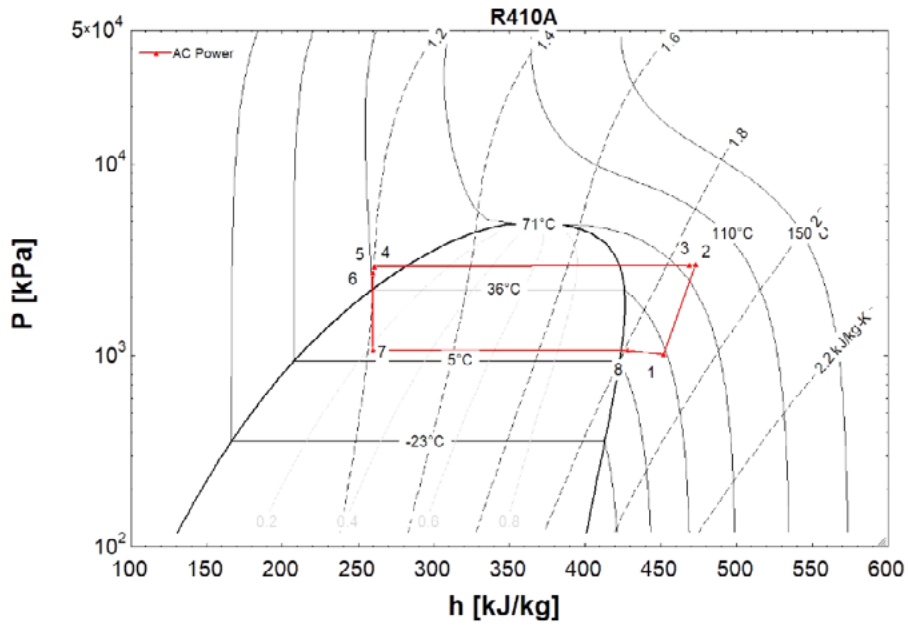

Table 6. Hybrid Heat Pump Test Case 1 Thermal Characteristics

Test Case	Electrical Configuration [-]	Indoor Air Flow [m^3/s]	Compressor Suction Superheat [C]	Compressor Suction Temperature [C]	Compressor Suction Pressure [kPa]	Compressor Discharge Temperature [C]	Compressor Discharge Pressure [kPa]
1-AC	230 VAC	0.6269	24.6	33.9	1016	81.2	3003
1-DC	350 VDC	0.6892	6.1	15.0	997.6	81.6	3002

As Table 6 reveals, the DC configuration maintained a higher indoor air flow rate under steady state conditions and a significantly lower compressor suction temperature. The state points for the AC and DC configurations under test case 1 are further illustrated in the P-h diagram shown in Fig. 5 and Fig. 6.

Since the compressor speed was controlled automatically by the heat pump, this may have resulted in the differences observed. In addition, the drive operation under DC conditions could not be readily evaluated against those under the AC configuration without supplemental manufacturer data. As a result, these factors demonstrated a need for further instrumentation and analysis to determine the source of the differences. Additional DC-watt transducers are planned for installation on the indoor and outdoor unit for increased fidelity of the power consumption, as well as coordination with service data to extract the compressor speeds in post-processing.

Fig. 5. P-h Diagram for the AC Configuration Running Test Case 1

3.1. DC Measurement Uncertainty Analysis

The DC power supply served as both the representative DC Nanogrid supply for the hybrid heat pump, and the monitoring device to capture the heat pump total power consumption. As a result of the significant dependence on this unit, uncertainty of the supply and monitoring capabilities is considered. From the supply side, the manufacturer specifications indicate an output load regulation of ±0.01% of full-scale voltage under a voltage control mode. In addition, an input line regulation of ±0.004% of full-scale voltage is maintained under the same voltage control. Load regulation in this case refers to the capacity of the power supply to maintain a specified output voltage while the load is varying, and line regulation describes the ability of the power supply to maintain the same specified output voltage while the input supply power to the power supply is varying. Collectively, these represent a combined uncertainty of ±0.011%. This is calculated using a

quadratic sum, which describes the uncertainty in measurements x, …, y, which are used to compute an uncertain output, δf. This is given below in Eq. 10.

$$\delta f = \sqrt{(\delta x)^2 + \cdots + (\delta z)^2} \tag{10}$$

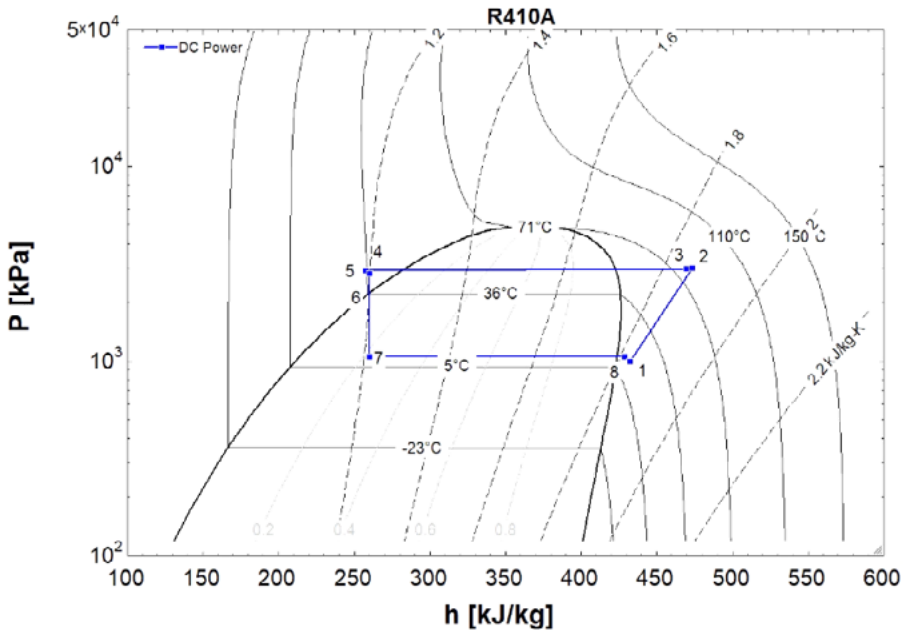

Fig. 6. P-h Diagram for the DC Configuration Running Test Case 1

Defining the full-scale voltage of the power supply to be 500 VDC, the output supply to the heat pump is calculated with an uncertainty of 0.054 VDC. These results are summarized in **오류! 책갈피가 자신을 참조하고 있습니다.**, where $\Delta V_{Controlled}$ represents the 350 VDC measured operating condition.

Table 7. DC Power Supply Output Uncertainty

Uncertainty Condition	Uncertainty [%]	Voltage Error [VDC]
Line Regulation	0.01	$V_{controlled} \pm 0.05$
Load Regulation	0.004	$V_{controlled} \pm 0.02$
Output Supply	0.011	$V_{controlled} \pm 0.054$

Using the power supply to monitor the heat pump power consumption, the measurement accuracy must then be considered. The manufacturer specifies a voltage readback uncertainty of ±0.2% of full-scale voltage, and a current readback uncertainty of ±0.02% of full-scale current. Defining the full-scale current of the power supply to be 30 A, the cumulative power measurement uncertainty reading can be tabulated as shown in Table 8. Since the power is calculated by the multiplication of the DC voltage and current, the resulting uncertainty is defined as the quadratic sum multiplied by the power measurement.

Table 8. DC Power Supply Measurement Uncertainty

Uncertainty Condition	Uncertainty [%]	Error
Voltage Reading	0.02	$V_{measured} \pm 0.1$ [V]
Current Reading	0.02	$I_{measured} \pm 0.006$ [A]
Power Measurement	0.011	$P_{measured} \pm 0.100$ [W]

4. Conclusions and Future Studies

This research presented the psychrometric evaluation of a retrofitted hybrid heat pump unit under a variety of environmental conditions using both AC and DC electrical configurations. The intent of this research is to demonstrate the feasibility of DC retrofits of devices traditionally configured for AC inputs, and to analyze improvements in performance and energy efficiency through the avoidance of AC and DC conversions. The DC power was supplied using a variable voltage power supply, which was implemented to represent a DC Nanogrid operating in a residential setting. The unit functioned successfully using a 350 VDC input, and was able to perform under each of the five test conditions described in Table 3. Based on the thermal and electrical measurements obtained, a need for additional instrumentation and further testing was identified. DC-based watt transducers are planned for installation on the indoor and outdoor units to provide insight into their representative energy consumption. This data coupled with supporting manufacturer measurements will be used to both verify the results obtained within this paper and analyze the difference in behavior between the AC and DC modes of operation. These results, along with additional test conditions and repeated trials, will be provided in a follow-on paper.

Beyond the laboratory setting, additional studies will analyze the hybrid heat pump results described here against an unmodified heat pump unit installed in the DC House using load-based testing methodology. These subsequent investigations will assist in confirming the hybrid heat pump AC and DC data obtained in this paper, and further support the potential energy improvement opportunities under DC operation. In addition, coordinated testing between the hybrid heat pump and unmodified heat pump is planned in order to establish a proportional relationship between testing results. Under this methodology, ambient temperature and humidity from the residential testing environment will be relayed in real-time to the test setup in the psychrometric chambers, allowing it to be recreated and applied to the heat pump under scrutiny there. These test results will be described in a future paper.

Lubricant-impregnated surfaces (LIS) incorporated with the oil supply system for enhanced durability and condensation heat transfer performance

Donghyun Seo, Jaehwan Shim, Choongyeop Lee and Youngsuk Nam*

Department of Mechanical Engineering, Kyung Hee University, Yongin 446-701, Korea

Abstract

Recently, lubricant-impregnated surfaces (LIS) has been introduced as a promising advanced condenser surface due to easy shedding of droplets and rapid clearing of nucleation sites induced by the infused lubricant layer. However, such surfaces have faced the critical limitation on the durability that the oil layer impregnated within surface structures can be depleted during condensation. Here we suggest a LIS condenser integrated with an oil supply system (LIS_O) which can achieve remarkable improvement in the durability and the condensation heat transfer coefficient. The stationary brush, which physically contacts onto the rotational tube condenser, is used to replenish the lost oil onto the LIS surface. The oil in the brush hairs are spontaneously and quickly recharged from the oil reservoir using the principle of the capillary rise effect. Using a controlled environmental chamber, the improved durability and condensation heat transfer of LIS_O are quantitatively compared to the conventional LIS surface. We experimentally demonstrate 86–232% and 26–61% higher condensation heat transfer coefficients compared to the untreated bare and the hydrophobic surfaces, respectively.

Keywords: Condensers; Condensation heat transfer; Lubricant-impregnated surfaces; Oil supply system; Lubricant oil depletion

1. Introduction

The improvement in heat transfer performance of condensers can provide significant energy and cost savings to various energy applications. Recently, lubricant-impregnated surfaces (LIS) have attracted much attention due to very high droplet mobility on LIS resulting from the extremely small contact angle hysteresis (< 5°)[1-3]. A suitable lubricant oil infused into hydrophobic micro/nanostructures offers a smooth and water-repellent interface, facilitating droplet shedding along with rapid reactivation of nucleation sites. Thanks to these advantages, LIS was reported to improve the condensation heat flux by ~400% and ~30% over the conventional filmwise and dropwise condensation, respectively[4-9].

However, there have been concerns about the depletion of the infused lubricant, which is closely linked to the durability of the surface. For example, a shear stress caused by the liquid flow can eliminate the infused oil layer from the surface[10]. Also, due to the difference in the interfacial tensions between the lubricant oil and condensate, a thin oil layer wraps over the condensed droplet, while the oil ridge forms around the droplet. This geometric configuration contributes to the concomitant oil loss when droplets were removed from the surface[4,8]. Nevertheless, few studies have focused on such oil depletion problem during condensation.

In this study, we propose an active oil supply system for tubular LIS condensers, which enable us to achieve remarkable improvement in both the surface durability and the condensation heat transfer coefficient. Our approach, which is schematically shown in Figures 1a and 1b, combine three schemes: the rotational motion

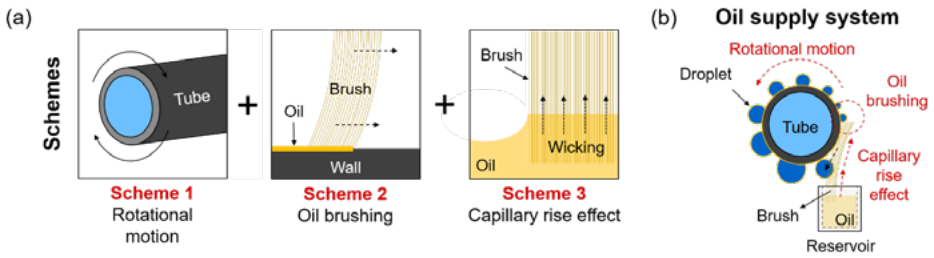

Fig. 1 (a) Concept of the oil supply system. (b) The principle of operation of an oil supply system.

of a tube (Scheme 1), oil brushing (Scheme 2) and oil refilling within brush by capillary rise (Scheme 3). The physical contact between the rotational tube wall and the soft brush hairs ensures lost oil on the condenser to be reliably replenished, while the oil within the brush hairs are spontaneously refilled from the oil reservoir by the capillary rise effect. Note that, in addition to the oil replenishment, LIS_O (LIS incorporated with the oil supply system) can impart additional benefit to heat transfer performance by facilitating the droplet removal via brush sweeping (Fig. 1c). These two characteristics can provide the significant improvement in both the LIS durability and the condensation heat transfer over the conventional LIS.

To evaluate the effectiveness of the proposed schemes, we study the longevity of LIS_O under various condensation rate conditions. Then, a long-term condensation performance of LIS_O: the sliding droplet size and condensation heat transfer coefficient is presented along with those on other control surfaces with different wettabilities, including LIS, hydrophobic surface (HPo) and superhydrophobic surface (SHPo). Unlike other control surfaces, a long-term, stable dropwise condensation mode on LIS_O is maintained up to 48 h without any sign of deterioration.

Then, the improved heat transfer performance on LIS_O over other surfaces is explained based on additional droplet sweeping by brushing. Finally, using a well-controlled environmental chamber, we demonstrate that LIS_O provides the highest condensation heat transfer coefficient (> 72 $kW/m^2 \cdot K$) at a wide range of supersaturation levels, achieving up to 61% heat transfer enhancement over hydrophobic surfaces.

2. Experimental setup and sample fabrication

All condensation experiments are conducted under well-controlled environmental conditions, shown in Figure 2. Non-condensable gases, which significantly deteriorate the condensation heat transfer process by acting as a diffusion barrier for water vapor at the droplet interface, are carefully controlled by using a vacuum pump. A stainless steel frame of this chamber is wrapped by resistive silicone rubber heater lines and then is insulated. A KF flanged bellow connected to an angle valve is integrated on the top of the chamber for a vacuum pump (BT-35A oil rotary vacuum pump, BESTECH). A liquid nitrogen cold trap is connected between the bellow line and the vacuum pump to block the inflow of moisture to the vacuum pump. A pressure gauge (275 Convectron Pirani Vacuum Gauge, MKS) is used to monitor vacuum pressure in the chamber.

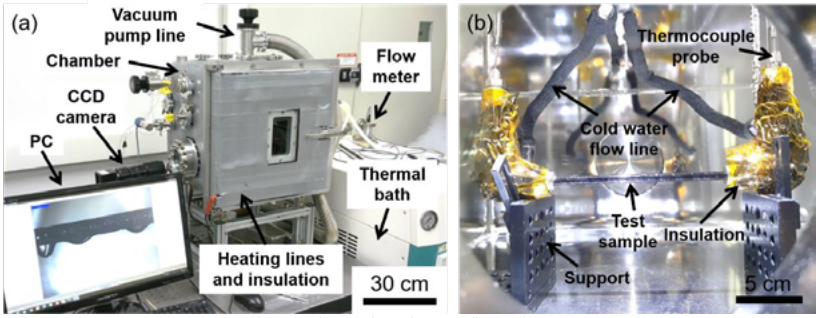

Fig. 2. (a, b) Condensation experimental setup.

Cooling water from a thermal bath (maximum flow rate of 40 L/min, maximum pump pressure of 3.3 bar, cooling capacity of 0.9 kW at 0 °C and temperature accuracy of ± 0.1 °C at 15 °C, Lab Companion, Korea) is circulated along two insulated water flow lines which are fed into the chamber. A flow meter (FLEX-HD1K, Honsberg Instruments, Germany) is integrated to monitor the flow rate.

Degassed water vapor is introduced into the chamber from a stainless steel water reservoir. This reservoir is wrapped by a bend heater and its temperature was controlled by a heater controller. Two needle valves are connected to two stainless steel tubes incorporated with a cover of the reservoir. The first tube is used to fill DI water into the reservoir. This tube line connects the bottom of the reservoir to the ambient. The second tube is used to supply degassed water vapor into the chamber. This tube line connects the top of the reservoir to the inside of the chamber, and it is wrapped by a heating tape.

Tube inlet and outlet temperatures are measured by two thermocouple probes. A saturation vapor temperature in the chamber is measured by a thermocouple probe wrapped with a wet bulb wick. All the thermocouples are calibrated before the experiment. The temperatures and the pressure information are monitored by using DAQ system. Condensation behavior is recorded by a CCD camera.

We use commercially available copper tubes (99.9% purity) with outer diameter, d_o = 6 mm, inner diameter d_i = 4 mm and length L = 125 mm. During all chemical fabrication, the tubes are capped by nipples to prevent any functionalization of their inside. Once capped, the samples are cleaned in an ultrasonic bath with acetone and ethanol for 5 min, respectively and rinsed with de-ionized (DI) water at room temperature. Then the tubes are dipped into a 2.0 M hydrochloric acid solution for 10 min to eliminate any native oxide layers on the surface. Once complete, the tubes are thoroughly rinsed with DI water and then are dried with clean N_2 gas. The CuO nanostructures are fabricated by immersing the cleaned tube inside a hot alkaline solution of ~95 °C composed of $NaClO_2$, NaOH, $Na_3PO_4 \cdot 12H_2O$, and DI water (3.75:5:10:100 wt.%) for 15 min. Sharp and knife-like CuO oxide structures fabricated by this method have height h of 1.0 ± 0.30 μm, pitch p of 300 ± 17 nm, solid fraction ϕ of ~0.023 and roughness factor r of ~10.2. After the oxidation process, the CuO nanostructured tubes are thoroughly rinsed with ethanol and DI water and are dried with clean nitrogen gas.

To render the surface hydrophobic, the samples are coated with self-assembled monolayers (SAMs). The substrates are treated by oxygen plasma to create hydroxyl group on the surfaces, and then they are dipped into a 1.0 wt.% hexane solution of HTMS (1H,1H,2H,2H-Perfluorodecyltrimethoxysilane, Sigma-Aldrich) for 2 h at room temperature. After the SAMs coating processes, the samples are strictly rinsed with ethanol and DI water and then sonicated in hexane for 5 min to remove excess polymerized monolayers on the surfaces. As the conventional LIS, the functionalized nanostructures are fully impregnated with the fluorinated oil of Krytox 1506 (oil-vapor interfacial energy γ_{ov} for Krytox 1506 is ~17 mJ/m^2 at 20 °C). SEM (scanning electron microscope) images of the fabricated CuO nanostructures can be found in the Supplementary Note 6. We chose the Krytox 1506 as the lubricant oil for LIS since it has a very small vapor pressure $P_{v,Krytox}$ of < 10^{-12} mmHg, which allows us to test LIS in our vacuum-based condensation chamber where P_{vacuum} is lowered down to < 0.5 Pa. In addition, Krytox satisfies the essential thermodynamic requirements for forming a stable and water-repellent lubricant interface on the nanostructured surface.

The smooth hydrophilic (Bare) tube for the filmwise condensation is achieved by the oxygen plasma treatment of the cleaned tube for 10 min. The smooth hydrophobic (HPo) tube for the dropwise condensation is obtained by depositing the SAMs on the plasma-cleaned Bare tube.

Advancing θ_a, static θ_s and receding contact angles θ_r for the tested surfaces are follow. Bare: θ_a < 10°, θ_s < 10°, and θ_r = 0°. HPo: θ_a = 123.2 ± 2.7°, θ_s = 111.2 ± 0.8°, and θ_r = 90.7 ± 2.7°. SHPo: θ_a = 168.2 ± 2.9°, θ_s = 167.0 ± 2.1°, and θ_r = 165.9 ± 2.1°. LIS: θ_a = 111.9 ± 1.7°, θ_s = 110.0 ± 1.3°, and θ_r = 108.2 ± 1.4°.

3. Results and discussion

3.1. Durability

We evaluate whether the oil replenishment can help sustain dropwise condensation mode on LIS_O without the oil depletion issue. To quantify the durability of LIS_O, the dropwise condensation behavior on LIS_O is compared with other dropwise condensing surfaces including HPo, SHPo and LIS. Figure 3a compares condensation images of HPo, SHPo, LIS and LIS_O over time at a high supersaturation level of S = ~1.5. All surfaces initially show dropwise condensation; however, HPo, SHPo and LIS undergo the gradual change in condensation mode from dropwise to filmwise condensation due to coating degradation (HPo), flooding (SHPo) or oil depletion (LIS), respectively. The ultra-thin hydrophobic coating layer cannot sustain long-term

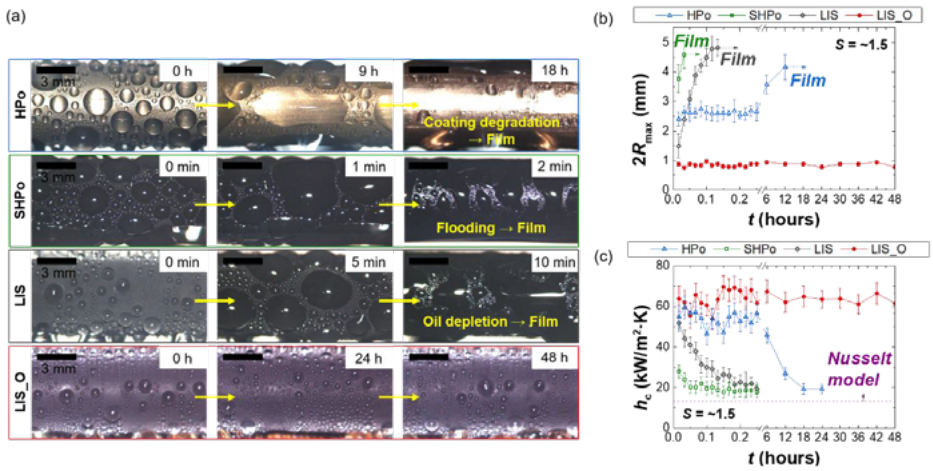

Fig. 3. Oil replenishment effect of LIS_O. (a) Condensation images of hydrophobic (HPo), superhydrophobic (SHPo), LIS and LIS_O over time. (b, c) Changes in $2R_{max}$ and the condensation heat transfer coefficient h_c at S of ~1.5 over time.

dropwise condensation at high supersaturation levels, as shearing by droplet movement and water penetration near the contact line gradually degrade the coating quality[11,12]. The presence of nanostructures on SHPo accelerates the transition into the filmwise condensation since the random nucleation within the nanostructures leads to irreversible surface flooding at a relatively high supersaturation level[11,13]. LIS also suffers flooding after underlying nanostructures are exposed after the complete oil depletion. Stable and long-term dropwise condensation is only observed on LIS_O. LIS_O maintains stable dropwise condensation up to 48 hours without any indication of surface degradation. The high durability of LIS_O can be quantitatively verified by measuring the temporal changes in the maximum hanging droplet size $2R_{max}$ and the condensation heat transfer coefficient h_c over time at S = ~1.5, as shown in Figures 3b and 3c. $2R_{max}$ for HPo, SHPo and LIS markedly increases and finally reaches the maximum value before the transition into the water film. During this transition process, h_c for the surfaces also quickly decreases and approaches to Nusselt model for filmwise condensation. Meanwhile, LIS_O displays nearly invariant $2R_{max}$ and h_c due to the successful oil replenishment by the oil supply system.

The oil replenishment effect is maintained as long as the oil remains in the reservoir, which means that the amount of oil in the reservoir determines the lifetime for LIS_O. We predict the minimum amount of oil required for sustaining LIS_O by measuring the amount of lost oil on LIS. Figure 4 displays the duration time t of LIS as function of the condensation heat flux q_c". In this figure, the symbols denote the experimental data and the solid line indicates the best fit to the experimental data with the correlation of $\log_{10}(t) \propto -\log_{10}(q_c")$. This correlation shows that t is inversely proportional with q_c"; the lifetime for LIS is shortened as the condensation rate increases. Based on t at the different q_c", we deduce the depletion rate of the oil volume such as $v_o = V_o / t$, where V_o is the volume of the impregnated oil. The V_o is given by $V_o = A_{O.D.}\delta_o$, where $A_{O.D.}$ is the tube outer surface area and δ_o is the thickness of oil covering the surface. δ_o is measured by the difference in the mass of the tube before and after oil impregnation (δ_o is ~1.3 μm in this study). This calculation predicts

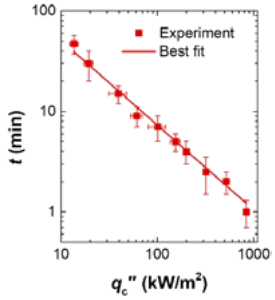

Fig. 4. The durability is evaluated as t as a function of q_c".

that under the present test tube dimension, the amount of the oil loss at q_c" of 839 kW/m^2 is about ~9.9 × 10^{-12} m^3/s, which translates to ~0.58 kg per a year (density ρ_{Krytox} for Krytox is ~1.86 × 10^3 kg/m^3). If condensers are operating in a lower q_c" (= 39 kW/m^2) in the presence of NCGs, LIS_O could work for a year just with < 0.05 kg.

3.2. Heat transfer performance

The heat transfer performance is directly evaluated by measuring condensation heat transfer coefficient h_c at various condensation conditions. Note that the precise measurement of the condensation heat transfer is possible only when NCGs are sufficiently removed from the environment, i.e. P_{vacuum} < 1 Pa. In this pure vapor environment, high q_c" more than 320 kW/m^2 can be obtained, but the heat transfer coefficient of LIS at such a high q_c" cannot be reliably measured because of too fast oil depletion. Therefore, the heat transfer of LIS_O is only compared with Bare, HPo and SHPo. Figure 5a displays representative condensation images of the tested surfaces at S = ~1.5. Figure 5b shows h_c as a function of S. Here, the symbols represent the experimentally measured data and the lines denote the prediction values estimated from the heat transfer model. The heat transfer data shows that LIS_O has the highest heat transfer coefficient at a wide range of supersaturation levels, e.g., h_c for LIS_O is 86–346% and 26–61% higher than HPi and HPo at the tested supersaturation ranges (1.1 < S < 1.6), respectively. Even though SHPo displays the highest h_c at S = ~1.1 by the coalescence-induced droplet jumping, h_c dramatically decreases below the value for LIS_O as a higher S due to the surface flooding limit. As such, LIS_O shows 75–153% higher h_c than the flooded SHPo at 1.1 < S < 1.6.

To understand the heat transfer results, we investigate the heat transfer model that incorporates the thermal resistance model for droplet growth, the emergent droplet wetting morphology, and droplet distribution theory. We obtain the prediction line for LIS_O in good agreement with the experimental data by using experimentally determined the droplet removal diameter $2\hat{R}$ of ~0.9 mm and contact angles. The nucleation density n for LIS_O is determined on the basis of the best fit between the analytical model and the experimental data. The predicted n for LIS_O is achieved by assuming $n_{LIS_O} = 3 \times n_{HPo}$, which means that the stable lubricant interface and the droplet sweeping effect by physical contact of the brush provide ~3 times higher nucleation density on LIS_O compared to HPo. h_c for HPi and flooded SHPo follows the Nusselt model due to the water film formation during condensation. This filmwise condensation provides much smaller h_c compared to dropwise condensation due to the water film acting as the dominant conduction resistance. The higher h_c for LIS_O than that for HPo is attributed to the smaller $2\hat{R}$ and the higher n resulting from the enhanced surface sweeping effect (note that $2\hat{R}$ for HPo is ~2.7mm). The smaller $2\hat{R}$ and higher n result in a higher distribution of smaller droplets, which helps reduce the overall conduction resistance on the surface and promote droplet growth, both of which lead to the increase in heat transfer rate.

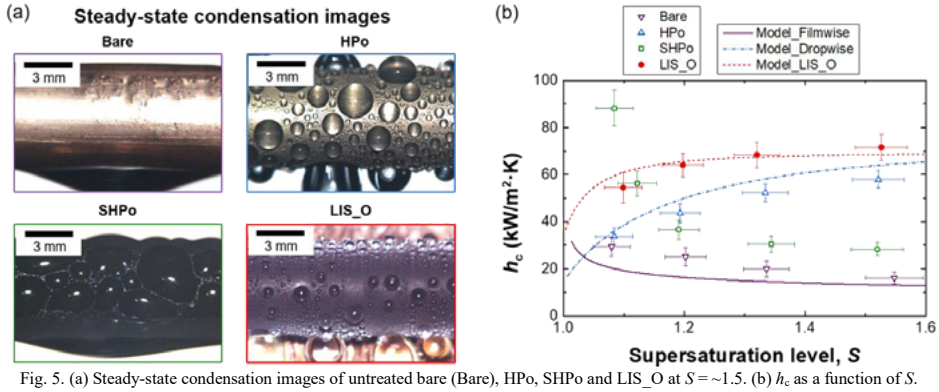

Fig. 5. (a) Steady-state condensation images of untreated bare (Bare), HPo, SHPo and LIS_O at S = ~1.5. (b) h_c as a function of S.

4. Conclusion

In summary, we demonstrated that LIS_O can achieve the remarkable improvement in the durability of LIS by reliably replenishing the depleted oil during condensation, while providing additional benefit to the

condensation heat transfer coefficient by brush sweeping. The traditional LIS suffered the unavoidable oil depletion limit during condensation, while undergoing the rapid degradation in the condensation heat transfer performance. Even typical dropwise condensing surfaces such as HPo and SHPo have showed critical limitations in sustaining long-term high heat transfer performance at high supersaturation levels due to the coating degradation and surface flooding. LIS_O overcomes this critical limit by incorporating the active oil brushing system, which can provide highly durable, superior heat transfer performance at a wide range of supersaturation levels. We believe that LIS_O can be a promising candidate for advanced condenser surfaces of various applications operating at a wide range of supersaturation levels, such as air conditioning, water collection, desalination, distillation towers, heat pipes, and power generation. In addition, we expect that the proposed oil brushing concept can contribute a wide variety of other applications utilizing LIS, such as anti-fouling, anti-corrosion, anti-freezing and self-cleaning, as providing the long-term durable lubricant interface.

Refrigerant circuitry optimization of an outdoor unit heat exchanger based on partial load operating conditions

Shehryar Ishaque[a], Man-Hoe Kim[b]

[a,b]School of Mechanical Engineering & IEDT, Kyungpook National University, Daegu, 41566, South Korea

Abstract

Finned tube heat exchangers have been widely used as a condenser and an evaporator in a residential air conditioning and heat pump system. These heat exchangers are mostly designed based on peak load operating points. Heat pump systems operate considerably for a longer period of time at partial load operating conditions rather than peak load design point. This study investigated refrigerant circuitry optimization based on rated and partial load operating conditions. The achieved optimal refrigerant circuitry for each operating condition is different from the other due to different outdoor conditions. The results revealed that significant performance improvement of 4.70% and 2.40% have been achieved in average heat exchanger capacity using optimized refrigerant circuitry based on the highest weighted partial load operating condition rather than peak load design point in cooling and heating modes respectively.

Keywords: Finned tube heat exchanger; refrigerant circuitry; optimization; partial load; operating condition

1. Introduction

The International Energy Agency (2013) has stated that air conditioning (AC) and heat pump systems account for almost 700 million metric tons of CO_2 equivalent direct (7%–19%) and indirect emissions (74%) per year, which is responsible for global warming and ozone depletion. This percentage is expected to increase drastically in the next half-century as the demand for AC and heat pump systems around the globe is increasing day by day due to the rapid rise in temperature and humidity [1]. Direct emissions can be reduced by introducing low GWP refrigerants, whereas, indirect emissions can be controlled using more efficient heat pump systems [2].

One of the main components of a residential air conditioning (AC) and heat pump system are the finned tube heat exchangers that are used as a condenser or evaporator. Thermo-hydraulic performance of these heat exchangers is influenced by several geometric parameters including tube length, tube diameter, number of tube rows, tube pitch, fin pitch, and fin configuration. One of the important design parameter is the sequence in which the tubes are connected in order to exchange heat efficiently with the air [3]. There are n! possible connections for n number of tubes and is, therefore, not possible to evaluate each design manually. Hence, more sophisticated optimization techniques are required to numerically investigate the optimized refrigerant circuitry. One such method is using a genetic algorithm (GA) that has been employed in Intelligent System for Heat Exchanger Design (ISHED) [4], which produces an optimal refrigerant circuitry for evaporators and condensers based on the applied operating conditions. This tool is commercially available in a simulation package EVAP-COND [5] developed by NIST 2003. It has the capability to cope with different parameters and the non-uniform airflow distribution which results in significant heat exchanger performance improvement [6]. Furthermore, optimal refrigerant circuitry also reduces the size, cost and amount of refrigerant [7-8]. Liu et al also reported an optimization technique to improve heat transfer capacity with minimized cost [9]. Peng et al applied particle swarm algorithm technique on multi-stream plate-fin heat exchangers to investigate the effect of non-uniform inlet flow distribution along with pass arrangement [10].

Most of the heat exchangers up to the date had been designed based on peak load operating conditions that occur for about 1%-2.5% of the year. Such heat exchangers performs well under rated load condition but are generally oversized and ineffective in conditions other than peak load [11]. Therefore, the focus has been shifted on maximizing part-load efficiencies of the heat exchangers which required peak load operating point

* Corresponding author: Man-Hoe Kim. Tel.: +82-53-950-5576; fax: +82-53-950-6550.

alongside the load profile [12]. Outdoor unit heat exchangers are exposed to environmental conditions that keep changing throughout the year. A refrigerant circuitry is sensitive to non-uniform airflow distribution along with other geometric and operating conditions. In many cases, the heat exchanger optimization process focuses on identifying refrigerant circuitry that provides the maximum heat transfer rate for given environmental constraints [13,14]. Thus, optimized refrigerant circuitry based on one set of technical and operating conditions may not perform well in other conditions. Therefore, the current study emphasizes developing an optimized refrigerant circuitry based on partial load operating conditions with the highest weighting factor that leads to significant heat exchanger seasonal performance improvement.

2. Physical description

Finned tube heat exchangers have been used as an outdoor unit with refrigerant R410A as a working fluid, inside the tubes circulating throughout the closed cycle. It consists of three depth rows with 30 tubes in each row. Louver wide fins have been used in the current study. Figure 1 is a basic model showing refrigerant flow path, with red circles indicating the inlets and blue circles indicating the outlets. The lower graph of air flow velocity distribution serve as an input to the EVAP_COND [5] in order to solve heat exchanger along with other geometric details i.e. tube length, tube diameter, fin pitch, etc. as given in Table 1.

Table 1. Geometric details of outdoor unit heat exchanger

Items	Outdoor unit
No. of tube rows	3
No. of tubes per row	30
Tube length	1720 mm
Tube inner diameter	6.3 mm
Tube outer diameter	7 mm
Fin pitch	1.7 mm
Fin thickness	0.092 mm
Fin type	Φ7 Louver(Wide)
Airflow	Non-uniform

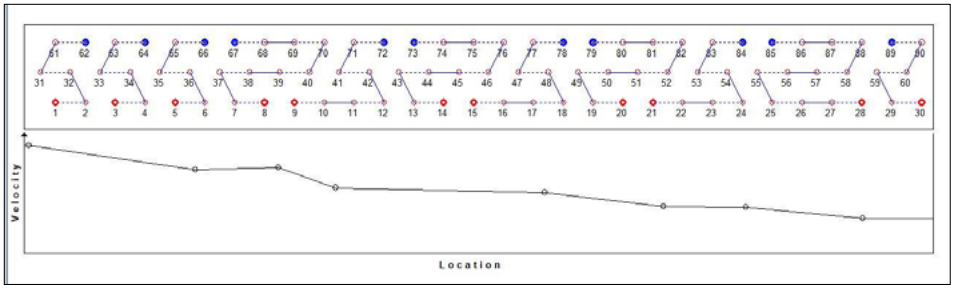

Fig. 1. Refrigerant path of outdoor unit heat exchanger used as a basic model

3. Operating conditions

Outdoor unit of a heat pump systems are exposed to environmental conditions and non-uniformly distributed air flows interact with the tubes. The magnitude and distribution of the flow velocity varies for each seasonal outdoor condition [15]. Heat pump and air conditioning systems operate in different outdoor seasonal conditions throughout the year. The actual weighting factor of the partial load operating condition is difficult to determine as it depends on the application and environment conditions of the AC and heat pump system. Alternatively, few standards are used nowadays, for better determination of the reflecting time of each load condition. One such method adopted in the current study is to utilize the weighting factors of the European standard EN14825 to calculate the average heat exchanger performance as given in Eqs. (1) and (2) for cooling and heating standards.

$$SEER = 0.03A + 0.33B + 0.41C + 0.23D \quad (1)$$

$$SCOP = 0.03A + 0.24B + 0.23C + 0.5D \quad (2)$$

where A, B, C, and D represent EER under 100%, 75%, 50%, and 25% load conditions for cooling mode and 100%, 84%, 51%, and 33% load conditions for heating mode respectively. Detailed partial load operating conditions in cooling and heating modes are summarized in Table 2 and Table 3.

Table 2. Partial load operating conditions in a cooling mode

S No	Part load ratio	Dry bulb Temperature (°C)	Wet bulb Temperature (°C)	Weighting coefficients	Airflow rate (m^3/min)	Average airflow velocity (m/s)	Refrigerant mass flow rate (kg/h)
Case 1	100	35	30	3%	182	3.18	430

Case 1	100	-7	-8	3%	149	2.61	176
Case 2	84	2	1	24%	135	2.36	159
Case 3	51	7	6	23%	86	1.50	95
Case 4	33	12	11	50%	65	1.14	65

4. Numerical methodology

The current study has been carried out using commercially available software EVAP-COND version 4. This program uses the tube by tube method, where outlets from the first tube are considered as inputs to the second tube, and the outlets of the second tube are considered as an inlet to the third one and so on. Parametric tube details; inlet conditions, properties, and mass flow rates for air and refrigerant are known parameters and provide input for the first tube. Airside heat transfer rate can be expressed as Eq. (3)

$$Q_a = \dot{m}_a C_{p_a} \left(DBT - T_{ri}\right)\left(1 - \exp\left(-\frac{U_{an} A_i}{\dot{m}_a C_{p_a}}\right)\right) \quad (3)$$

where $\dot{m}_a$ is the air mass flow rate, C_{p_a} is the specific heat capacity of air-side, DBT is the air dry-bulb temperature, T_{ri} is the refrigerant inlet temperature, where U_{an} is the overall heat transfer coefficient, A_i is the surface area exposed to air. Based on heat transfer, outlet parameters are evaluated, with subsequent pressure drop calculations across each circuit.

Refrigerant side heat transfer and pressure drop correlations are based on flow quality i.e. annular flow ($0< x \leq 0.8$), dispersed flow ($0.8< x \leq 1$) or superheated flow ($x>1$). Overall heat transfer coefficient can be calculated using Eq. (4).

$$1/U_{an} = R_t = R_i + R_t + R_o + R_f = \sum R \quad (4)$$

where U_{an} is the overall heat transfer coefficient, R_t is the total thermal resistance, R_i is the inside tube resistance, R_t is the tube thermal contact resistance, R_o is the outside tube resistance and R_f is the fin to tube contact resistance. These variables are defined as follows,

$$R_i = \frac{A_i}{A_{i_ht} h_{an}}, R_t = \frac{A_i t}{A_{pm} k_t}, R_o = \frac{A_i}{A_{o_ht} h_{co}}, R_f = \frac{1}{h_t (1 - \frac{A_{fs}}{A_i})(1 - \phi)}$$

where A_{fs} is fin surface area, A_{i_ht} is tube inside surface area, A_{pm} is mean surface area, A_{o_ht} is tube outside surface area, t is tube thickness, k_t is tube thermal conductivity, h_{an} is inside tube heat transfer coefficient, h_{co} is air side heat transfer coefficient, ϕ is the fin efficiency. Two phase heat transfer coefficient can be found using Gungor Winterton [16] correlation as given by Eq. (5).

$$h_{an} = Eh_l + Sh_{pool}, \tag{5}$$

where E is the enhancement factor, h_l is the liquid heat transfer coefficient, S is the suppression factor, and h_{pool} is pool boiling heat transfer coefficient. Similarly air side heat transfer coefficient for louvered fins can be calculated using Eq. 6.

$$h_{co} = \frac{jGC_{pa}}{\Pr^{\frac{2}{3}}}, \tag{6}$$

Where j-factor for louvered fins can be found using J. Dong [17] air-side heat transfer coefficient correlation. G is refrigerant mass flux, Pr is the Prandtl number and C_{pa} is the specific heat capacity of air-side. Finned tube heat exchangers have several numbers of refrigerant circuits, with different lengths. Hence each circuit will have different refrigerant mass flowing through it. Fraction of refrigerant through each circuit can be expressed as Eq. (7)

$$F_i = \frac{m_i}{m_{tot}} = \frac{1}{\sum_{j=first}^{last} \left(R_i / R_j \right)^{0.571}}, \tag{7}$$

where $R_i = \Delta P_i / \Delta G_i^{1.75}$ is the total refrigerant flowing through the i-th circuit, $R_j = \Delta P_j / \Delta G_j^{1.75}$ is the total flow resistance for all branches splitting from that point. The first iteration loop estimates R_i. Resistance in each tube is assumed to be the same regardless of flow quality. Therefore, initial Ri depends on the number of refrigerant circuits and their paths. Subsequent iterations update R_i and F_i values. Iteration continues until the pressure drop across each circuit becomes uniform.

5. Results and discussion

ISHED is an optimization tool that provides optimized refrigerant path with maximum heat exchanger capacity as an objective function. Figure 2(a) shows optimized designs for different outdoor cooling conditions according to the European standard EN14825. Each optimized design differs from the other based on non-uniform airflow velocity distribution, outdoor air temperature, and refrigerant mass flow rate. In each case, different flow velocity profile interacts with the tubes which leads to different optimized design. Figure 2(b) shows a significant increase of 4.64%, 6.97%, 4.42%, and 10.36% in heat exchanger capacity for optimized designs as compared to the basic model under cooling conditions A, B, C, and D respectively.

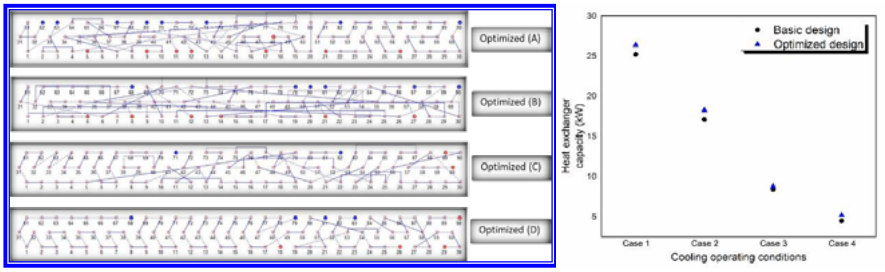

Fig. 2. Cooling mode (a) Optimized refrigerant paths, (b) Heat exchanger capacities for each optimized design

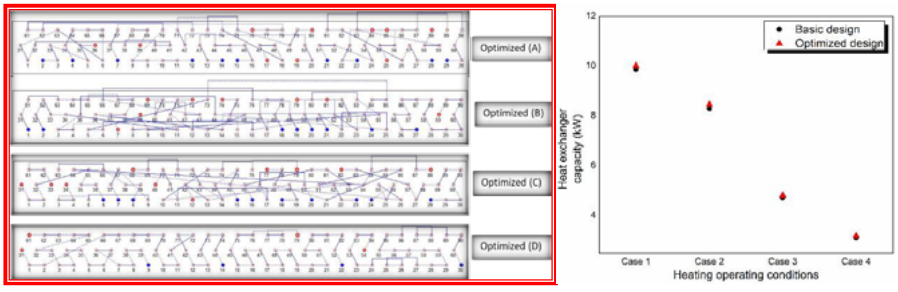

Fig. 3. Heating mode (a) Optimized refrigerant paths, (b) Heat exchanger capacities for each optimized design

Figure 3(a) shows optimized designs for different heating conditions according to the European standard EN14825. The optimized designs differ from the cooling mode as the outdoor operating conditions are changed. Figure 3(b) shows a significant increase of 1.52%, 2.05%, 2.96%, and 2.25% in heat exchanger capacity for optimized designs as compared to the basic model under heating conditions A, B, C, and D respectively.

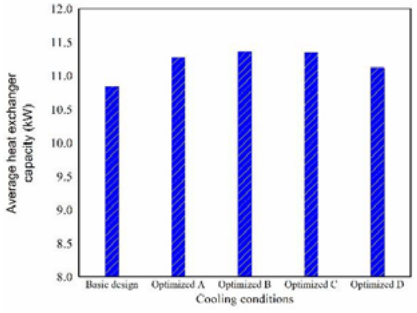

Fig. 4. Average heat exchanger capacities for each optimized design in cooling mode

Heat exchangers worked under different load conditions and are usually designed based on rated load conditions that worked for about 1%-2.5% of the time. In order to choose an optimal refrigerant path, the best approach is to determine an optimized refrigerant circuitry that worked well under all conditions. One similar approach is used here by finding the optimal refrigerant paths for all partial load operating conditions. Once all optimized paths have been achieved, the same paths are used for each condition and the average cooling capacities based on their weighting factors are calculated. Although it is difficult to accurately reflect the operating time under each load condition as it varies with respect to the application and environmental conditions. Alternatively, European standard EN14825 has been utilized to emphasize on the importance of refrigerant circuit optimization based on the most weighted load factor.

In the current study, the same outdoor unit has been optimized for all operating conditions and based on their weighting factor the average heat exchanger capacities have been calculated using Eq. (1). Figure 4 reveals that refrigerant circuitry optimized for the partial load operating condition with the highest weighting factor can significantly increase up to 4.70% in the average heat exchanger cooling capacity. Heat exchanger

capacities based on weighted load factor does not increase linearly with optimized designs. A maximum heat exchanger capacity has been found for using optimized design B in all conditions. Similarly, optimized design C is also better than optimized design A and D because the performance under part-load conditions of B and C were more highly weighted than the others. Therefore, it is recommended to use an optimized refrigerant circuitry based on the highest weighting factor throughout the year instead of the peak load.

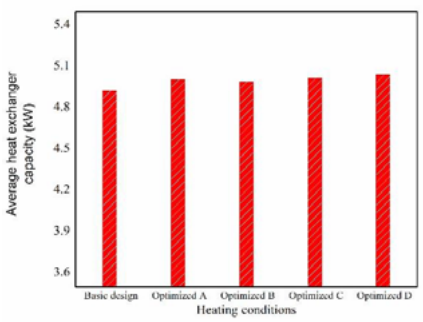

Fig. 5. Average heat exchanger capacities for each optimized design in heating mode

Similarly, Fig. 5 shows the average heat exchanger capacities using optimized designs A, B, C, and D. Each optimized design is tested for all four partial load operating heating conditions and the average heat exchanger capacity in each case has been calculated using the weighting factors of Eq. (2). The results reveal that the average heat exchanger capacity based on an optimized design for the highest weighted factor can improve heat transfer performance up to 2.4%. Sometimes the optimized design based on rated load condition shows more improvement but that is not realistic as the same design performs poorly in other more weighted partial load conditions.

6. Conclusion

The current study has been carried out to determine an optimized refrigerant path of an outdoor unit heat exchanger under rated as well as partial load operating conditions. One basic outdoor unit heat exchanger model has been selected with non-uniform airflow distribution. Heat exchanger capacity has been determined using a commercially available software EVAP-COND. The built-in refrigerant circuitry optimization tool ISHED was utilized to find the optimal refrigerant paths for all partial load operating conditions. Each partial load operating condition is applied to the obtained optimized designs. Average heat exchanger capacities have been calculated using weighting factors of the European standard EN14825. The findings of the present study have been listed below.

- A significant increase of 4.64%, 6.97%, 4.42%, and 10.36% in heat exchanger capacity have been achieved for optimized designs as compared to the basic model under cooling conditions A, B, C, and D respectively.
- A significant increase of 1.52%, 2.05%, 2.96%, and 2.25% in heat exchanger capacity have been achieved for optimized designs as compared to the basic model under heating conditions A, B, C, and D respectively.
- A maximum percentage increase of 4.70% has been achieved in average heat exchanger capacity using optimized refrigerant circuitry based on the highest weighted factor among the partial cooling loads.
- A maximum percentage increase of 2.40% has been achieved in average heat exchanger capacity using optimized refrigerant circuitry based on the highest weighted factor among the partial heating loads.

The current study is limited to the optimization of refrigerant circuitry using ISHED that optimized the refrigerant path for a single condition at a time. Further studies will extend the matrix by optimizing different geometric parameters based on the partial load operating conditions rather than a single peak load. Designing heat exchangers based on rated as well as partial load conditions can reduce huge energy consumption. A similar idea can also be extended to other types of heat exchangers used in industrial applications.

Status on the Electric-thermal Energy Storage Technology and Application of a Supercritical Carbon Dioxide Power Cycle

Junhyun Cho[a], Chulwoo Roh[a], Hyungki Shin[a], Gilbong Lee[a], Bongsu Choi[a], Jongjae Cho[a], Beomjoon Lee[a], Ho-Sang Ra[a], Young-Jin Baik[a,*]

[a]Thermal Energy Systems Laboratory, Korea Institute of Energy Research, Daejeon 34129, South Korea

Abstract

A large-scale energy storage system becomes more essential as a proportion of the renewables increases in the future electricity supply mix. Intermittent electricity supply characteristics by renewables causes instability of a grid, therefore electricity time shift technologies are needed. Batteries are representative electricity energy storage system, however, it is hard to expand for large-scale system, because of high cost, short discharge duration characteristics. The electric-thermal energy storage technology, recently called as a Carnot Battery, has been focused as a solution for the large-scale grid level energy storage applications, because it uses conventional robust heat engine technologies suitable for large-scale system. It is composed of electricity-to-heat, heat storage and heat-to-electricity system. In case of heat-to-electricity, a supercritical carbon dioxide power cycle (sCO2) is attractive option because of its potentials of wide operation range, dry-cooling, high efficiency and small foot print. Korea Institute of Energy Research (KIER) has been developed a sCO2 power cycle test loop with the turbomachinery. In this paper, concept of the electric-thermal energy storage and the technical development highlights of the sCO2 power cycle in KIER are presented.

Keywords: Carnot Battery, Electric-Thermal Energy Storage, ESS, Supercritical Carbon Dioxide Power Cycle

1. Introduction

The interest in renewable energy sources (RES) such as solar and wind has been growing due to its climate change mitigation and economic benefits. Based on REN21's 2018 report, RES accounted for approximately 18.2% of global energy consumption and the ratio have been rising gradually. In addition, in 2017, South Korea's Ministry of Trade, Industry and Energy announced the "Renewable Energy 3020" implementation plan which aims to increase a share of renewable energy from 7% to 20% of the total energy mix by 2030. Therefore, Korea will need additional 63.8 GW capacity of renewable power sources which is similar to present Korea power plant capacity (~100 GW) in 2030.

Energy storage systems (ESS) are essential because of the intermittent power generation features of renewable generation sources that can generate electricity only when the sun is there and when it is windy. The battery-based small-capacity energy storage system is applied to the small-scale new renewable power generation source, and serves as voltage correction and frequency adjustment. However, if large-scale renewable of GW class are introduced in the future, a commercially appropriate large-capacity energy storage system is required. Obviously, this will be limited by existing high-cost battery-based storage devices.

Therefore, in order to continuously use these large-capacity renewable energy sources with reliability and stability of the electric grid, low-cost, long-term energy storage devices are required. In this way, it is necessary to develop a large-capacity energy storage device that can make a time-shift of intermittent power generation at the grid level to enable renewables as a base power source uses.

Electrochemical energy storage technologies such as a battery, a super-capacitor and a flow battery have characteristics of high efficiency, high energy density, no geographic limitation and relatively simple configuration. However, the system capacity is several kW-MW, the capacity is limited to cope with the grid and the discharge time is under several hours so that it is limited to use for a long-term storage purpose. Therefore, these are suitable for voltage correction/frequency adjustment with short discharge time. The efficiency is high, but the cost corresponding to LCOE (Levelized Cost of Electricity) is about 10 times of the pumped storage hydropower (PSH) [1].

Recently, a Carnot Battery concept is proposed for a large-capacity energy storage system. The Carnot cycle is a reversible heat engine thermodynamic cycle, the Carnot Battery uses thermodynamic cycles for the purpose of electricity storage. To use a power cycle when the ESS system generates electricity, the electricity has to be stored as a thermal type which is enough to drive a turbine. Therefore, an electric heater or a heat pump have to be used to convert the electricity to the heat. The heat pump is well known thermodynamic system for efficient heat conversion. The electric heater is simple and cheap conventional technology.

Currently, 70% of the electricity used in Korea is obtained by the steam turbine power generation cycle method that generates electricity by using steam from coal and nuclear fuel to drive turbines, and 22% is gas turbine power generation cycle is used in which the turbine is driven by high temperature air obtained from the heat of combustion of natural gas [2]. In other words, 92% of electricity is obtained through thermal-power conversion heat engine technology: power cycle, which is suitable for a large capacity plant of hundreds of MW.

In this point of view, energy storage systems that can cope with future GW-class distributed power supply systems should use technically and commercially proven power cycle technology, and have a minimum unit of several MW to several hundred MW system. Therefore, when the surplus electricity generated from the renewable is stored in the form of a large amount of thermal energy in the conditions that can generate electricity by driving a turbine, which means the Carnot Battery, it is possible to implement an energy storage system capable of low-cost/long-term power generation.

It is early stage of research, so in this paper as an introductive purpose, the concept of the Carnot Battery, technical issues and its status of global research trends are described. There are several configuration of the Carnot Battery corresponding to the heat storage temperatures, various types of heat pumps and power cycles can be used. A supercritical carbon dioxide power cycle (sCO2) which is recently studied for a promising power cycle, is attractive option for the Carnot Battery due to its high efficiency, small footprints, fast response, dry cooling and wide heat source temperature range. A turbine, a compressor, a heat exchanger and thermodynamic devices for the supercritical carbon dioxide could be also used for the supercritical carbon dioxide heat pump for the Carnot Battery. Korea Institute of Energy Research (KIER) have developed core technologies of the sCO2 from 2013. And KIER try to apply sCO2 to the Carnot Battery. Brief research history and accomplishments of sCO2 in KIER are described.

2. Carnot Battery

The Carnot Battery as shown in Fig. 1 is composed of three parts: electricity-to-heat, heat storage and heat-to-electricity sub-systems. The methods of heat-to-power are (1) electric heater and (2) heat pump technology. The electric heater is a relatively simple method of converting electricity into heat to drive a heat engine. In this case, efficiency of the conventional resistive electric heater is 95-98%, then, the thermodynamic charge-discharge round-trip efficiency (RTE) is dominantly affected by efficiency of the heat-to-electricity unit which is a power cycle. In case of power cycle, ideal thermodynamic efficiency is expressed as a Carnot efficiency according to the heat source and sink temperature, in this case, the storage temperature. If a practical maximum efficiency of the power cycle is near 70% of the Carnot efficiency as temperature, at least 800℃ heat storage is required to actually implement a 50% of RTE system. The heat engine that can be used above 800℃ is a combined gas turbine power cycle. When the electric heater is used as the charging technology for simple configuration, a layout in which ultra-high heat storage and gas turbine power cycle can be used.

On the other hand, if power cycle (discharge) using a high temperature heat storage and convert to a low temperature storage, then a low temperature heat can be pumped back to a high temperature heat by using a heat pump (charging), as shown in Fig. 1. Assuming an ideal reversible process without loss (Carnot cycle), a closed charging-discharging cycle without energy loss can be configured, so called as a Carnot Battery. However, due to the presence of irreversible losses (heat losses, mechanical losses, etc.) in the actual energy utilization process, the actual round-trip efficiency of the charging and discharging process decreases.

When the layout using a heat pump is actually implemented, proper high and low temperature storage configuration is an important technical issue because trade-off of heat pump performance expressed by a

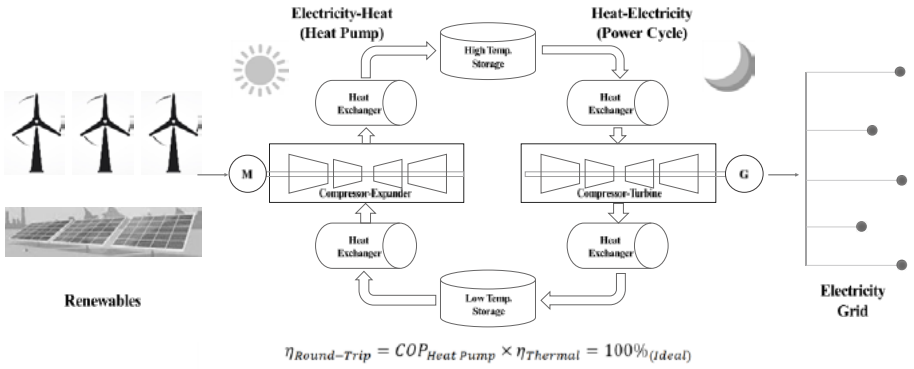

Fig. 1. Concept of the Electric-thermal energy storage system [3]

coefficient of performance (COP) and power cycle efficiency occurs. For example, if the high temperature heat storage temperature is increased to increase the efficiency of the power cycle unit, the COP of the heat pump will be reduced. This layout can be configured using by conventional steam power generation system of turbine inlet temperature 500-600℃, but there is a new technical issue of the development of ultra-high temperature heat pump. The current maximum production temperature of conventional heat pump is about 180℃ based on compressor discharge temperature by using a refrigerant.

Heat storage medium is also a technical issue. In case of high temperature heat storage, it is important to select a heat storage material according to the heat storage temperature. In case of molten salt, which is currently being used in Concentrating Solar Power (CSP) application, the operating temperature is about 280-550℃. Therefore, the molten salt is used in combination of a steam power cycle using the sensible heat of molten salt. Sand or rock may be used to store the high temperature of 800℃ or higher, which has the advantage of being inexpensive but has a disadvantage of poor heat exchange performance. In addition, the power cycle (discharge) system, the heat pump (charging) system, the low temperature heat storage material, the heat exchanger types are changed according to the temperature of the low temperature storage device, and thus, various system layouts can be configured according to the configuration and operating conditions of the entire cycle. [3]

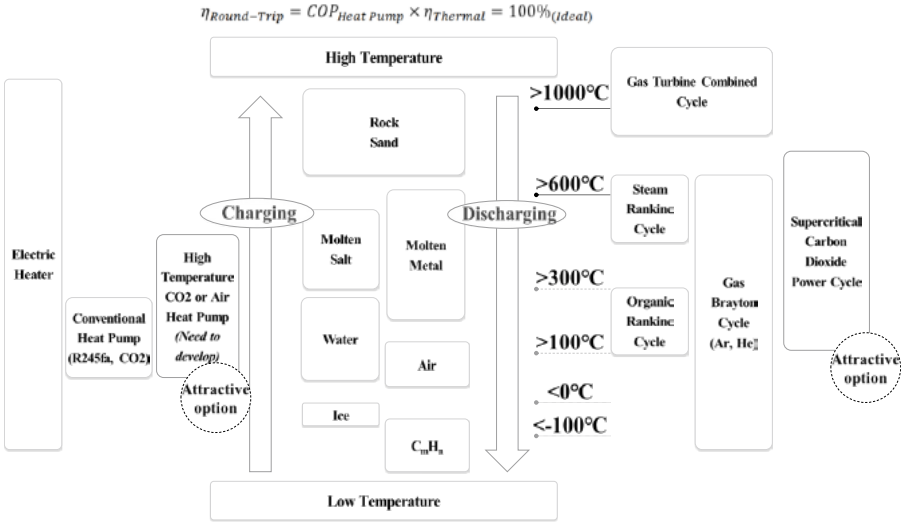

Fig. 2. Technical candidates for an electric-thermal energy storage system according to temperature [3]

Figure 2 shows technical candidates for the Carnot Battery system according to temperature. In case of thermal storage medium, a molten metal such as Tin, Sodium can be used for relatively wide operation range of the power cycle. Water is the attractive thermal storage medium due to its advantages of low cost, stability,

reliability and safety for relatively low temperature range for high temperature storage. In that case, an organic Rankine cycle (ORC) and a supercritical carbon dioxide power cycle (sCO2) can be used. Although efficiency of the power cycle is low due to low heat source temperature, the COP of the heat pump is high, therefore, RTE can be achieved by using a conventional heat pump devices.

Gas Brayton cycle using an Ar or Ne or He is possible power cycle which can make wide temperature differences between hot side and cold side of heat storage. In particular, this layout can utilizing cryogenic heat sink, so temperature difference between high and low temperature of the power cycle could be increased which means it can get a better power cycle efficiency.

Recently, a supercritical carbon dioxide power cycle has been focused on a promising power cycle technology due to its advantage of high efficiency, reduced size, small foot-print, fast response, low cost, dry-cooling, and wide operation range suitable to various heat sources. In addition, core components of the sCO2 power cycle such as a turbine, a compressor, a heat exchanger, a valve, a pipe and so on could be applied in the high temperature supercritical carbon dioxide heat pump. Therefore, a sCO2 heat pump-sCO2 power cycle Carnot Battery layout is possible.

An important consideration in this Carnot Battery concept is the cost issue. It is important to evaluate the leveled cost of storage (LCOS) value considering the costs of charging and discharging stages as well as heat storage. Economic Carnot Battery will survive in the future large-scale capacity ESS market because it will utilize surplus or cheap electricity in the off-peak time and then generate electricity in the peak time. Therefore, LCOS of Carnot Battery is a key factor for electricity time shift in the electricity grid. Since this value is determined by the hot/cold operating temperature of the cycle, the cycle working fluid, the heat storage system and the cycle layout, the optimal cycle design to minimize the LCOS value is a major technical issue. [3]

3. Research Trends

The Carnot Battery which utilize the heat pump and the heat engine for large-capacity ESS have been studied recently, and now preliminary feasibility studies were started by governments and global power system companies.

In terms of the heat pump, a supercritical or transcritical carbon dioxide heat pumps were considered by GE and ABB.

GE investigated a hybrid type of Carnot Battery using the electric heater and the supercritical carbon dioxide heat pump cycle as a part of power-to-heat unit as shown in Fig.3. Since this configuration utilize the conventional steam power cycle in the heat-to-power part that turbine inlet temperature of near 500℃, the

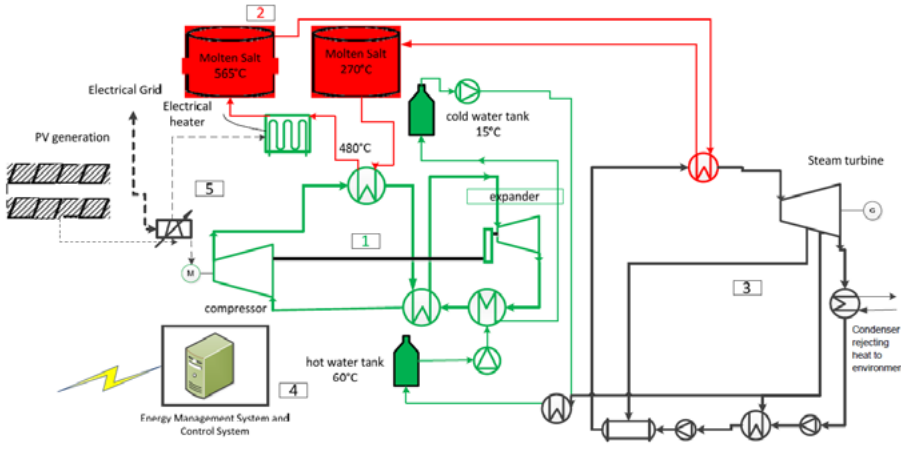

Fig. 3. GE's Carnot Battery concept using a supercritical carbon dioxide heat pump [4]

molten salt is used as a high temperature heat storage like CSP application. The molten salt storage uses

sensible heat transfer between about 250-550°C, a supercritical carbon dioxide heat pump in attractive because heat exchange profile is well matched with a sensible heat application. Also, natural refrigerants have to be used in such high temperature application of the heat pump. However, there is no high temperature supercritical carbon dioxide heat pump in these days yet, so GE suggest additional electric heater for power-to-heat purpose reducing development risk of a high temperature of supercritical carbon dioxide heat pump. [4]

ABB investigated the carbon dioxide heat pump in the Carnot Battery, however, a Transcritical carbon dioxide heat pump and a Transcritical carbon dioxide power cycle are configured as shown in Fig.4. Since, about 120°C temperature of carbon dioxide heat pump is conventional technology, all commercially available thermodynamic systems are easily configured in this Carnot Battery concept. A -2°C ice storage is used for low temperature storage. The RTE of commercial scale this Carnot Battery is evaluated up to 65% from their calculation, however, a carbon dioxide expander, a compressor and a turbine have to be developed sophisticatedly for commercialization. [5]

Recently, preliminary pilot plant scale Carnot Battery system have being constructed in Germany by Siemens. A rock is used as a high temperature heat storage, an electric heater is used for power-to-heat unit and a conventional steam power cycle is used for heat-to-power. It has lower RTE because it uses an electric heater than a heat pump, however, it is very cheap and simple so that LCOS is favourable.

US DOE have started feasibility concept studies for various Carnot Battery system layouts. NREL is investigating an electric heater – sand – gas turbine combined cycle, Brayton Energy is investigating a molten salt-gas Brayton cycle concept and Echogen is investigating concept using a supercritical carbon dioxide power cycle. [6]

DLR in Germany, has started a project for the Carnot Battery technology focusing on the power plant retrofit. Since, a coal-fired or a nuclear power plant have a steam power block so the Carnot Battery configuration would be easily constructed by substituting a boiler or a nuclear steam generator to a heat pump or an electric heater. [7]

A project called Malta, which is being promoted as a future technology by Google (Google Project X), is a Laughlin-Brayton Carnot Battery that stores electricity in the form of thermal energy in molten salt and discharges it into the power generation cycle. The company is developing the Brayton cycle and has designed the turbomachinery required for the system. [8]

4. Supercritical Carbon Dioxide Power Cycle (sCO2) in KIER

In these Carnot Battery concepts, a supercritical carbon dioxide power cycle (sCO2) is an attractive option for both medium-high and low temperature of hot storage source. In addition, small foot print of the sCO2 system due to high pressure operating condition makes Carnot Battery to be compact and modular design. Dry-cooling is also important advantage of the sCO2 because lots of PV complex would be constructed inland area.

Korea Institute of Energy Research (KIER) has developed a fundamental sCO2 test loop from 2013, now, KIER is operating a kWe-class and a tens of kWe-class sCO2 experimental test loops and is commissioning the final hundreds of kWe-class test loop. In this paper, brief descriptions of our test loops are presented.

(1) kWe-class, 500°C turbine inlet temperature (TIT), Transcritical test loop, Radial turbo-generator
(2) tens of kWe-class, 200°C turbine inlet temperature, Transcritical test loop, Axial turbo-generator
(3) hundreds of kWe-class, 500°C turbine inlet temperature, Dual Brayton test loop, 2 Axial turbo-generators, Centrifugal compressor

Figure 5 and 6 show a kWe-class for 500°C TIT(turbine inlet temperature) radial turbo-generator, a tens of kWe-class for 200°C TIT axial turbo-generator its test loops with operational results respectively.

Both test loops were developed as a transcritical cycle by using a liquid carbon dioxide pump for focusing on the developing a turbo-generator driven by a supercritical carbon dioxide, investigating cycle characteristics and developing operation and control strategy of sCO2 cycle.

In case of small kWe-class turbo-generator, a radial type of turbine was designed with a 10% of partial admission nozzle to reduce rotational speed of the rotor. Designed rotational speed was a 120,000 RPM. An angular contact ball bearing lubricated by oil mist was installed to support both radial and thrust force of the rotor due to high operating condition of the sCO2 turbomachinery. Designed capacity of the turbine was a 4.5 kW without mechanical loss.

The main components of the test loop are two pumps, a turbo-generator, two immersion type of electric heaters, a printed circuit heat exchanger (PCHE), a recuperator, a settling chamber, a chiller, and pressure vessels. The two pumps pressurized liquid CO2 into supercritical state. The supercritical CO2 flows through

the recuperator and is heated by the residual heat of turbine outlet flow. In the two electric heater, CO2 is more heated until the turbine inlet condition is reached and then, its flow characteristic becomes uniform at the settling chamber. Next, the heated sCO2 drives the turbo-generator by the expansion work and the generated power is measured with a power meter. In the turbine outlet, because the supercritical CO2 still has a large amount of energy, it is cooled down at the recuperator. In the cooler PCHE, it is cooled to make a pump inlet condition which is equal to the minimum temperature of the cycle. A separator is used to divide two phase CO2 into liquid and gas because pump can pressurize the liquid CO2 only. A reservoir and an inventory are used to control the filling amount of CO2 in the test loop.

In 2017, power generating operation was successful, a 287 We of electricity was obtained at TIT of 401℃. There were rotordynamics issues induced by high axial force at high temperature and high rotating speed condition. After modification, a 30 minutes of continuous power generating results were obtained over 300℃ of TIT condition.

Through this very small sCO2 test loop, basic characteristics of closed sCO2 cycle were investigated. In particular operation strategy of sCO2 cycle was developed including inventory control to fine proper mass flow rate of working fluid. [9]

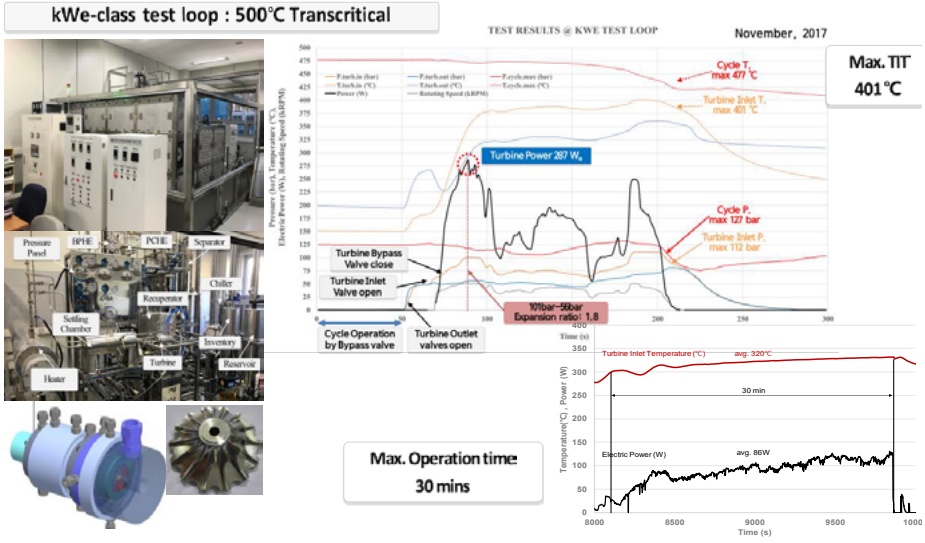

Fig. 5. 500℃ kWe-class radial turbo-generator and Transcritical test loop with operation results

Figure 6 shows a tens of kWe-class for 200℃ TIT axial turbo-generator and its test loop. The axial turbo-generator was actually designed for 392℃ TIT condition for KIER's final target test loop. Before constructing whole test loop, the low temperature turbine was firstly fabricated and was tested under off-design condition by using existing test facilities. In this approach, in order to overcome reported failure problems of the radial-type turbine induced by high rotational speed and axial force, an axial-type impulse turbine and partial admission nozzle was designed and manufactured to reduce the rotational speed by up to 45,000 RPM, as well as the axial force. Thereafter, the turbine wheel part was separated by carbon ring-type mechanical seals to use the commercial oil-lubricated tilting-pad bearings. As these bearings place a limitation on the rotational speed, it was important to reduce the shaft rotational speed. The rotor mean diameter was 73 mm and the blade height was 8.36 mm. A 60 kWe permanent magnet (PM) generator type was also designed. Using an axial-type turbine with a mechanical seal similar to the dry-gas-seal and oil-lubricated bearings, the design is meaningful as it can be applied to further MW-scale turbo-generator designs.

In order to develop a step-by-step, systematic technology, a transcritical cycle was constructed at the turbine inlet at 200°C in one step, and the turbine was operated to obtain data under relatively stable temperature conditions through power production operation. The maximum temperature was 200°C as the first step target, which is a relatively mild condition for the piping, valves, and pressure vessels of the system. Liquid CO2 at 20°C, 57 bar, and 1.566 kg/s was pressurized into a supercritical state at 135 bar using a plunger-type reciprocating liquid CO2 pump (Catpumps, USA) with an inverter-controlled electric motor in order to

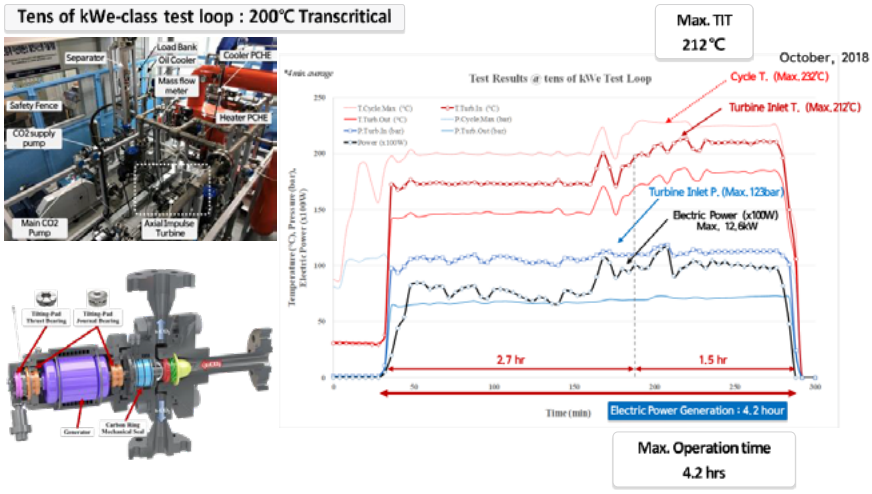

Fig. 6. 200℃ tens of kWe-class axial turbo-generator and Transcritical test loop with operation results

test the various flow conditions. An LNG-fired thermal oil boiler heated the CO2 to 200°C through a printed circuit heat exchanger (PCHE), and after driving the turbine the CO2 was cooled through the PCHE.

In order to use a technically stable oil-lubricated bearing, a mechanical seal was installed in the turbo-generator, which inevitably leads to turbine leakage flow. In the current turbo-generator design, a 2 to 3% leakage flow was estimated; therefore, the leakage management system was constructed to re-inject CO2 into the system. An oil separator, cooler, and buffer tank were constructed for cooling the hot leakage flow and removing incoming bearing oil. A three-stage reciprocating oil-free-type CO2 compressor was constructed for pressurizing up to 80 bar in order to recharge the atmospheric leakage flow into the main loop. The leakage flow amount was measured with a Coriolis mass flow meter.

In 2018, a 4.2 hours continuous electricity generating operation was successful under TIT of 212°C. A robust turbo-generator design, a leakage make-up system and operation strategy leads success of safe operation. [9]

In 2019, a 500°C hundreds of kWe-class two axial turbo-generator and Brayton test loop was commissioning. In this test loop, 650°C, 1.75 MWth burner was developed for heat source and a shell-and-finned-tube type heat exchanger was also fabricated for heating a 135 bar of supercritical carbon dioxide. In addition, for Brayton cycle, a centrifugal supercritical carbon dioxide compressor was developed and fabricated. A compressor was driven by high-speed motor connected with a coupling. A design rotating speed of the compressor was 70,000 RPM. In this compressor, in order to reduce leakage flow, a dry gas seal (DGS) was fabricated in the rotor. In addition, in order to supply dried carbon dioxide into seal face, an additional DGS supply control system consists of a booster, a heater and so on was developed.

Two axial turbo-generator for 500°C and 392°C of TIT were developed for this test loop. As described above, the second low temperature turbo-generator for 392°C already fabricated and tested in the previous tens of kWe-class transcritical test loop. In this final test loop, new 500°C of TIT axial turbo-generator was developed which is composed of an oil-lubricated tilting pad journal and thrust bearing that operates at 70,000 RPM. In this turbo-generator, a balancing piston which is driven 6 bar of compressed air was fabricated to reduce axial force on the rotor. By controlling a pressure of supply air, semi-active axial force balancing is possible.

Two PCHEs were fabricated for recuperators and one PCHE was fabricated for a cooler. Since there are leakages from two turbo-generator and one compressor, one leakage recompressing system was developed in the loop, and a 600 L of inventory tank was fabricated for supplying carbon dioxide corresponding to leakage. All piping were constructed as ASME standard. All test loop was assembled. Now commissioning progress is conducted. After investigating these core components of supercritical carbon dioxide power cycle, a part of preliminary Carnot Battery system would be constructed and tested in the future.

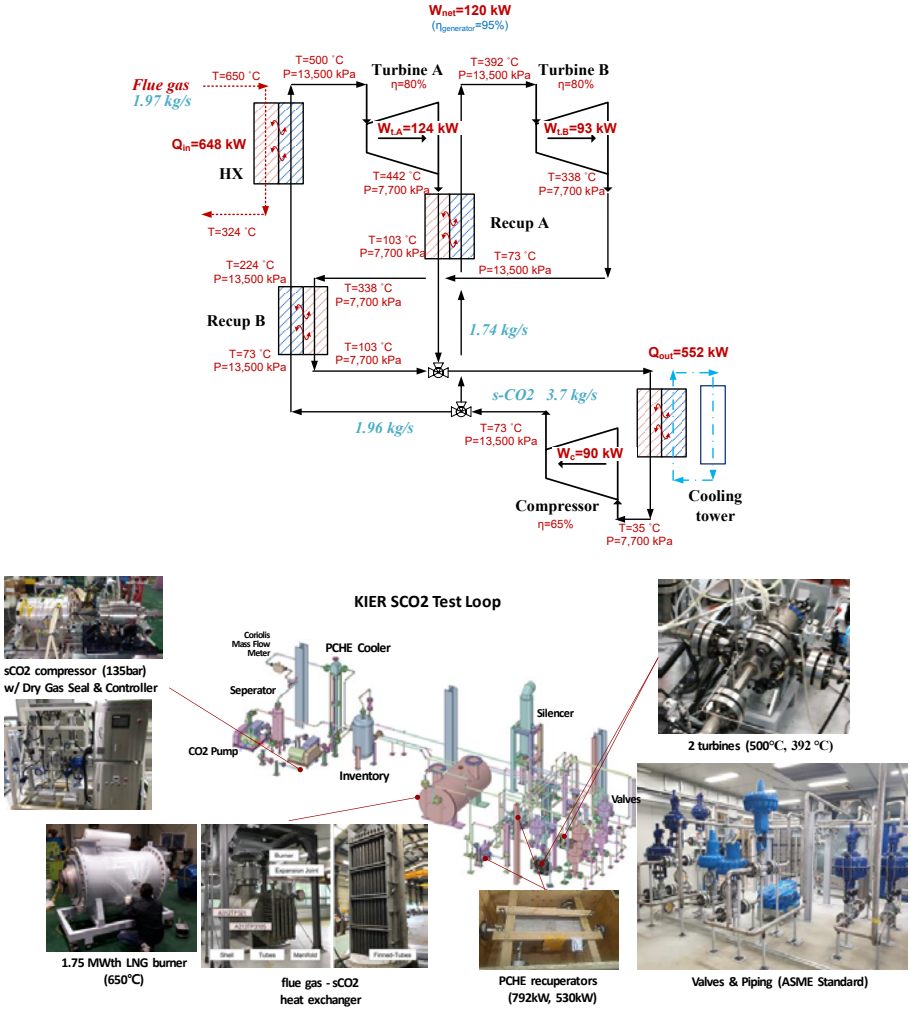

Fig.7. 500℃ hundreds of kWe-class two axial turbo-generator and Brayton test loop

5. Summary and Future Works

There are several layout options for the Carnot battery as a hot storage temperature. A conventional gas turbine combined cycle and a conventional steam turbine cycle can be utilized. In addition, a supercritical carbon dioxide power cycle is an attractive option in the Carnot battery concept due to its advantages. KIER has been developed sCO2 power cycle technology for future power generation system. Various capacities of sCO2 turbomachinery and test loops have been developed and operated as shown in this paper.

Therefore, KIER is now considering sCO2-Carnot Battery concept utilizing our sCO2 technology. Further studies on cycle layouts, economics and development of a small-scale test loop of the Carnot battery would be done as a next step.

Abstract

Two phase condensation heat transfer and pressured drop characteristics of R-513A in a 9.52 mm O.D. horizontal microfin copper tube are investigated experimentally. Test facility has a straight test section with a length of 2.0 m and is cooled by cold water circulated in a surrounding annular space. The water-side annular space heat transfer coefficients are measured using the Wilson plot method. Average heat transfer coefficients and pressure drop data are reported at the condensation temperature of 35°C in range of 100-440 kg/m^{2}s mass flux. The test data of R-513A are compared with those of R-134a, R-1234yf and R-1234ze(E).

Keywords: Microfin tube; low-GWP refrigerants; condensation heat transfer; R-513A; R-1234yf; R-1234ze(E)

1. Introduction

In recent years, the use of energy systems including refrigeration and air conditioning systems is gradually increasing due to the advancement of technology and improvement of living standards, and energy supply and demand and environmental problems are emerging as important issues. Among the energy systems, the environmental impact of the refrigeration and air conditioning systems is the global warming effect that occurs in generating the working fluids of the system and power required for the system operation. The global warming is highly affected by air-conditioning, refrigeration and heat pump systems which account 700 million metric tons of CO_2 equivalent direct (7%–19%) and indirect emissions (74%) per year [1]. Therefore, it is very important to increase the energy efficiency of the system, and use eco-friendly alternative refrigerants such as carbon dioxide and HFO refrigerants with a small global warming potential [2-3]. Heat exchangers in air conditioning and heat pump applications play an important role on system efficiency and physical size. Finned round tube or flat tube heat exchangers are widely used for the evaporators and condensers in residential air-conditioning and heat pump systems. To investigate the overall performance of the finned tube heat exchangers, tube-side heat transfer and pressure drop characteristics as well as air-side performance should be investigated simultaneously. Several investigators [4–10] conducted investigations on two phase thermal and hydraulic performance in smooth and enhanced tubes. Kim and Shin [5, 6] investigated experimentally evaporation and condensation heat transfer characteristics using R-22 and R-410A in 9.52mm OD smooth and microfin tubes. They found that average evaporation and condensation heat transfer coefficients of R-410A for microfin tubes were 1.86-3.27 and 1.7-3.19 larger than those of smooth tubes, respectively. And they also reported that the evaporating heat transfer coefficients for R-410A were 97–129% of R-22 when compared to R-22 at the same test conditions. Due to the EU Regulation No 517/2014, the refrigerant R-134a is already banned in mobile air-conditioning and household refrigerator-freezer systems and will be also prohibited for commercial refrigerator-freezers from 2022 [7]. Hence studies to find low-GWP alternative refrigerants for R-134a have attracted to prevent negative effects on climate change by many researchers. Table 1 and Fig. 1 show general properties and vapor pressures of R-134acompared to alternative refrigerantsR-1234yf, R-1234ze(E), and R-513A. GWP values of R-1234yf and R-1234ze(E) are significantly lower than R-134a. However, R-1234yf and R-1234ze(E) are mildly flammable and classified as A2L. R-1234ze(E) has a lower saturation pressure than R-134a (75% of R-134a at a saturation temperature of 35°C), so it the design of the system requires to be modified and the pressure drop is relatively

high. R-513A refrigerant is an azeotropic mixture with a mass ratio of R-1234yf and R-134a of 56 to 44, and its GWP value is slightly higher at 573, but it is not flammable and has an advantage that is very similar to R-134a in thermodynamic properties. Yang et al. [8] and Diani et al. [9] conducted experimental studies on condensation heat transfer of R-1234yf and R-1234ze refrigerants in small diameter microfin tubes, respectively. Diani et al. [10] investigated condensation heat transfer of R-513A at the saturation temperatures of 30 and 40 °C in the range of 100-1000 kg/m^{2}s mass fluxes inside 3.5 mm ID smooth and microfin tubes.

In this study, condensation heat transfer and pressure drop characteristics in a 9.52 mm OD microfin tube are experimentally performed for R-513A, R-1234yf, R-1234ze(E), and R-134a at a condensation temperature of 35°C in the range of 100-440 kg/m^{2}s mass fluxes. The correlation equation of the heat transfer coefficient for the annular space of the test section is obtained using the Wilson plot, and the condensation test results of the refrigerant R-513A are compared with those of R-134a, R-1234yf and R-1234ze(E).

2. Experiments

2.1 Experimental facility

A schematic diagram of the experimental facility is shown in Fig. 1. The facility consists of one refrigerant loop and two water loops. The refrigerant loop is designed to measure the mean heat transfer coefficient of refrigerant condensing inside a micro fin tube. It is mainly composed of a gear pump, a pre-heater, a test section, a heat exchanger and a receiver tank. Refrigerant in liquid state is pumped from the bottom of the receiver tank to the preheater where it is heated up until it reaches a state of superheated vapour. With the preheater, it is possible to control the refrigerant superheat when it enters the test section. The refrigerant enters the test section in superheated vapor state and leaves in subcooled liquid. The test section with a length of 2m as shown in Fig. 2 consists of a simple tube-in-tube counter flow heat exchanger. The refrigerant inside the inner tube condensates and the water that flows in the annular duct between the two tubes is heated. Chiller 1 (6) is designed to control the conditions of the water entering the test section. After the test section, the refrigerant enters the plate heat exchanger as a subcooled liquid. The role of the plate heat exchanger is to control the system pressure. Chiller 2 (7) controls water temperature and flow rate at the inlet of the plate heat exchanger.

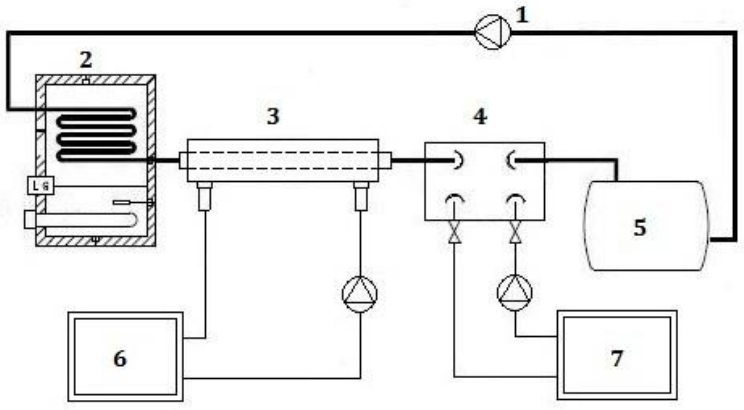

Fig. 2. Schematic diagram of experimental facility (1. Refrigeration pump, 2. Preheater, 3. Test section, 4. Plate heat exchanger, 5. Receiver tank, 6. Chiller1, 7. Chiller2

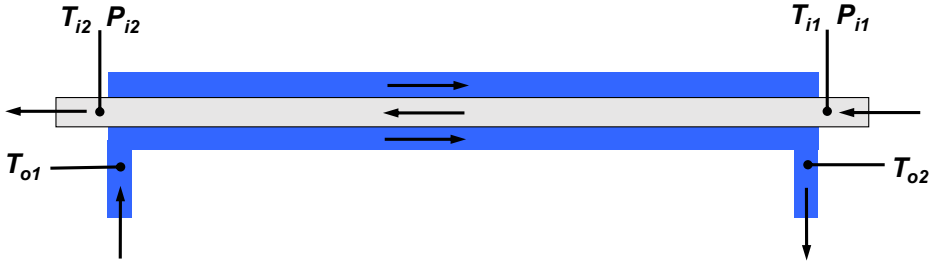

Fig. 3. Schematics of test section

The refrigerant pump (1) is a positive displacement gear pump with the maximum flow of 100 kg/h liquid refrigerant. Special attention is given to the refrigerant inlet pressure and temperature conditions to ensure that the refrigerant's pressure is higher than its vapor pressure at any point in the pump and avoid any bubble

formation within the pump. For that reason, the refrigerant's pressure and temperature is measured at the suction line to ensure that the refrigerant remain in liquid state. The pre-heater (2) is an insulated tank that contains a coil of the main loop refrigerant on the top, electrical resistances on the bottom and a low-pressure fluid; its role is to heat up the liquid refrigerant to a superheated vapor state. The electrical resistor heaters heat the low-pressure refrigerant which evaporates on the bottom of the tank. Then, low-pressure refrigerant vapor condensates on the surface of the main refrigerant loop coil on the top of the tank. The test section (3) can be described as a simple tube in a tube heat exchanger. It consists of an inner grooved tube mounted inside an outer shell tube, so that the refrigerant flows counter-current through the inner tube, with the cooling water around it. Refrigerant condensates in the test section under fully controlled conditions. The pressure and temperature are measured at the inlet and outlet of the test section. Both inlet and outlet state of the refrigerant are single phase, thus the inlet-outlet specific enthalpies can be determined using thermodynamic data. The condensation heat capacity is calculated as the product of the mass flow and the differential enthalpy. The plate heat exchanger (4) role is to control the refrigerants pressure; this is accomplished by heating or cooling the refrigerant loop with water as a secondary mean. The heating or cooling rates at the plate heat exchanger are small in order to accomplish a high precision pressure regulation. The water flow rate and temperature are controlled. The receiver tank (5) contains refrigerant in both liquid and vapor state at the bottom and top respectively. The refrigerant outlet is located on the bottom of the receiver tank so that only liquid refrigerant is pumped.

2.2 Experimental methods and conditions

The test conditions are described in Table 2. The condensation experiments are conducted at the saturation temperature of 35 °C for the mass flux of 100-440 kg/m^{2}s with R-134a, R-513A, R-1234yf and R-1234ze(E). The inlet superheat and outlet subcooling of condenser are 5 and 2 °C, respectively. The refrigerant flow is regulated by controlling the input power of the variable speed magnetic gear pump. The test conditions and data to be collected were monitored throughout the test, and data sets were recorded and averaged over 10 min after test conditions reached steady state. Before the condensation experiment, a series of water-to-water experiments are first performed to find the correlation of the heat transfer coefficient of the annular space. Water to water test data are collected with increasing the water flow rate of the annular space from 200 to 800 kg/h in increments of 100 kg/h. The tested microfin tube has 60 fins with fin height of 0.25 mm, an apex angle of 60°, and bottom wall thickness of 0.35mm.

Table 2. Test conditions

Refrigerants	R-134a, R-513A, R-1234yf, R-1234ze(E)
Condensing temp. [°C]	35
Mass flux [kg/m^{2}s]	100-440
Degree of superheat/subcooling [°C]	5/2

2.3 Data reduction

Condensation heat transfer coefficients can be calculated using the following equations

$$\frac{1}{U_o A_o} = \frac{1}{h_i A_i} + R_w + \frac{1}{h_o A_o} \quad (1)$$

Where U_oA_o is the overall heat transfer coefficient. R_w is the thermal conduct resistance of the tube wall and it can be neglected because the tube material is copper and the thickness of the tube wall is very thin.

$$Q = U_o A_o \, LMTD \quad (2)$$

Where Q is the heat transfer rate of the test section and the arithmetic mean of tube- (Q_i) and annular-side (Q_o) heat transfer rates that obtained from the following equations

$$Q = \frac{Q_i + Q_o}{2} \quad (3)$$

$$Q_i = m_i c_p \, (T_{i1} - T_{i2}) \quad (4)$$

$$Q_o = m_o c_p \, (T_{o2} - T_{o1}) \quad (5)$$

And the *LMTD* is the log mean temperature difference which is defined as

$$LMTD = \frac{(T_{i2} - T_{o1}) - (T_{i1} - T_{o2})}{\ln\left[\frac{(T_{i2} - T_{o1})}{(T_{i1} - T_{o2})}\right]} \quad (6)$$

If the heat resistance ($1/h_oA_o$) of the annular space is known from Eq. (1), the heat transfer coefficient (h_i) in the tube can be obtained from the heat resistance ($1/h_iA_i$) in the tube. Refrigerant properties were calculated using NIST REFPROP [11].

3. Results and discussion

Figs. 4 and 5 show the Wilson plot and the correlation equation for obtaining the heat transfer coefficient of the annular space with variation of water flow rate of 200-800 kg/h, respectively. As shown in Fig. 4, the total thermal resistance value ($1/U_oA_o$) of the test section is well expressed as a function of the tube-side thermal resistance ($1/h_iA_i$). The total thermal resistance value decreases with the increase of the flow rate of the annular space at the same flow rate in the tube-side, because the heat transfer coefficient of the annular flow path increases with the increase of the flow rate. The refrigerant-side heat transfer coefficients are calculated from Eq. (1) using correlation of $1/h_oA_o$ from Fig. 5.

Figs. 6 and 7 present average heat transfer coefficients and pressure drops at the condensing temperature of 35°C in ranging of 100-440 kg/m^{2}s mass flux, respectively. The heat transfer coefficients of the test refrigerants including R-513A increase with the refrigerant mass flux as expected, and all four refrigerants have similar heat transfer coefficient values at low mass flux. However as the mass flux increases, the heat transfer coefficient of R-513A has a similar value to that of R-1234ze(E), while it is about 10% higher than that of R-134a. The heat transfer coefficient of R-1234yf represents the lowest value among the test refrigerants, and the difference in heat transfer coefficient with other refrigerants becomes larger as mass flux increases. Table 3 presents the major thermodynamic and transport properties of R-134a alternative refrigerants. These properties are attributed to the higher R-513A and R-1234ze(E) heat transfer coefficients and lower R-1234yf heat transfer coefficient compared to R-134a [12,13]. The pressure drops for all test refrigerants are increased with mass flux as expected as shown in Fig. 7. The pressure drops of R-513A and R-1234yf are smaller than that of R-134a when the mass fluxes are larger than 150 kg/m^{2}s, while the pressure drops of R-1234ze(E) are

relatively higher than that of R-134a. This is partly due to the higher vapor viscosity of R-1234ze(E) compared to R-134a as shown in Table 3.

4. Conclusion

The present study has been conducted to investigate two-phase condensation heat transfer and pressure drop characteristics in a horizontal 9.52 mm OD microfin tube with refrigerant R-513A. The experimental results are compared with those of R-134a, R-1234yf and R-1234ze. The findings of the present study have been listed below.

- The average condensation heat transfer coefficients of R-513A and R-1234ze (E) are similar to that of R-134a in the lower range of tested mass fluxes (100-150 kg/m^{2}s). As mass flux increases, the heat transfer coefficients of R-513A and R-1234ze (E) become higher than that of R-134a.
- The average condensation heat transfer coefficients of R-1234yf is lower than that of R-134a for the full range of tested mass fluxes.
- The pressure drop of R-513A is similar to R-1234yf and lower compared to that of R-134a
- R-1234ze(E) pressure drops are higher compared to that of R-134a.

An Experimental Study on Thermal Comfort Improvement For Residential Air Conditioner Applying a Wind-free Technology

Youngju Joo[a], Jun Hwang[a*], Hyeongjoon Seo[a], Byongguk Lim[a]

[a]Samsung Electronics, Suwon-si, Gyeonggi-do, 16677, Republic of Korea

Abstract

This paper focused on the indoor thermal comfort improvement by the wind-free air conditioner. Evaluate the indoor thermal comfort and air quality to meet the growing demands of the occupants, a hybrid flow path was applied to the air conditioner. There are various parameters which are influenced thermal comfort, Especially, Air flow is the most essential parameter to achieve comfort condition. This study presents the thermal comfort improvement for wall mount type, floor-standing type and ceiling type air-conditioner, respectively. When the occupant zone reached to comfort condition, the air flow can be changed to the wind-free mode, it can be reduced cold draft and energy consumption. The air flow visualization and temperature distribution was measured compare general cooling mode with wind-free mode.

Keywords: Wind-free; Thermal comfort; Air-conditioer;

1. Introduction

With improved living standards and the increase in the desire and importance for comfortable indoor environment, the penetration rate of residential air conditioners in South Korea is increasing every year. According to the survey report on home appliance penetration rates published by the Korea Power Exchange, the penetration rate of residential air conditioners increased from 2% in 1985 to 61% in 2011 and to 75% in 2015[1]. The cause of this increase is the increase in the various desires of consumers for indoor thermal comfort. While air conditioners were recognized as summer products for reducing the indoor air temperature in the past, the development of air conditioners is being expanded from temperature-oriented air conditioning to comprehensive comfort air conditioning by reinforcing various additional functions, such as heating, dehumidification, and air cleaning.

Indoor thermal comfort not only improves personal satisfaction but also has the economic effect of increased productivity. Dorgan[2] estimated that the annual profit resulted from the productivity improvement and medical cost savings caused by indoor air quality improvement is $62.7 billion, and Fisk[3] reported that the economic effect of the reduction in diseases and the increase in work efficiency caused by the improvement of indoor environment amounts to $40.0 - $200 billion. It can be said that indoor thermal comfort is a basic and essential condition in modern society.

1.1 Principles of wind-free air conditioners

Indoor thermal comfort can be secured by controlling the four elements of air conditioning, i.e. the indoor temperature, humidity, airflow, and cleanliness. Among them, the airflow acts as a positive element by rapidly forming a comfort condition in the space during the initial operation. The airflow, however, has double-sidedness because it acts as a negative element that induces cold draft after the formation of the comfort condition. [4][5]

To maintain continuously comfortable environment for indoor occupants without the discomfort caused by the airflow, wind-free air conditioners were developed using the hybrid flow path.

E-mail address: neojun.hwang@samsung.com

For the wind-free air conditioners, the hybrid flow path is constructed so that the indoor temperature can be rapidly reduced with the opening of wind doors during the initial operation and the internal flow path can be changed with the closing of the wind doors when the wind-free mode is selected after a comfort condition is reached in the residential space. The airflow is uniformly discharged at low speed through micro-holes to maintain the comfort of the residential space without the feeling of airflow.

In this study, the cases of residential and system air conditioners with the hybrid flow path for wind-free cooling and the effect of wind-free cooling on the improvement of indoor thermal comfort were analyzed.

2. Theories on Indoor Thermal Comfort and Their Application

2.1 PMV and PPD

To quantify human thermal sensation, Fanger (1970) presented the predicted mean vote (PMV) by combining the results of the experiment performed with 1,300 participants and the heat balance equation for the human body.

PMV is determined by six elements, including four environmental elements (room air temperature, mean radiation temperature, relative humidity, and air velocity), metabolism, and thermal resistance of clothing. It can be expressed as a function of the human body thermal load (L) calculated with the body surface temperature and sweat evaporation rate that provides neutral thermal sensation in the metabolism (M) as shown in equation (1).

$$\mathrm{PMV} = 0.303\exp(-0.036\mathrm{M}) + 0.028 \tag{1}$$

The PMV value was set based on the seven-point thermal sensation scale of ASHRAE. The predicted percentage of dissatisfied (PPD) represents the expected percentage of people who are not satisfied with the given environment. There is a correlation between PMV and PPD as shown in equation (2). The given environment is evaluated as "comfortable" if PMV is within ±0.5 and PPD is less than 10%.[6]

$$\mathrm{PPD} = 100 - 95\exp[-(0.03353PMV^4 + 0.2179PMV^2)] \tag{2}$$

2.2 Application of PMV and PPD

For the calculation of PMV and PPD, equations (1) and (2) were automatically calculated by programming. The input parameters required for the calculation are shown in Table 1.

Table 1. Input parameters of PMV-PPD Program

Input Parameter	Unit
Metabolism (M)	met=W/m^2
External work (W)	W/m^2
Thermal resistance of clothing (I_{clo})	clo=m^2°C/W
Room air temperature (Ta)	°C
Mean radiation temperature (Tr)	°C
Air velocity (Va)	m/s
Relative humidity (Rh)	%

The environmental elements, i.e. the room air temperature, mean radiation temperature, air velocity, and relative humidity, were automatically obtained using sensors, and the elements related to the human body that could not be measured were treated as constants as shown in Table 2.

Table 2. Constants of PMV-PPD Program

Parameter	constant
Metabolism	1.2met = 69.84 W/m^2 (Office, Home)
External work	0W/m^2 (for everyday activities)
Thermal resistance of clothing	0.5 clo = 0.078m^2°C/W(Summer)

3. Experimental Setup and Method

3.1 Experimental setup

Experiments were performed in a residential environment laboratory that simulated the actual environment. The residential environment laboratory consisted of an outdoor environment chamber for simulating various outdoor environments and a model house.

The model house simulated the living room and main room of an apartment. Fig. 1 shows the schematic diagram of the model house. Thermocouples were installed in three dimensions to measure the temperatures inside the model house, and indoor thermal environment elements were measured using relative humidity sensors, radiation thermometers, and wind speed measuring instruments.

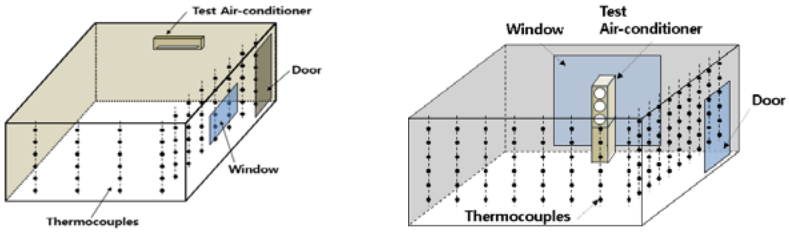

Fig. 1. Schematic diagram of model house

3.2 Experimental method

Table 3 shows the experimental test conditions in model house. The initial outdoor load conditions were a dry-bulb temperature of 35℃ and a wet-bulb temperature of 24℃ (relative humidity 39%). Tests were conducted after both the model house and the outdoor environment chamber were stabilized. The air conditioners were operated after the windows and doors had been closed to minimize the entry and exit of heat, and the indoor temperature, relative humidity, mean radiation temperature, and air velocity were measured every 20 seconds. To analyze the effect of the hybrid flow path on indoor thermal comfort, the cooling set temperature was fixed at 24℃ and the air conditioners were operated while the air volume setting was varied. In the case of residential and system air conditioners, they adopt inverters and maintain a constant indoor temperature by varying the cooling capacity through the control of the revolutions of the compressor when the indoor temperature reaches the set temperature. When the indoor temperature was stabilized at 24℃, the indoor temperature distribution, air velocity, and thermal comfort for each air volume setting were compared.

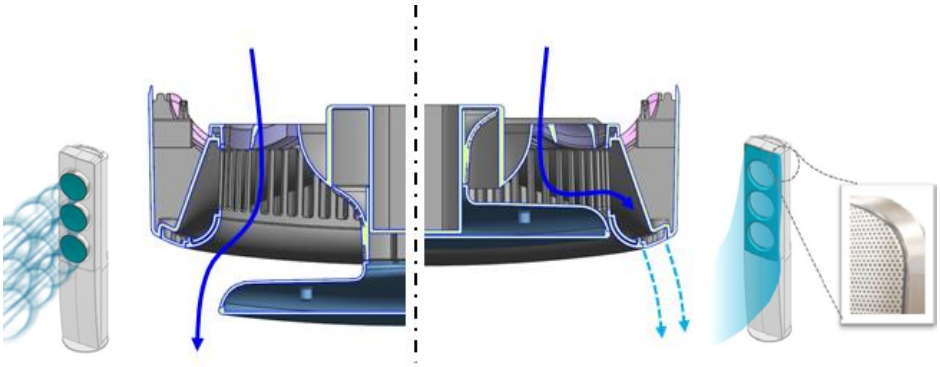

Table 3. Experiment test conditions

Parameter	Value
Initial Dry bulb temperature	35
Initial wet bulb temperature	24

Set temperature of air-conditioner 24

4. Experiment Results and Discussion

4.1 Stand-type wind-free air conditioner

(a) Cooling mode (b) Wind-Free mode

Fig. 2. Schematic of hybrid flow path

For residential air conditioners, the airflow is essential for creating comfortable conditions through the suction of hot and humid air indoors and air conditioning. Most indoor occupants, however, have the perception that direct exposure to the cold airflow from an air conditioner is harmful to their health.

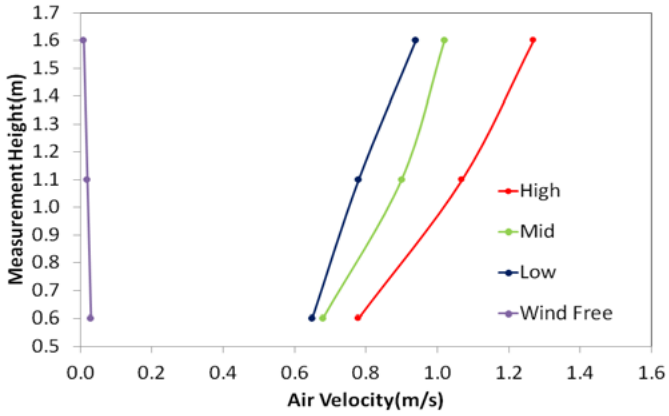
Considering this double-sidedness of the airflow, the hybrid flow path was applied to stand-type air conditioners, which dominate the domestic market, to rapidly reduce the indoor temperature with powerful cooling during the initial operation and to generate comfortable environment without the feeling of airflow after the set temperature is reached.

When the hybrid flow path is applied, powerful and fast airflow is discharged from the front with wind doors opened for rapid cooling during the initial operation as shown in Fig. 2(a). When the wind-free mode is selected after the residential space reached a comfort condition, the internal flow path is changed as the wind doors are closed as shown in Fig. 2(b). In this case, the airflow is uniformly discharged at low speed through the 135,000 micro-holes in the front panel.

4.1.1 Indoor temperature and air velocity

To analyze the indoor thermal comfort of a stand-type residential air conditioner in an indoor residential space (the indoor activity range of occupants: less than 1.8m height from the floor, more than 0.3m distance from the external wall, and within 1 m from the air conditioner) [7], the air velocity and indoor temperature distributions at the cooling and wind-free modes are shown in Figs. 3 and 4, respectively.

When the air velocities at 1.5 m from the air conditioner were compared, the air velocity exceeded 0.5 m/s at all points even at the low airflow mode, resulting in non-uniform indoor temperatures. ASHRAE defines the air velocity of 0.15 m/s or less in a residential space as still air [8].



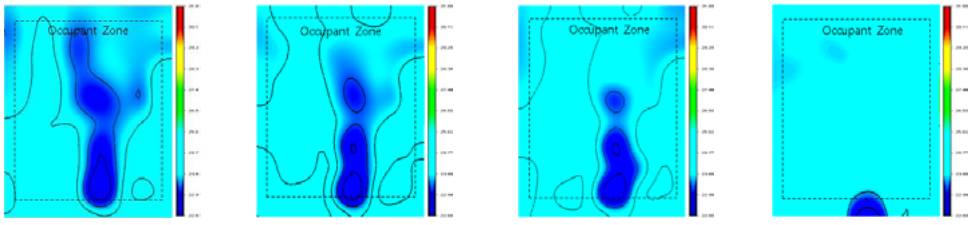


Fig. 3. Air flow velocity distribution of cooling mode and Wind-Free mode

(a) High Airflow mode (b) Mid Airflow mode (c) Low Airflow mode (d) Wind-Free mode

Fig. 4. Temperature distribution of cooling mode and Wind-Free mode

At the wind-free mode, the air velocity was 0.15 m/s or less, and thus the airflow could not be felt. As the indoor temperature was maintained while the air velocity in the residential space was 0.15 m/s or less, a uniform indoor temperature distribution was formed as shown in Fig. 4(d).

4.1.2 PMV and PPD

To compare the indoor thermal comfort of the cooling mode with that of the wind-free mode, PMV and PPD were shown in Figs. 5 and 6, respectively. In the case of the cooling mode, as the air volume setting decreased while the indoor temperature was maintained at 24℃, the air velocity decreased and the PMV and PPD values slightly increased to thermal neutrality. Even at the low airflow mode, however, it is expected that at least 30% of the occupants exposed to the discharged airflow will experience discomfort caused by the cold.

At the wind-free mode, the air velocity was 0.15 m/s or less and the influence of the airflow was minimized. As PMV approached zero, thermal neutrality was closer, and PPD was also in the comfort zone of10 or less. Uniform thermal comfort was secured in the residential space because the air velocity was no more than 0.15 m/s and the indoor temperature was uniformly maintained as shown in Fig. 4(d).

4.2 Wall-mounted wind-free air conditioner

As wind-free air conditioning is also required in personal spaces, such as bedrooms and studies, the hybrid flow path was applied to wall-mounted residential air conditioners. When the hybrid flow path is applied, the wind doors are opened and rapid cooling is performed with powerful and fast airflow as shown in Fig. 7, and

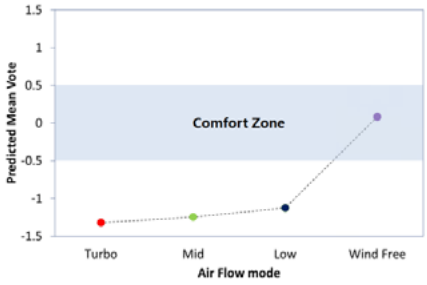

Fig. 5. Comparison of the PMV at cooling mode and Wind-Free mode

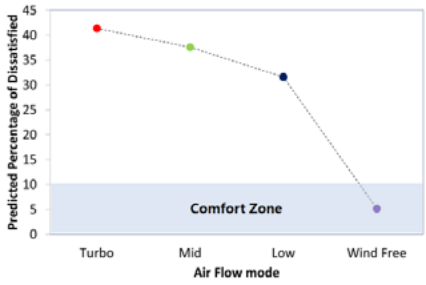

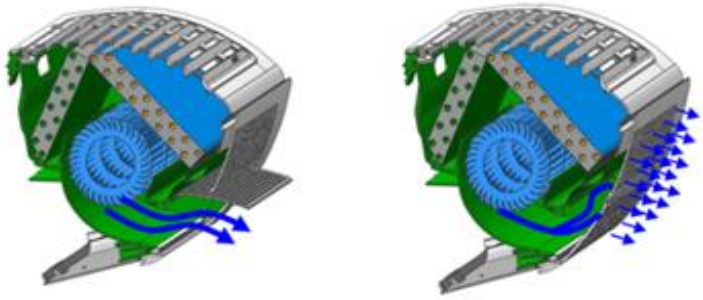

Fig. 6. Comparison of the PPD at cooling mode and Wind-Free mode

the internal flow path is changed as the wind doors are closed when comfortable cooling is required after the set temperature is reached. The residential space can remain comfortable without wind as the airflow is uniformly discharged at low speed through the micro-holes in the front panel.

To analyze the indoor thermal comfort of a wall-mounted wind-free air conditioner, it was installed in the residential environment laboratory, and the indoor temperature and air velocity were analyzed in the same manner as the stand-type wind-free air conditioner.

(a) cooling mode (b) Wind-Free mode

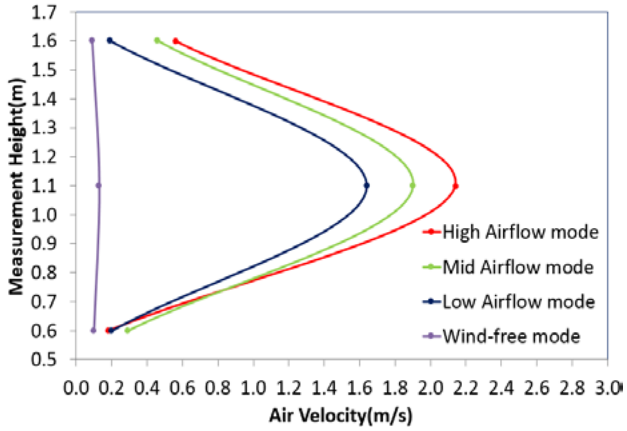
Fig. 7. Schematic of hybrid flow path

4.2.1 Indoor temperature and air velocity

To analyze the indoor thermal comfort of the wall-mounted air conditioner in an indoor residential space (the indoor activity range of occupants: less than 1.8m height from the floor, more than 0.3m distance from the external wall, and within 1 m from the air conditioner) [7], the air velocity and indoor temperature distributions at the cooling and wind-free modes are shown in Figs. 8 and 9, respectively.

When the air velocities at 1.5 m from the air conditioner were compared, the air velocity exceeded 1.0 m/s at the cooling modes, including the high, mid, and low airflow modes, thereby causing non-uniform indoor temperatures (Fig. 9(a), (b), (c)).

At the wind-free mode, the air velocity was 0.15 m/s or less and thus the airflow could not be felt. As the indoor temperature was maintained while the air velocity in the residential space was 0.15 m/s or less, a uniform indoor temperature distribution was formed as shown in Fig. 9(d).



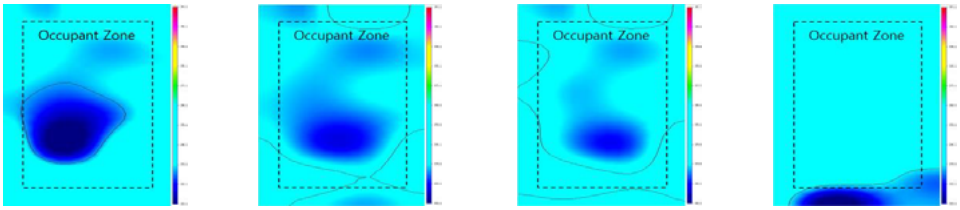


Fig. 8. Air flow velocity distribution of cooling mode and Wind-Free mode

(a) High Airflow mode (b) Mid Airflow mode (c) Low Airflow mode (d) Wind-Free mode

Fig. 9. Temperature distribution of cooling mode and Wind-Free mode

4.2.2 PMV and PPD

To compare the indoor thermal comfort of the cooling mode with that of the wind-free mode, PMV and PPD were shown in Figs. 10 and 11, respectively. In the case of the cooling mode, as the air volume setting decreased while the indoor temperature was maintained at 24℃, the air velocity decreased and the PMV and PPD values were slightly improved to thermal neutrality. Even at the low airflow mode, however, it is expected that at least 20% of the occupants will experience discomfort caused by the cold.

At the wind-free mode, the air velocity was 0.15 m/s or less and the effect of the airflow was minimized. As PMV approached zero, thermal neutrality was closer, and PPD was in the comfort zone of 10 or less. Uniform thermal comfort was secured in the residential space because the air velocity was no more than 0.15 m/s and the indoor temperature was uniformly maintained as shown in Fig. 9(d).

4.3 Ceiling-type 1-way cassette wind-free air conditioner

To expand the wind-free function from residential air conditioners to system air conditioners, the hybrid flow path was applied to 1-way cassette air conditioners, which are mostly built-in products, as shown in Fig. 12.

In the case of 1-way cassette air conditioners, the airflow arrival distance is important for uniform and fast cooling due to their installation characteristics. The conventional 1-way cassette air conditioners exhibited an approximately 40% flow loss due to the airflow resistance caused by blades when remote-distance airflow was implemented. In the case of the wind-free 1-way cassette air conditioners with the hybrid flow path, however, the air volume loss could be reduced to approximately 20% by raising the flow path by 10° compared to the

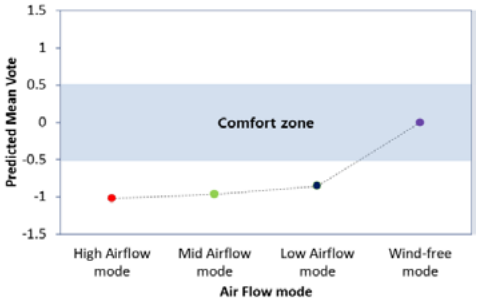

Fig. 10. Comparison of the PMV in the cooling mode and wind-free mode

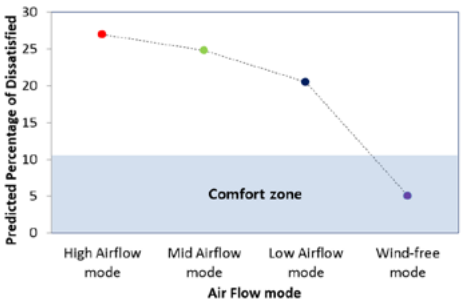

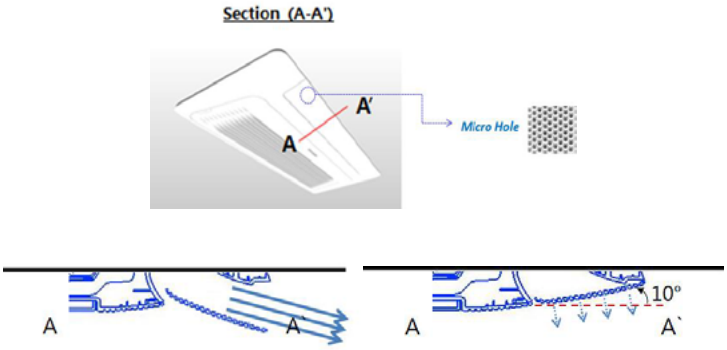

Fig. 11. Comparison of the PPD in the cooling mode and wind-free mode

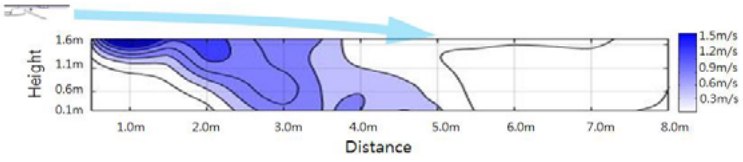
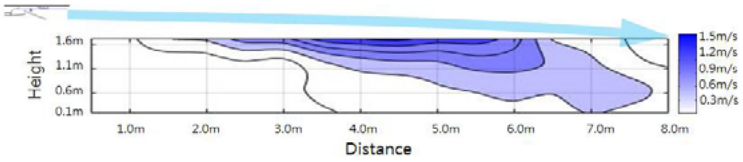


conventional flow paths. Moreover, while the geometry of the internal flow path of the conventional 1-way cassette air conditioners was almost perpendicular to the ceiling surface, that of the wind-free 1-way air conditioners was inclined according to the angle of the discharged airflow.

As a result, the remote-distance airflow of the wind-free 1-way cassette air conditioners with the hybrid flow path increased by approximately 60% compared to that of the conventional 1-way cassette air conditioners as shown in Fig. 13(b).



(a) Long air flow mode (b) Wind-Free air flow mode

Fig. 12. Schematic of hybrid flow path

(a) Conventional 1-way CST

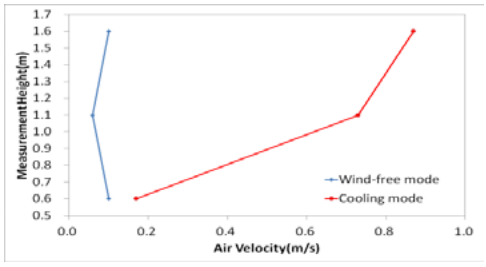
(b) Wind-Free 1-way CST

Fig. 13. Air flow velocity distribution

4.3.1 Indoor temperature and air velocity distribution

To compare the thermal comfort according to the airflow when a comfort condition is formed after reaching the set temperature, the air velocity and temperature distributions under the cooling mode of a conventional 1-way cassette air conditioner and the wind-free mode of a wind-free 1-way cassette air conditioner were shown in Figs 14 and 15, respectively.

When the air velocities at 1.5 m from the air conditioner were compared, the air velocity of the conventional 1-way cassette air conditioner exceeded 0.7 m/s as shown in Fig. 13, and non-uniform indoor temperatures were maintained because the temperatures at the points through which the air flew were low as shown in Fig. 14(a). On the other hand, the air velocity of the wind-free 1-way cassette air conditioner at the wind-free mode was 0.15 m/s or less as shown in Fig. 14, and a uniform temperature distribution was maintained in the residential space as shown in Fig. 15(b).



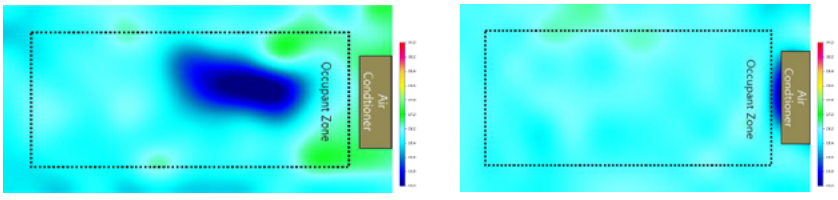


Fig. 14. Air flow velocity distribution of cooling mode and Wind-Free mode

(a) Cooling mode (b) Wind-Free mode

Fig. 15. Temperature distribution of cooling mode and Wind-Free mode

4.3.2 PMV and PPD

To compare the indoor thermal comfort of the cooling mode with that of the wind-free mode, PMV and PPD were shown in Figs. 16 and 17, respectively. In the case of the conventional 1-way cassette air conditioner, the indoor temperature was not uniform and PMV was approximately -1.49 due to the discharged airflow. Therefore, discomfort caused by the cold is predicted and it is expected that approximately 50% of the

occupants will experience discomfort when PMV is converted to PPD. In the case of the wind-free 1-way cassette air conditioner at the wind-free mode, on the other hand, the air velocity was 0.15 m/s or less in the residential space and a uniform indoor temperature distribution was formed. Therefore, it is expected that the occupants will be comfortable regardless of their positions.

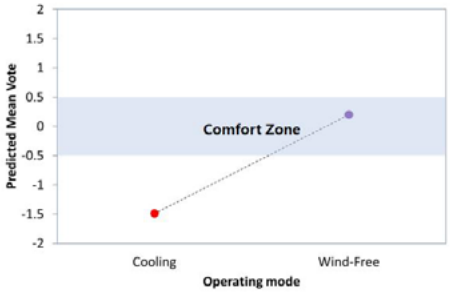

Fig. 16. Comparison of the PMV in the cooling mode and Wind-Free mode

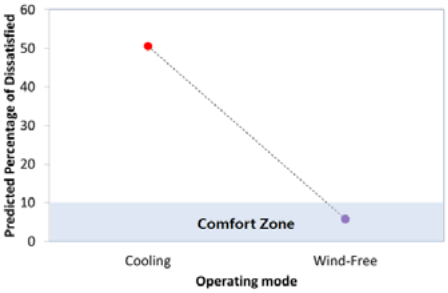

Fig. 17. Comparison of the PPD in the cooling mode and Wind-Free mode

5. Conclusion

In this study, the thermal comfort of the wind-free air conditioners that applied the hybrid flow path to residential and system air conditioners was analyzed to implement powerful cooling during the initial operation and comfortable environment without discomfort caused by the cold airflow from the air conditioner after reaching the set temperature. To this end, experiments were performed in the residential environment laboratory that simulated the actual environment, and the results of the air velocity, indoor temperature distribution, predicted mean vote (PMV), and predicted percentage of dissatisfied (PPD) at the conventional cooling mode and the wind-free mode were compared.

In the case of the stand-type wind-free air conditioner, the indoor temperature distribution was not uniform due to the discharged airflow faster than 0.5 m/s at the cooling mode when the indoor temperature was maintained at 24°C, and it is expected that at least 30% of the occupants will experience discomfort caused by the cold. At the wind-free mode, the air velocity in the residential space was no more than 0.15 m/s and a uniform indoor temperature distribution was confirmed.

In the case of the wall-mounted wind-free air conditioner, an experiment was performed under the same conditions as those of the stand-type wind-free air conditioner. At the cooling mode, the indoor temperature distribution was not uniform due to the discharged airflow of 1.0 m/s or faster, and it is expected that at least 20% of the occupants will experience discomfort caused by the cold. At the wind-free mode, the air velocity in the residential space was 0.15 m/s or less and a uniform indoor temperature distribution was confirmed.

To expand the wind-free function to system air conditioners, the hybrid flow path was applied to 1-way cassette air conditioners, which dominate the built-in market. As a result, the airflow arrival distance increased by approximately 60% compared to the conventional 1-way cassette air conditioners, making it possible to rapidly and uniformly cool a large space during the initial operation.

Under the condition of maintaining the same indoor temperature when a comfort condition is formed after reaching the set temperature, the air velocity of the conventional 1-way cassette air conditioner exceeded 0.7 m/s, resulting in non-uniform indoor temperatures. In addition, it is expected that approximately 50% of the occupants will experience discomfort due to the discharged airflow. In the case of the wind-free 1-way cassette air conditioner, still air (with an air velocity of 0.15 m/s or less) defined by ASHRAE was formed in the residential space at the wind-free mode, confirming that a uniform indoor temperature distribution was maintained.

When the hybrid flow path is applied to residential and system air conditioners and wind-free cooling is performed, it is expected that occupants can secure uniform thermal comfort in their residential spaces because discomfort and non-uniform indoor temperatures caused by the discharged airflow are removed.

Abstract

Recently, the demand for high-temperature heat in the industrial field has increased. Hence, improvement in conversion efficiency to generate thermal power is strongly required for surplus steam heat that is of significant value along with a process with low heat generation efficiency in factories. Given the aforementioned problems, a significant energy saving effect for the complete process is expected by introducing a heat pump to the thermal process. However, it is extremely difficult to experimentally examine the energy saving of the system due to cost and installation space. The final goal of the study is to construct integrated analysis technologies that can realize optimization of the system including the design and control system from the selection of various refrigerants and cycles via simulations. The study compared and examined introduction model cases applied to high temperature heat pump and confirmed that the annual simulation results were reasonable when compared to measured values.

Keywords: Waste heat recovery, Industrial heat pump, integrated simulation, Annual performance evaluation;

1. Introduction

With the development of heat pump technology, there is an increasing interest the introduction of heat pump technology to save energy in the industrial field. However, the existing factory is large in scale and includes a complicated configuration with many devices. Thus, it is necessary to quantitatively clarify several parameters including the type of heat pump and temperature zone that are required for a factory. Therefore, it is difficult to evaluate the effect of experimental heat pump introduction. Hence, the introduction method of heat pump and evaluation method of introduction effect are not established to date.

Therefore, in the study, we propose a heat pump introduction method and evaluation of the introduction effect in the industrial field via simulations. First, it is necessary to model a large and complex factory to realize this type of a simulation. Additionally, annual performance evaluation is performed when conducting simulations in countries with four seasons, such as Japan, and hence a significant amount of calculation is expected from the simulation period and size of the factory. In the analysis logic in the simulation, it is necessary to increase calculation speed while maintaining calculation accuracy. Furthermore, it is necessary for the built simulator to entail ease of use for the user to operate and output energy saving and economic efficiency prior to and after the introduction of the heat pump.

Given the aforementioned factors, the purpose of the study is to construct a general-purpose evaluation tool on the effects of introducing industrial heat pumps. The study focuses on the construction of basic system configuration patterns and construction of general-purpose analysis logic for the model.

2. Method

2.1. Simulation overview

Fig. 1 shows the overall algorithm to evaluate the effects of introducing a heat pump. In the simulation in the study, the method to evaluate the effect of introducing heat pump is determined via dividing it into three main processes.

First, the target systems are classified by basic patterns. It is difficult to perform calculations with a model that divides element devices such as boilers and heat pumps into smaller elements, such as valves, heat exchangers, and compressors, because of the large scale of the target system. (In this paper, combustion-type heating devices including burners are collectively referred to as “boilers”) Additionally, accuracy can be obtained to analyze long-term performance such as annual performance although it is not practical due to the significant calculation time involved. Therefore, although the details are subsequently described, we aim to increase the calculation time by classifying the basic pattern proposed in the study with the boiler and heat pump as an element. Second, the target system is constructed by combining the classified patterns, and input variables are set for each pattern. Here, in order to correspond to the patterns classified in the previous stage, it is necessary to select variables that can be calculated even if the model of each pattern is divided. Finally, the heat pump introduction effect is calculated from the model of the target system and the input variables. Thus, even if the target is divided and modeled, it is still necessary to construct a method that decreases the calculation time by assuming annual performance calculations. Based on the aforementioned flow, it is possible to verify the effect of introducing the heat pump to the target system. The system before and after the introduction is compared, the performance parameters are graphed and displayed, and the user evaluates the introduction effect. Additionally, we construct a simulator that can be handled easily by any user and experts on heat pumps as a whole to save energy in the entire industrial field.

The following sections describe each process.

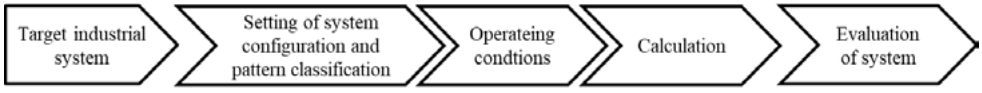

Fig. 1. Overall logic in the study

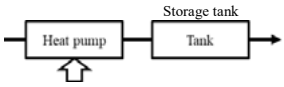
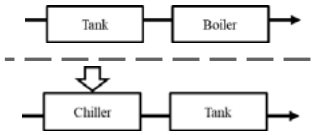
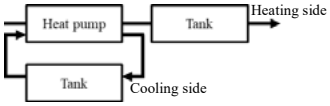
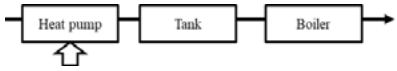
2.2. Pattern classification

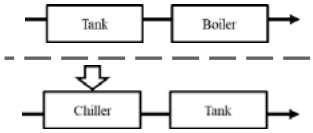
In order to organize a complicated system configuration, a basic pattern is constructed based on various systems in which heat pumps are already introduced. In the study, we propose a patterning method based on four indicators (i.e., device, heating method, introduction use) via surveys of heat pump products developed for existing industries, literature surveys, and interviews with experts.

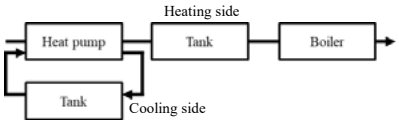


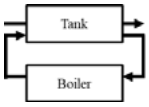


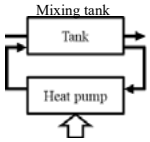


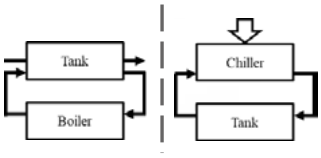


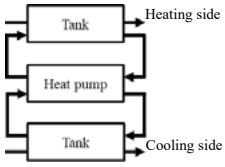


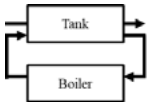


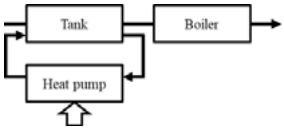


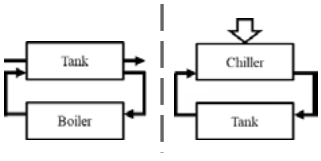


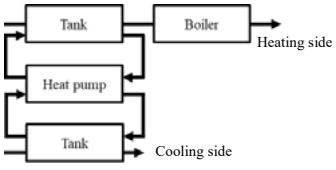












First, in order to compare the use of a conventional boiler with a heat pump, the former “device” is set to “boiler” and the latter is set to the “heat pump”. We then consider an eco-cute system that supplies hot water as a system that includes a heat pump. Household water heaters are popular although large-scale industrial eco-cutes were developed to generate hot water instead of boilers. This corresponds to an introduction example targeted in the study. In this type of a water heater, there is a difference in the heating method between storing hot water in the tank and temporarily supplying hot water. Therefore, the former “heating method” is set to “circulation” and the latter is set to “non-circulation”. Furthermore, the CO2 hot air generation heat pump was developed as an industrial heat pump that generates hot air without burning fuel like a boiler. The product makes it is possible to generate hot air at a higher temperature that consumes less fuel than before by replacing the boiler with a heat pump or heating the hot air preheated with a heat pump with a conventional heater. Therefore, the former “introduction use” is set as “replacement” and the latter is set as “preheating”. Finally, heat pumps that can realize applications including cold / hot water generation, hot water supply, and hot water tank heating with a single unit were developed using waste heat recovery technology. The heat pump can simultaneously extract cold and warm heat from the high temperature side and low temperature side such as recovering the heat released to the atmosphere during cooling operation by a conventional air conditioning system and using it as a heat source for hot water supply. Therefore, the “cold heat utilization” is set as “cold heat generation” and otherwise “hot heat generation” is set.

In the present study, a total of 16 patterns are proposed by combining the aforementioned "used equipment" (boiler, heat pump), "heating method" (circulation, non-circulation), "introduction use" (preheating, replacement), and "cool use" (cold heat generation, heat generation). However, if it corresponds to “cold heat

generation" and the device used is a boiler, then it is assumed that a refrigerator is present at the same time. The outline of the 16 patterns is listed in Table 1.

The user inputs the target system configuration via a combination of the 16 basic patterns. Similarly, it is possible to perform a comparison with the case where the heat pump is introduced by using the basic pattern and to clarify various effects of introduction.

Table 1. Basic pattern of system configuration

Type No.	Conventional type	Heat pump type
Type1 ・Non-circulation ・Replacement ・Hot heat generation		
Type2 ・Non-circulation ・Replacement ・Cold/Hot heat generation		
Type3 ・Non-circulation ・Preheating ・Hot heat generation		
Type4 ・Non-circulation ・Preheating ・Cold/Hot heat generation		
Type5 ・Circulation ・Replacement ・Hot heat generation		
Type6 ・Circulation ・Replacement ・Cold/Hot heat generation		
Type7 ・Circulation ・Preheating ・Hot heat generation		
Type8 ・Circulation ・Preheating ・Cold/Hot heat generation		

In these patterns figure, a white arrow indicates a heat source input. Each tank functions either as a storage tank or as a mixing tank, which is indicated in Table 1. If there is no tank, apply the pipe model to the tank. In all patterns proposed in this study, heating source is basically needed for heating process in the system, and cooling heat source is adjusted to get hot water or air as much as possible considering the heat balance between high and low temperature heat sources.

2.3. Simulation input and calculation

After classifying the target system configuration into patterns, input variables for boiler and heat pump elements in each basic pattern are set. Input and output variables for each element are shown in Tables 2 and 3, and the expressions used are shown below. Given that each pattern consists of a boiler, heat pump, and tank, models were created for the same. Various methods are available for mathematical model creation. In the study, in order to evaluate the annual performance, a model based on the pinch temperature was established in the heat transfer part of the heat pump to ensure sufficient validity while focusing on the calculation speed. As an example, the heat pump calculates variables including the heating capacity, COP, and primary energy consumption from the input variables listed in Table 3. In order to quantitatively evaluate the introduction effect under the same temperature and flow conditions in the heat pump type as compared with the boiler type, the simulator in the study mainly calculates the primary energy consumption as the output of each pattern.

Table 2. Input and output variables (Boiler)

Input			Output		
Variable	Code	Unit	Variable	Code	Unit
Boiler efficiency	η_{Boiler}	%	Heating capacity	Q	kW
Rated heating capacity	Q_{rated}	kW	Primary energy consumption	W_{prim}	kW
Inlet temperature	T_{in}	℃	Load factor	η_{load}	%
Outlet temperature	T_{out}	℃			
Mass flow	G	kg/s			

$$Q = G c_p (T_{out} - T_{in}) \tag{1}$$

$$W_{prim} = \frac{Q}{\eta_{boiler}} \times 100 \tag{2}$$

$$\eta_{road} = \frac{Q}{Q_{rated}} \tag{3}$$

Table 3. Input and output variables (Heat pump)

Input			Output		
Variable	Code	Unit	Variable	Code	Unit
Rated heating capacity	Q_{rated}	kW	COP	COP	
Inlet temperature at condenser	$T_{con,in}$	℃	Heating capacity	Q	kW
Outlet temperature at condenser	$T_{con,out}$	℃	Load factor	η_{load}	%
Mass flow	G	kg/s	Energy consumption	W	kW
Source temperature	T_{source}	℃	Primary energy consumption	W_{prim}	kW
Refrigerant	-	-			
Isentropic efficiency	η_{ad}	%			
Pinch point temperature at condenser	ΔT_{con}	℃			
Pinch point temperature at evaporator	ΔT_{eva}	℃			
Primary conversion efficiency	η_{prim}	%			

$$COP = \frac{h_{con,in} - h_{con,out}}{h_{con,out} - h_{eva,in}} \quad (4)$$

$$Q = Gc_p(T_{con,out} - T_{con,in}) \quad (5)$$

$$W = \frac{Q}{COP} \quad (6)$$

$$W_{prim} = \frac{W}{\eta_{prim}} \times 100 \quad (7)$$

2.4. Simulation output

By passing the system configuration and input variables with the aforementioned patterns to the analysis algorithm, simulation results including the total primary energy consumption and reduction rate of the entire system are output from each basic pattern of the input system. From the results output from the simulator, the effect varies based on how the heat pump is introduced into the target system, it is possible to evaluate and examine the overall system configuration that can achieve the maximum effect after the introduction of the heat pump. Additionally, it is possible to compare systems that already include heat pumps installed and changing the type, cycle configuration, and refrigerant used. For annual performance evaluation, there is a method to evaluate from the performance of each season, a method to evaluate from the performance of the representative day set every month, and a method to evaluate 365 days every minute or every hour. Thus, it is necessary to output data that can correspond to the output desired by the user and evaluation method. The simulator constructed in the study outputs time-series calculation results for each variable of the input system.

2.5. Verification

A prototype was specifically constructed for the simulator that enables evaluating the effects of introducing the industrial heat pump proposed above. Using the simulator, the measurement data of a factory where an industrial heat pump is already introduced was input to the simulator, and the analysis logic and calculation accuracy were verified. Figure 2 shows the flow chart of the target factory. In the factory, hot air from a gas burner is mainly used in the product drying process although a heat pump is used as part of the heating. Therefore, the classification described in 2.2 corresponds to Type4. Given that the measured values corresponding to the input items set in 2.3 are 1-minute intervals, the power consumption of the heat pump at 1-minute intervals is calculated for each representative day of 12 months. Furthermore, given that the measured value of power consumption corresponds to the total every 30 min, the calculated value was converted to an average every 30 minutes for comparison purposes. The results and measured values are compared to verify the accuracy of the simulator constructed in the study. The annual performance by the representative day of each month was calculated, and the representative day was set on the third Wednesday, which is used as the average value of each month. Additionally, we analyze the case of assuming a system configuration in which heating by a heat pump in the target factory is performed by a boiler. Based on the results, we evaluate the extent to which the primary energy consumption as a heat pump introduction effect can be annually reduced from the use of conventional boilers.

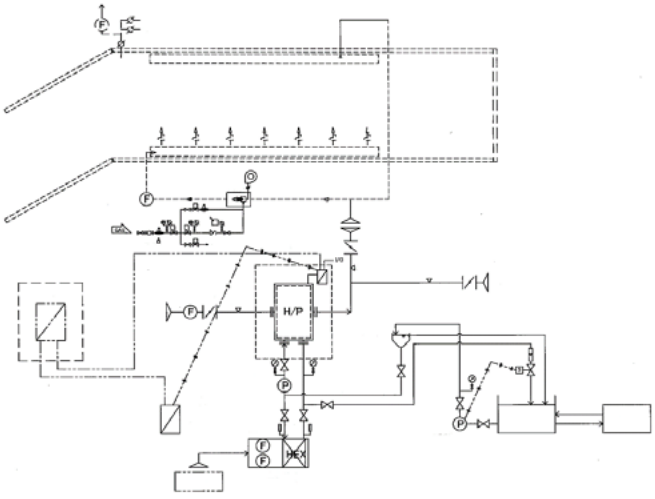


Fig. 2. Flow of the target factory

3. Simulation results and discussion

With respect to the power consumption of the heat pump, Fig. 3 shows the simulation results and measured values of daily transition for each representative day of the month and the total relative error of the day. Based on the results, in the analysis logic constructed in the study, the total annual power consumption multiplied by the number of factory operating days in each month corresponds to 5.47 GWh for the simulation result, 5.76 GWh for the measured value, and the relative error corresponds to 5.19%. With respect to Fig. 3, the power consumption on the representative day of each month is calculated lager than measured value except for March although the analytical values and the measured values exhibit similar fluctuation trends. Most of the time when the heat pump is operating in a stable manner, it exhibits an error of approximately 5%. Therefore, the analysis logic and calculation model of the simulator constructed the time exhibit sufficient calculation accuracy in practice. The reason why the calculated value exceeds the measured value is that the pinch temperature in the heat exchanger was set as constant to match the capability under the rated operating conditions defined by JIS. The COP is calculated as low, and thus it is necessary to set the pinch temperature as the performance of the heat exchanger smaller than the value determined in the rated operating conditions and set it based on the conditions of every minute. Hence, more accurate calculation results can be obtained via correcting the fluctuation of the heat exchanger pinch temperature under actual operating conditions. Henceforth, in order to achieve the specifically, we plan to set the pinch temperature input and investigate and correct the calculation logic.

Additionally, Fig. 4 shows a comparison of changes in the primary energy consumption before and after the introduction of the heat pump in June, when the relative error was the smallest, as the output of the simulator. Fig. 5 shows a comparison of annual primary energy consumption before and after the introduction of the heat pump.

As shown in Fig. 4, the primary energy consumption decreases by 35% per year with an error of 5.19% per year by introducing the heat pump to the target factory. In the simulation, a heat pump with a single-stage vapor compression cycle was modeled. However, in order to quantitatively evaluate the effects of introducing the heat pump in a wider range, it is necessary to model other models in the same manner as the proposed method.

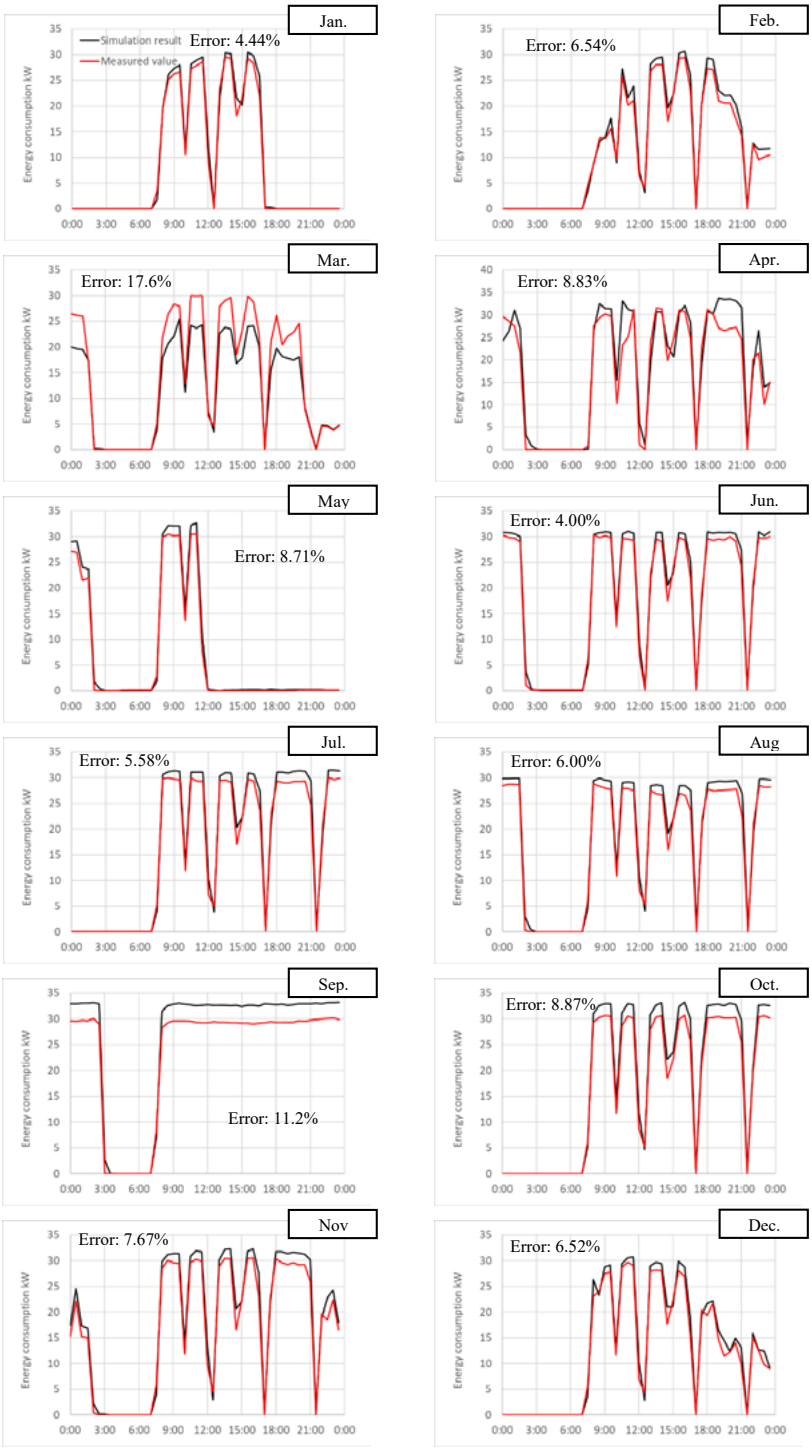

Fig. 3. Annual energy consumption fluctuation

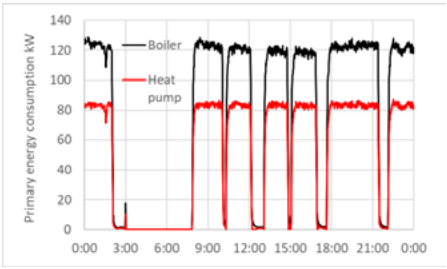

Fig. 4. Primary energy consumption fluctuation (June)

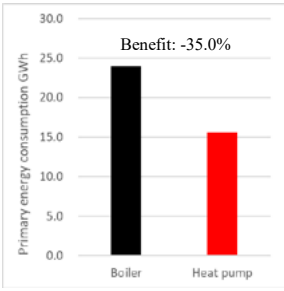

Fig. 5. Annual effect of introducing heat pump

4. Conclusions

In the study, we proposed 16 basic patterns that can categorize heat utilization systems including almost all boilers and heat pumps. Additionally, by incorporating the basic pattern model into the analysis logic, various system simulations are possible. Therefore, it was possible to quantitatively compare the primary energy consumption between a conventional system and new heat pump introduction system. In the study, we created an example that served as the basis for a simulator that incorporated the basic patterns and the built model and verified the accuracy by comparing the actual measurement data and simulation results at a factory where an industrial heat pump was already installed. Thus, the results that the annual power consumption (which is the output of the simulator) can be calculated with a relative error of 5.19% when compared to the actual measurement. Under the accuracy, the results indicated that the primary energy consumption decreased by 35% per year when compared to the case where the target factory was operated with a boiler under similar operating conditions. Henceforth, in order to further improve the accuracy of simulation calculations, we plan to develop and extend the model and specifically develop a simulator.

Acknowledgements

The study was the result of commissioned work by the New Energy and Industrial Technology Development Organization (NEDO). Additionally, when verifying the accuracy of the simulation, we received significant cooperation from Minami Denki Seisakusho Co., Ltd., Shikoku Electric Power Co., Ltd., and Shikoku Research Institute, Inc. for installation of measurement equipment and provision of various measurement data. The authors express their sincere appreciation to the aforementioned institutions.

Abstract

In order to reduce the gas consumption in LNG satellite stations, the authors have developed LNG vaporization systems applying hybrid ground source heat pumps (HGSHPs) combined ground heat exchangers (GHEXs) with air-water heat exchangers (AWHEXs). The heat pumps can vaporize the LNG with high efficiency because it is possible to vaporize the LNG by using the low-temperature hot water of around 25ºC. The ground source heat pumps (GSHPs) can supply the hot water stably even in the winter season due to no need of defrosting operation. In addition, the HGSHP system with AWHEXs can prevent the decrease of ground temperature due to the excess heat extraction. The authors constructed the field experimental apparatus and carried out the vaporization experiment with a HGSHP. The results indicated that it is possible to vaporize the liquid Nitrogen (Instead of LNG) by using hot water with the temperature of 25ºC and the low-temperature hot water supply with GSHP yields the reduction of energy consumption.

Keywords: Hybrid ground source heat pump; LNG vaporization; Ground heat exchanger; Air-water heat exchanger; Field experiment

1. Introduction

Recently, the number of facilities applying LNG satellite station is increasing in the case where the facilities has high gas demand such as factories. In some LNG satellite stations, it is necessary to burn the vaporized natural gas in order to supply the natural gas stably. In this case, 3~5% of the vaporized natural gas is used for burning, therefore, it is required to reduce the gas consumption for energy saving.

It is possible to reduce the energy consumption by applying the heat pump system because the natural gas can be vaporized by using the hot water with lower temperature compared to the usual hot water with the temperature of 60ºC. Especially, installation of GSHP systems is effective because of no need of the de-frosting operation. However, if the GSHP systems are applied for LNG vaporization, in which the heating demand is generated through the year, there may be a long-term decrease of ground temperature due to the excess heat extraction.

Therefore, the HGSHP system with AWHEXs is applied to prevent the decrease of ground temperature. Although the solar collectors that can absorb the solar heat are also used in the hybrid GSHP system [1], [2], the efficiency of the solar system drops during cloudy and rainy days. In addition, the solar heat cannot be collected during the night. In comparison, the AWHEXs can extract the heat from air even in the condition of

* Corresponding author. Tel.: +81-11-706-6284 ; fax: +81-11-706-6284.
E-mail address: katsura@eng.hokudai.ac.jp

cloudy or rainy weather if the air temperature is higher than the temperature of heat carrier fluid. It can recover the ground temperature by injecting heat regardless of the weather condition. In addition, the efficiency of heatpump can be improved compared to the conventional GSHP system if the hybrid GSHP provides heating in summer season. The authors constructed the field experimental apparatus of gas vaporization system with HGSHP and the experimental proof of gas vaporization with HGSHP was carried out. In addition, the energy saving effect of HGSHP was evaluated by using the result of experiment.

2. Outlines and advantage of system

Figure 1 shows a concept diagram of LNG vaporization system applying HGSHP. The system consists of heat pump units, GHEXs, AWHEXs, and LNG vaporization heat exchangers. Depending on the outside air temperature conditions, it is possible to select only the GHEXs or a combination of GHEXs and AWHEXs as the heat source. Then, the heat pump units supply hot water to the LNG vaporization heat exchangers and the LNG is vaporized. Here, the LNG vaporization heat exchangers are designed so that the hot water does not freeze even in the case where the hot water with lower temperature is supplied.

The following advantages of LNG vaporization system applying HGSHP are mentioned;

A. It is possible to obtain the heating output to stably vaporize the LNG.

B. There is no decrease of heating output and heating COP occurred by the de-frosting operation.

C. In summer season, the outside air with high temperature can be utilized as the heat source. In addition, the ground temperature surrounding GHEX can be recovered by injecting the surplus heat to the ground.

D. The hot water with temperature of 25ºC can be supplied from heat pump units because the LNG is vaporized with the hot water. Therefore, the energy efficiency and energy saving effect are larger than those in the common heating in which the hot water with temperature of 35~45ºC is supplied.

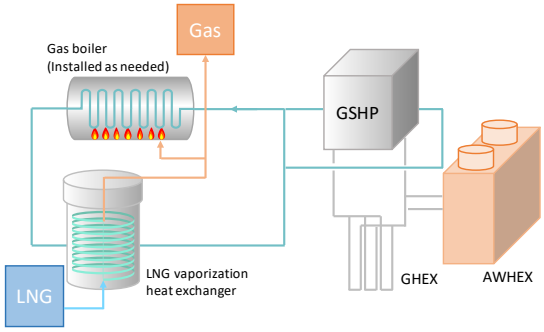

Fig.1 Concept of LNG vaporization system with hybrid GSHP system

3. Field experiment of gas vaporization system with HGSHP

3.1 Outlines of field experimental apparatus

The experimental apparatus of gas vaporization system with HGSHP shown in Figure 2 was constructed in the field of Hokkaido University in Sapporo city. The apparatus is a cut-down version of actual LNG vaporization system. In the experiment, the liquid nitrogen was used instead of LNG. Table 1 indicates the specification of heat pump unit (HP in Figure 2). The heat pump unit has two inverter compressors. The heat pump unit was connected to the two GHEXs with length of 100 m in the primary side and the vaporization heat exchanger in the secondary side, respectively. In addition, the AWHEX was connected between the heat pump unit and GHEXs. Therefore, it is possible to switch only the GHEXs or a combination of GHEXs and an AWHEX as the heat source. Table 2 indicates measurement points in the field experiment. The inlet and outlet temperatures and the flow rates in the primary side and the secondary side of heat pump unit were measured. By using the measured values of temperatures and flow rates, the heating output and the heat extraction rate were calculated. Additionally, the mass flow rate of vaporized nitrogen gas and the temperatures

before and after vaporization were measured, so that the consistency between the heating output from heat pump unit and the amount of heat used for vaporization could be confirmed. The heat pump COP and system COP were also evaluated by measuring the electric powers of a heat pump unit, circulation pumps, and a fan of AWHEXs.

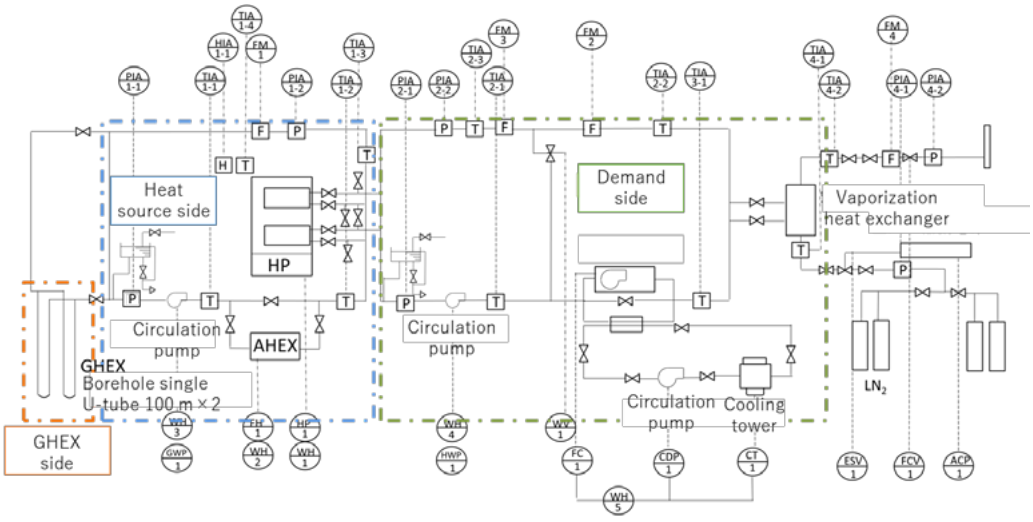

Figure 2 Diagram of field experimental apparatus

Table 1 Specification of heat pump unit

Heat exchanger	Plate heat exchanger
Flow rate	21 L/min
Rated heating output	13.6 kW
Rated electric power	4.2 kW

Table 2 Measurement items

Equipment (Number)	Measuring items	Unit
Pt-100 sensor TIA1-1	Outlet temperature of GHEXs	°C
Pt-100 sensor TIA1-2	Inlet temperature of HP in the primary side	°C
Pt-100 sensor TIA1-3	Inlet temperature of GHEXs	°C

Power meter WH-2	Electric energy of fan of AWHEX and circulation pump	kWh

3.2 Conditions of field experiment

Table 3 indicates conditions of field experiment. The experiments V1-1~V1-5 were carried out in winter season and only the GHEXs were used as heat source. The supply temperature of hot water and the mass flow rate of nitrogen gas were changed. The experiments V2-1~V2-3 were carried out in summer season and a combination of GHEXs and an AWHEX were used as heat source. The mass flow rate of nitrogen gas was changed.

Table 3 Conditions of field experiment

Test number	Test period	Heat source	Hot water temperature [°C]	Nitrogen flow rate [Nm³/h] (Load ratio)
V1-1	19/1/23 10.30-11.00	Ground	45	90 (100%)
V1-2	19/1/23 11.37-12.07		35	90 (100%)
V1-3	19/1/23 14.00-14.30		25	90 (100%)
V1-4	19/1/23 14.30-14.50			68(75%)
V1-5	19/1/23 15.06-15.36			45(50%)
V2-1	18/8/8 11:20~12:00	Ground +Air	25	90 (100%)
V2-2	18/8/8 12:00~13:00			45(50%)
V2-3	18/8/8 13:00~14:00			30(33%)

3.3 Results and discussions

Figure 3 shows the inlet and outlet temperatures (TIA2-1, TIA2-3) and the flow rates (FM-3) in the secondary side of heat pump unit in the experiments V1-3~V1-5. The variations of nitrogen gas temperature (TIA4-2) and mass flow rate of nitrogen gas (FM-4) are also drawn in Figure 3. The mass flow rate was close to the set value and the gas temperature changed from 10°C to 20°C. The liquid nitrogen temperature was about -170°C, therefore, it was confirmed that the liquid nitrogen was vaporized. Next, the outside air temperature (TIA1-4), the inlet and outlet temperatures (TIA1-2, TIA1-3), and the flow rates (FM-1) in the primary side of heat pump unit in the experiments V1-3~V1-5 were demonstrated in Figure 4. Although the inlet temperature in the primary side decreased, the temperature was higher than the outside air temperature. In addition, Figure 5 indicates the heating output, the heat extraction rate, and the electric power of system (Heat pump unit + Circulation pump in the primary side) in the experiments V1-3~V1-5. In the experiment V1-3, the heating output was approximately 12 kW and the electric power of system was approximately 2.2 kW, respectively. The system COP, which is the ratio of heating output to electric power of system, was approximately 5.5. This result indicated that the high value of system COP was obtained by supplying the hot water with temperature of 25°C even in the winter season.

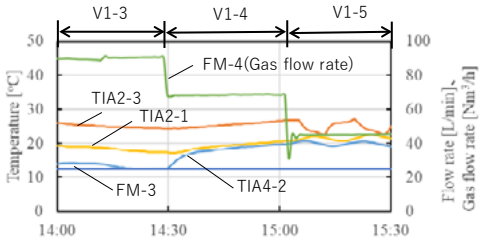

Figure 3 Variation of temperature and flow rate in the secondary side

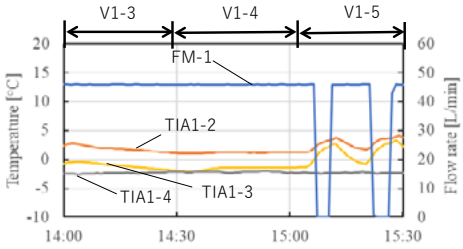

Figure 4 Variation of temperature and flow rate in the primary side

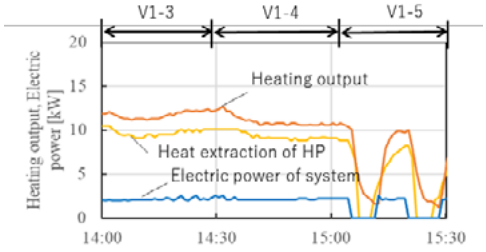

Figure 5 Variation of heating output, heat extraction and electric power

Figure 6 shows the inlet and outlet temperatures (TIA2-1, TIA2-3) and the flow rates (FM-3) in the secondary side of heat pump unit in the experiments V2-1~V2-3. The variations of nitrogen gas temperature (TIA4-2) and mass flow rate of nitrogen gas (FM-4) are also drawn in Figure 6. The mass flow rate was almost kept at the set value and the gas temperature varied from 10ºC to 25ºC. Therefore, the liquid nitrogen was stably vaporized as well as the experiments V1-3~V1-5. The outside air temperature (TIA1-4), the inlet and outlet temperatures (TIA1-2, TIA1-3), and the flow rates (FM-1) in the primary side of heat pump unit in the experiments V2-1~V2-3 were demonstrated in Figure 7. The inlet temperature was approximately 20ºC higher than the temperature in the experiments V1-3~V1-5. This was due to the heat extraction from the AWHEX. In addition, Figure 8 indicates the heating output and the electric power of system (Heat pump unit + Circulation pump in the primary side + Fan of AWHEX) in the experiments V2-1~V2-3. Although the heating output was not constant, the average heating output in the experiment V2-1 was almost as much as the heating output in the experiment V1-3. Figure 9 shows the heat extraction rates of heat pump unit, GHEXs, and AWHEX. The heat extraction rate of AWHEX were much higher than the heat extraction rate of heat pump unit. This result indicated that the surplus heat from AWHEX was injected to the ground via the GHEXs.

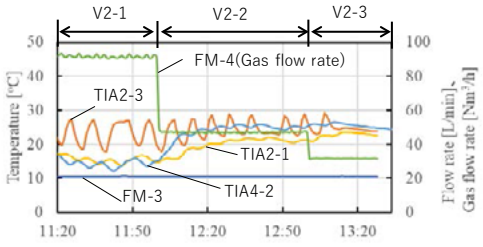

Figure 6 Variation of temperature and flow rate in the secondary side

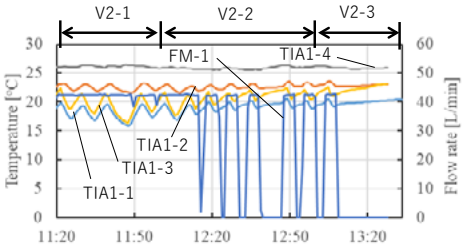

Figure 7 Variation of temperature and flow rate in the primary side

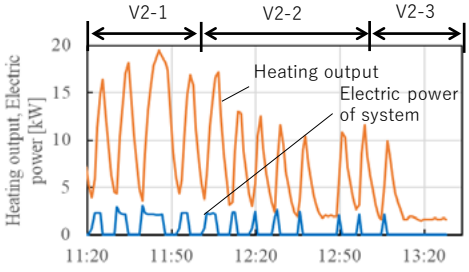

Figure 8 Variation of heating output, and electric power

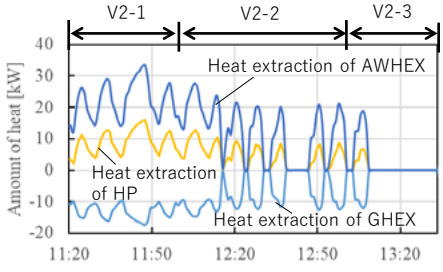

Figure 9 Variation of heat extraction

Table 4 summarizes the heating output from heat pump unit, the heating output for vaporization, the electric power of system, and the system COP(SCOP). The heating output from heat pump unit and the heating output for vaporization were almost equality. Therefore, the heating output from heat pump was used for vaporization. When the SCOPs in the experiments V1-1~V1-3 were compared, the SCOP in V1-3 (Hot water temperature: Approx. 25ºC) was approximately 1.3 times of the SCOP in V1-2 (Hot water temperature: Approx. 35ºC) and approximately 1.7 times of the SCOP in V1-1 (Hot water temperature: Approx. 45ºC). From this result, the improvement of SCOP by supplying the hot water with lower temperature was confirmed. In addition, the SCOPs in the experiments V2-1~V2-3, in which the AWHEX was used in summer season, were more than 10. Basis on these results, the primary energy consumptions in V1-3 and V2-1 were calculated and were compared to the conventional gas boiler system (Boiler efficiency: 0.85). If the primary energy consumption per the electric energy was set as 9.76 MJ/kWh [3], the energy saving effects were approximately 57% in V1-3 and approximately 76% in V2-1, respectively.

Table 4 Summary of field experiment

Test number	Heating output from GSHP [kW]	Heating output for vaporization [kW]	System electric power [kW]	SCOP
V1-1	13.3	13.6	4.2	3.2
V1-2	12.6	13.1	2.9	4.3
V1-3	11.9	12.6	2.2	5.4
V1-4	11.0	10.0	2.4	4.6
V1-5	5.5	6.5	1.1	5.0
V2-1	11.4	12.4	1.1	10.8
V2-2	6.7	6.2	0.5	13.4
V2-3	3.0	3.5	0.2	15.0

4. Summary

1) The outlines and advantages of LNG vaporization system with HGSHP were explained.

2) By using the field experimental apparatus of vaporization system with HGSHP, the authors tested the vaporization of nitrogen liquid instead of LNG. As the result, it was possible to stably vaporize the liquid nitrogen by supplying the hot water with temperature of 25°C. In addition, when the hot water temperature was kept at around 25°C, the SCOP of HGSHP system was 5.4 in the winter season. This SCOP was approximately 1.7 times of the SCOP in the case where the hot water temperature was around 45°C.

3) The SCOPs in the experiments V2-1~V2-3, in which the AWHEX was used in summer season, were more than 10.

4) Basis on the field test result, the primary energy consumptions were calculated and were compared to the conventional gas boiler system. When the hot water temperature was around 25°C, the energy saving effects were approximately 57% in winter season (Only GHEX was used) and approximately 76% in summer season (Combination of GHEX and AWHEX was used), respectively.

Feasibility of using ground source heat pumps in heating and cooling of residential buildings

Seama Koohi-Fayegh*
OntarioTech University, 2000 Simcoe St. N, Oshawa, ON L1G 0C5 Canada

Abstract

In many building types, heating and cooling demands are often unbalanced and using a single ground source heat pump (GSHP) to meet both heating and cooling demands introduces various options to designers in sizing the ground heat exchangers coupled to the heat pumps. Due such unbalanced heating and cooling demands, use of ground source heat pumps may not be feasible, or not financially feasible if coupled with a supplementary system. In this study, the impact of heating and cooling demands typical of a residential building on the feasibility of use of ground source heat pumps is studied. A typical residential building block in Ontario, Canada is modeled in eQuest 3.65. Simulation results of the models for space heating and cooling demand are used in RETScreen to arrive at a combination of technologies that may be able to provide heating and cooling to the buildings. Comparison of the approximate cost estimations for the various design options show the importance of employing customized coupling strategies in order to take maximum advantage of ground source heat pump systems and promoting their financial feasibility.

Keywords: Ground-source heat pumps; Heating and cooling; Balanced; residential; eQuest; RETScreen;

1. Introduction

As governments place more stringent requirements on energy performance of buildings and provide financial incentives for construction of sustainable buildings, use of more efficient heating and cooling energy systems in building designs is becoming more popular compared to a decade ago. For example, City of Toronto has mandated employment of renewable energy technologies in city properties [1]. Ground source heat pumps (GSHPs) seem to be suitable options to promote sustainable building designs and their financial and technical feasibility is assessed with varying levels of detail in several studies [2][3][4]. For example, in order for their use to be financially feasible over the system life cycle, the variation in heating and cooling load of the building need to be reviewed. Accurate estimation of building energy performance is possible with computer programs that are able to perform hourly building energy simulations, such as eQuest 3.65 and Hourly Analysis Program (HAP) [4]. eQuest 3.65 is a computer program based on a solver engine developed for the US Department of Energy and performs hourly building energy simulations [5]. While it has been used in a number of scholarly articles to show building energy performance and/or to calculate building heating and cooling loads [3,6-7], it has not been used in combination with other software to show financial feasibility of GSHPs. RETScreen [8] provides a tool to perform technical and financial feasibility analyses of various energy system types and has been used in several scholarly studies [4,9-12]. This software is used for many feasibility analyses in early stages of the design when various heating and cooling options are explored. Another software used for analysis of the systems when system details are available is TRNSYS; however, this software is often used by scholars aiming to evaluate existing designs or systems [3]. Except a few studies on economic analysis of GSHPs [13], their financial feasibility has not been widely studied and not compared for various design options as the current study has.

In the preliminary stage of building design, i.e., design development stage, a preliminary feasibility assessment is sometimes performed to estimate the financial feasibility of use of geothermal heat pumps. The

outcome of this feasibility study is important since it would consequently impact the decision whether to select geothermal heat pumps as the optimum candidate for a given building type or not. The objective of the current article is to show how sensitive such preliminary analysis outcome is to the selection of parameters such as building loads, design strategy studied for a given building load, and system component costs. Some details are intentionally not included in the study to ensure that the conclusions are based on what is indeed the limited inputs in the ground source heat pump feasibility analyses. If geothermal heat pumps are shown to be financially feasible, further detailed analysis needs to be performed. However, in some cases, the preliminary feasibility analysis may not show satisfactory financial feasibility for incorrect reasons. It may be concluded that some parameters need to be the subject of more focus to ensure the preliminary feasibility analysis shows results that are accurate enough. In this study, the impact of heating and cooling demands typical of a residential building in Ontario, Canada, selected design strategy, and system component costs on the financial feasibility of use of ground source heat pumps is studied.

2. Method

The method used in this study consists of two parts: estimation of heating and cooling energy requirements and feasibility of providing such energy, fully or partially, through ground-source heat pump(s).

2.1.Building energy consumption

In this section, information regarding the characteristics of typical newly-built residential buildings in Ontario, Canada, such as floor area and HVAC systems used are included. In addition, the general method used in estimating the heating and cooling energy consumptions of the building block is provided.

The information used in the models includes the total residential building area (total and square footage), building envelope characteristics, building use characteristics and number of residential units. A summary is provided in Table 1. Note that while much detail is included in the model to generate hourly heating and cooling demands of the building, only main ones are included in this section. Further details on the building are deemed unnecessary for the purpose of discussions in this article and the level of accuracy aimed.

Table 1: Building general characteristics

Building Specification	Value
Site location	Toronto, Ontario[1]
Total building area	3135 m^2
Building footprint	784 m^2
Percentage of building residential area	90%
Number of houses	32
Floor height	3.0 m

[1] weather file for Toronto in 2016 is used in the eQuest model.

Using the information in Table 1, the heating and cooling demands of the building block is calculated in eQuest 3.65. The eQuest model inputs are categorized in three section and are selected from building standards currently used in Ontario, Canada (see Table 2). They are building envelope characteristics, internal gains, outdoor air requirements and air distribution systems.

Table 2: Building envelope and use characteristics

Building characteristic	
Weather file	Toronto, Ontario
Envelope	NECB[1] 2015 standards
Internal gains	NECB 2015 standards
Window-to-wall ratio	20%

2.2.Heating and cooling provision using ground source heat pumps

Once the space heating and cooling loads are estimated for the building block, the model is further developed in RETScreen to include the heating and cooling systems. A base case and four cases with various ground source heat pump strategies are investigated (see Table 3). Note that the information listed in the table are based on RETScreen database that is supported by available heat pump models. However, performance details of such heat pumps are not included in the analysis as in [15][16]. For example, an average COP for heating is used for calculation of the electricity requirements of the heat pump in the heating mode and seasonal load variations and their impacts on the performance of the heat pump is not accounted for. As a result, much of the details of a heat pump system such as refrigerant type and compressor type are not included in the current article. Such technical detail on various heat pump models can be found on the heat pump manufacturer websites such as the one used in the current article [17], but is not included in preliminary feasibility models. It is only after a feasibility analysis shows positive results of feasibility of use of ground source heat pumps that inclusion of details of heat pump performance are included in the model. The systems used as the base case, are heating and cooling systems typical of those used in conventional townhomes built in Canada. The strategies are selected based on individualized versus centralized systems. Individual systems refer to heating and cooling systems that that are installed in each townhome and only meet the needs of that individual townhome. Central systems refer to one system for heating and/or cooling all townhomes. The strategies are also based on how heating and cooling energy demand is covered. In many locations such as in Toronto, Ontario, annual heating and cooling demands of residential buildings cannot be covered using a single ground source heat pump with heating and cooling capacities equal to the demand. In such cases, GSHP systems can either be sized for cooling demand or the heating demand. In Toronto, Ontario, residential buildings have larger heating demands than cooling ones. However, when using a heat pump to provide heating and cooling to the building, the amount of heat that is exchanged with the ground is larger during cooling than during heating. This is due to the fact that the energy that is transferred to the ground via a heat pump in the cooling season includes the compressor energy as well as the energy extracted from the space which increases the energy transfer to the ground. Similarly, the energy that is delivered to the space in the heating season includes the compressor energy as well which reduces the amount of energy needed from the ground. In order to keep the heat exchange between the building and the ground balanced, two strategies arise in sizing the GSHP: sizing for heating demand and for cooling demand. When the systems are sized for cooling demand, theoretically all the heat removed from the space is transferred to the ground and only some of that is used to meet the heating demand in the heating season while the rest is rejected to the outside air when not needed. This is to avoid temperature rise in the ground as the cycle repeats seasonally. In this case, the energy transferred to the ground in the cooling season is first calculated as

$$Q_{g,inj} = Q_{sp,c} + \frac{Q_{spc,c}}{COP_C} \quad (1)$$

where $Q_{g,inj}$, $Q_{sp,c}$, and COP_C are heat to be transferred to the ground (heat injection), space cooling needs, and coefficient of performance of the heat pump in cooling mode, respectively.

In this case, the heat available for heating is more than needed in the space and is calculated as:

$$Q_{g,ext} = Q_{g,inj}\left(\frac{COP_H}{COP_H - 1}\right) \quad (2)$$

where $Q_{g,ext}$ and COP_H are heat to be extracted from the ground and coefficient of performance of the heat pump in heating mode, respectively.

Table 3: Building envelope and use characteristics

		Heating system	Cooling system	Peak cooling system
Case 0		Furnace	AC [3]	
Base system	Ind.[1]	80% efficiency	COP 3

[1] Ind. Individual system for each dwelling

[2] Cen. Central system for all dwellings

[3] AC Vapor compression air conditioner

[4] GSHP Ground source heat pump

The additional heat that need to be rejected to the outside air is calculated as

$$Q_{additional\ heating} = Q_{g,ext} - Q_{spc,h} \tag{3}$$

where $Q_{spc,h}$ is the space heating need.

Alternatively, when the systems are sized for heating demand, only part of the heat removed from the space in the cooling season is transferred to the ground via a GSHP. The amount of heat corresponds to the heating energy demand during the heating season. The rest of the space heat in the cooling season could be removed via a vapor compression air conditioning unit. In this case, the energy transferred from the ground in the heating season is first calculated as

$$Q_{g,ext} = Q_{sp,h} + \frac{Q_{spc,h}}{COP_H} \tag{4}$$

In this case, the heat allowed to be rejected to the ground, in order to maintain balanced ground temperature over one heating and cooling cycle, ($Q_{\mathrm{spc,c,al}}$) is less than space cooling demand as and is calculated as:

$$Q_{spc,c,al} = Q_{g,ext}\left(\frac{COP_C}{COP_C + 1}\right) \tag{5}$$

where $\mathrm{COP_C}$ is the coefficient of performance of the heat pump in cooling mode. The additional heat that needs to be provided via a cooling system other than the ground source heat pump (e.g., and air conditional unit) is calculated as

$$Q_{cooling\ deficit} = Q_{spc,c} - Q_{spc,c,al} \tag{6}$$

Note in Table 3 that the values used for efficiency of systems, are those typically found in many manufactured systems available in Canada. In addition, it must be noted that that the use of seasonal COPs in the current feasibility analysis is only acceptable for analysis done in design development stage where no detailed design information is available. Once detailed designs are available, a more thorough analysis must be performed to validate the COPs used for the ground source heat pump that vary based on ground temperature variation as heat is stored and collected from the ground.

In cases 2-4, a ground heat exchanger component is modeled in RETScreen which uses the heating and cooling demand calculated in the previous section and approximates the size of heat exchangers needed to exchange the required heat with the ground. Such analysis could become very complex and required use of specialized numerical methods and tools to estimate the size of the heat exchanger. Such accurate analysis is often encouraged for detailed design of ground source heat pump systems, but is often not used for preliminary feasibility analyses preceding the design stage. For this reason, the simplified method used to approximately estimate the heat exchanger length in RETScreen is considered satisfactory for this study. In the current study, boreholes, i.e., vertical ground heat exchangers (shown in Figure 1), are used in the model due to their small land area requirements compared to horizontal ground heat exchangers. While horizontal heat exchangers offer better financial benefits, their use in buildings with small outdoor land area (e.g., backyard) may not be technically feasible. Ground properties for clay rich soil are used in the model as they are closest to the type

of soil observed in north Toronto area when reviewing cross-section of geological conditions in Toronto [21]. The soil properties used in the model are listed in Table 5. Assumptions made in the heat exchanger model as well as estimated calculated length for the boreholes are included in Table 6.

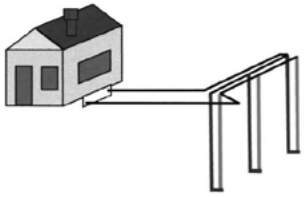

Figure 1: Schematic of vertical ground heat exchangers [22]

2.3.Other system assumptions

The pumping head is calculated based on the length of the boreholes and 15 m of head is added to the pumping head to account for the pressure losses in piping. The mean ground temperature is assumed to vary from 7.5°C by an altitude of 21.4°C on the ground surface with variations decreasing to zero at depths more than 15 m. The temperature of the water flowing into the heat pump is assumed as 0°C and 25°C for heating and cooling modes, respectively. The variation in the ground temperature as heat is injected and extracted from the ground is not accounted for in RETScreen. Such detailed analysis would not be performed at the early stages of design and is therefore neglected in the current study.

2.4.System cost estimation

Once technical specifications regarding the heating and cooling systems are included, capital and operating costs are included in the RETScreen model to analyse the impact of various system selection strategies on financial feasibility of the systems. A summary of the cost information used to compare the various selection strategies is provided in Table 4.

Table 4: Capital and operating costs used in the model [8, 18-20]

Item	Cost
Electricity	$0.13 /kWh
Natural gas	$0.30 /m^3
Fuel cost escalation rate	4.5%
Natural gas furnace	$88 /kW Heating
Heat pump	$350 /kW heating[1]
Vapor compression air conditioner	$350 /kW cooling[1]
Ground heat exchanger loop - pipe	$4 /m
Ground heat exchanger loop – drilling and grouting	$21 /m
Ground heat exchanger pump	$800/kW
Townhouse unit sub-meter	$400 /house
Central heating/cooling plant (sub-meter and piping)	$6000
Operation and maintenance cost	$2-3/ m^2 [2]
Inflation rate	2%
Discount rate	3.5%
Debt ratio	30%
Debt interest rate	3%
Debt term	20 years

[1] 10% reduction in capital costs are assumed for central systems

[2] space unit area

In the next section, a summary of preliminary findings of the RETScreen model (e.g., as system size information) are provided.

3. Results and Discussions

The method described in the previous section is used for a base case and four cases with various ground source heat pump design strategies to compare their financial performance.

Table 5: Thermal properties of soil

Characteristic	Value	
Conductivity	1.3	W/m°C
Diffusivity	6.45 x 10^{-7}	m^2/s
Density	2100	kg/m^3
Heat capacity	0.96	kJ/kg°C

Table 6 Ground heat exchanger characteristics

Characteristic	Value
Borehole diameter	150 mm
Borehole total length	920-1420 m[1]
Borehole distance	12 m

[1] Estimated in RETScreen

Conventional furnace heating and compression cooling were assumed as a baseline for the townhouses. As shown in Table 3, the baseline energy systems use natural gas and electricity to operate.

Simulation results of heating and cooling loads in eQuest are shown in Figure 2. As expected in Ontario, Canada, the heating and cooling maximum space demand for the building in the occurs in months of January and July and are approximately 73 kW and 77 kW, respectively. This is typical of residential systems in Ontario, Canada, weather where the cooling loads are larger than the heating loads. Such effect is often magnified in other building use types such as office buildings where there is much internal heat gains to be removed by the cooling systems.

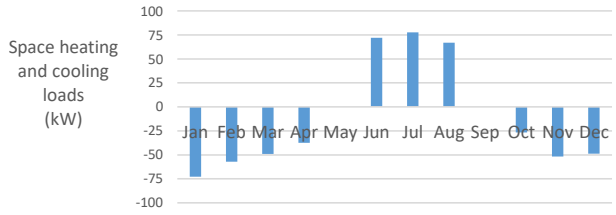

Figure 2: Simulation results of heating and cooling loads for the residential building block

As explained in the previous section, in order to keep the heat exchange between the building and the ground balanced, either the heat pump needs to be sized for cooling and be oversized for heating, or the system must be sized for heating and a supplementary air conditioning unit be used for cooling. In this study, both options are investigated since the first has reduced the capital and operating costs due toavoidance of a secondary cooling system in addition to the ground source heat pump, but has larger ground heat exchangers which generally contribute to about 80% of capital costs. The latter case, i.e., sizing for heating and using a supplementary cooling system, results in a smaller size ground heat pump, and therefore, fewer boreholes that would need to be installed for the smaller heat pump. The distribution of cooling design capacities are shown in Figure 3 for Cases 1 and 2, respectively. It is seen that compared to sizing the GSHP for cooling (Figure 3a), when the system is sized for heating, only a portion of cooling demand can be met by the GSHP and an additional cooling system, in this case a vapor compression air conditioner, is needed to cover the remaining cooling demand (Figure 3b). If heating and cooling loads were each 10% lower and higher than the case modeled in the current study, respectively, the size of the supplementary cooling system would become more pronounced. It is shown in Figure 3c that the additional 3% cooling demand covered by a supplementary

system in Figure 3b would increase to 23% in such case. This would affect the cost and financial feasibility of the hybrid system design where the cooling loads are met by GSHP and a supplementary cooling system.

It should be noted that the distribution of cooling loads for the 10% lower and higher heating and cooling demands would resemble that of Figure 3a for Case a where GSHP is sized for cooling demand. Such case, however, would result in a much more oversized system for heating.

Figure 4 shows the amount of heat available in the ground to meet the building heating needs. The additional heat available must be removed from the ground to ensure balanced ground temperatures over the annual operation of GSHPs. In cases where there is no use for this additional heat, it can be transferred to the outside air. Comparing Case 1 and Case 2 with cooling distributions in Figs. 4a and 4b shows how a perfect balance of heat exchange with the ground may never be achieved when using a GSHP. As expected, Figure 3c and the 10% cases in Figure 4 show that the larger the imbalance between space heating and cooling demands, the larger the supplementary system capacity is when sizing the GSHP for heating, or the larger the amount of heat that needs to be removed from the ground when it is not needed when sizing the GSHP for cooling.

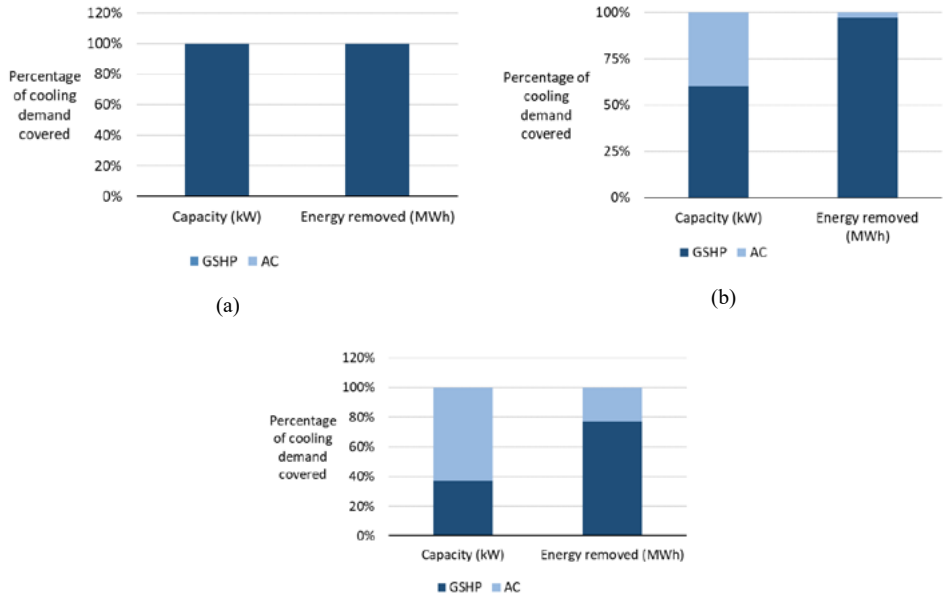

Figure 3: Distribution of cooling design capacities for (a) Case 1, GSHP sized based on cooling demand, (b) Case 2, GSHP sized based on heating demand, (c) Case 2, Case 2 for 10% more cooling demand and 10% less heating demand.

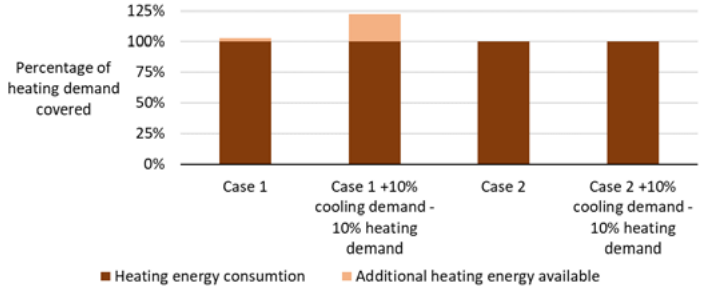

Figure 4: Distribution of heating energy available from the GSHP in four cases

To understand how these various design options contribute to the cost of the system and to its financial feasibility, Figure 5 shows the cumulative cash flow diagram for Case 1, when GSHP is used for heating and cooling with no supplementary cooling system. It is shown that the payback period for this case is about 7 years which could lead to the conclusion that the GSHP alone with no supplementary cooling system and oversized for heating would be profitable. Similar analysis on Cases 2-4 were made and the results for estimated payback periods are shown in Figure 6. It is seen in Figure 6 that although sizing for cooling demand and use of a supplementary cooling system (Case 2) is expected to result in lower capital costs due to smaller ground heat exchangers (estimated 18% lower size of the ground heat exchangers), it would still result in higher costs for the case in the current study. This is due to the higher costs associated with maintenance of air conditioners compared to GSHPs as well as the larger capital costs associated with two cooling systems as opposed to one GSHP (Case 1).

To examine how such conclusions would vary if a central system was used for Cases 1-2, Cases 3-4 were analyzed which included 10% reduced capital costs for the GSHP and supplementary systems. Such assumption was made due to lower design oversizing factors needed for systems serving more than one residential units. However, the costs of metering each residential unit within the block were estimated to be higher than that of individual systems. This led to the overall capital cost of the central systems for Cases 3 and 4 to be larger than their individual system equivalents (Cases 1 and 2, respectively), as seen in Figure 6. Lower metering costs and a larger block size may contribute to their improved financial performance. Such detailed focus is part of ongoing research and is outside of the scope of the current analysis. Another parameter that could greatly impact the comparisons made between the various cases is the coefficient of performance (COP) of the GSHP in heating and cooling modes and that of the supplementary cooling system. In the current study standard values were selected (see Table 4), but it is suggested that the results of the current study be used in cases with comparable heat pump and air conditioner COPs.

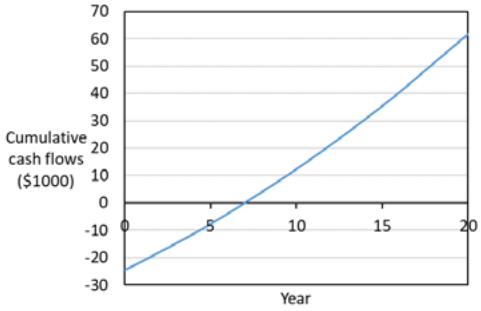

Figure 5: Cumulative cash flow for Case 1, GSHP used for heating and cooling with no supplementary cooling system

Lastly, the four cases described in Table 3 were compared against four cases with an increased unbalance between heating and cooling demands, i.e., 10% lower heating demand and 10% higher cooling demand compared to the demands simulated in eQuest 3.65 in the current study. It was found that although more unbalanced demands may result in more unbalances in system design and heating and cooling system sizing (see Figure 3c and Figure 4), their impact on system financial performance and payback period would remain relatively the same. More unbalanced systems with larger cooling demands and smaller heating demands may results in slightly lower payback periods for Cases 1 and 3 where the amount of heating demand directly affects the cooling via the GSHP and the ground heat exchanger. A lower heating demand, in the case of sizing the GSHP on heating demands, will result in lower amount of heat transferred to the ground in the cooling season. As a result, the GSHP and the ground heat exchanger sizes are reduced compared to the case of the current study. The cooling load would have to be covered using a larger supplementary system, but the decrease in capital costs due to smaller GSHP and smaller ground heat exchanger sizes would dominate the impacts and would result in slightly lower payback periods. However, the variation in payback periods observed in this case is considered negligible (less than 5%) and it is concluded that the results of Figure 6 could represent such unbalanced cases as well. From a more general perspective, this could refer the importance of coupling loads of various building types in order to maximize financial advantage of using ground source heat pump systems.

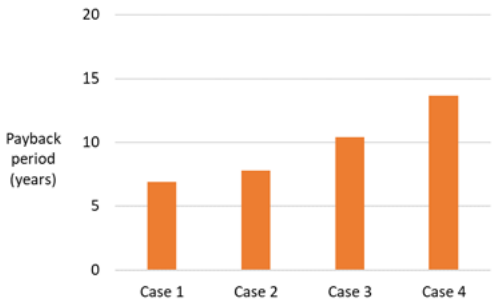

Figure 6: Payback periods estimated for various GSHP cases (refer to Table 3 for details of each design case)

For example, central geothermal heat pumps designed for a number of buildings of more than one type with various load profile characteristics could result in an overall heating and cooling load whose distribution is closer to one corresponding to an optimum geothermal heat pump design. Such optimum load profile could avoid use of supplementary cooling devices or oversized geothermal heat pumps which negatively impact financial feasibility of geothermal heat pump use.

4. Sensitivity Analysis

Here, the calculated payback period for the four cases (shown in Figure 6) are analyzed using a sensitivity analysis to verify the impact of a number of system cost components on the overall feasibility of using geothermal heat pumps for heating and cooling residential building use in the current study.

In the current analysis, it is assumed that heat pumps and chillers will have the same cost and that the additional cost of a geothermal heat pump systems is related to the ground heat exchanger costs. However, in some countries, higher costs are involved with heat pumps. In order to examine how the variation in cost affects the results of the analysis, a sensitivity analysis is performed to examine the variation in results of Figure 6 when the cost of heat pumps are 20% higher than the cost of chillers. It is found that a 20% increase in the cost of the heat pump compared to a chiller results in approximately 9-17% increase in the payback period, i.e., 8-15 years. The effect of variations in cost of geothermal heat pump compared to the cost of a vapor compression air conditioner is considered relatively small on the overall outcome of the feasibility analysis. With more advances in heat pump technologies and their increased use, it is estimated that the payback period would not exceed their current-day values and that geothermal heat pumps will become more favorable in the future.

In addition to varying the cost related to the heat pumps and chillers, the cost of electricity and gasoline is also expected to greatly impact the results of the analysis. Since Ontario has one of the higher electricity rates in Canada, a sensitivity analysis is performed by decreasing the cost of electricity up to 20%. It is seen that, compared to the capital costs associated with the geothermal heat pump and the air conditioner, the cost of electricity has a much higher impact (approximately 40-60% increase) on the payback period in the current case calculated for use of geothermal heat pump and consequently on the decision whether to use geothermal heat pumps or not. This is due to the fact that the large capital costs of geothermal systems are often compared to the annual operating costs of the base system, in this case the furnace and the vapor compression air conditioner that operates using electricity. A lower electricity price would result in a longer payback periods making geothermal heat pumps less favorable and in some cases financially infeasible (Case 4 in the current study). Similarly, it is expected that higher costs of gas in regions where gas heating is typical will result in lower payback periods for use of geothermal heat pumps (approximately 15-45% decrease for 20% increase in gas price in the current case). This is result is important as the cost of electricity and gas in various regions around the world vary and could make the feasibility of use of geothermal heat pumps for residential heating and cooling vary greatly in addition to the design strategy discussed earlier in this section.

The largest component contributing to the cost of geothermal heat pump systems is the cost of grouting and filling for installation of ground heat exchangers. A sensitivity analysis is performed to estimate the impact of 20% reduction in costs of filling and grouting on the financial feasibility of the system. It is seen that up to 17% reduction in payback period for Case 1, i.e., less than 6 years payback period, is resulted for the building under study.

5. Conclusions

A preliminary feasibility assessment is performed to estimate the importance of parameters used in such analysis on the financial feasibility of use of geothermal heat pumps. Such feasibility study is often performed at the early stages of design and its outcome would consequently impact the decision whether to select geothermal heat pumps as the optimum design for a given building type or not. The impact of parameters such as building loads, design strategy studied for a given building load, and system component costs on the outcome of such feasibility analysis is examined in the current study. Financial feasibility of geothermal heat pumps is decided using payback periods calculated when using geothermal heat pumps as opposed to a typical heating and cooling system used in Ontario, Canada, over the life of the system. It is concluded that some parameters such as the price of gasoline and electricity over the life cycle of the technology need to be the subject of more focus to ensure the preliminary feasibility analysis shows results that are accurate enough. Knowledge of such information could guide designers, developers, and energy modelers in equipment recommendation, infrastructure and operational requirements, constraints, estimated costs and off-site opportunities. They are listed as follows:

5.1.Building loads

A few GSHP design strategies are examined in the current study. They are mainly sizing the GSHP and its coupling ground heat exchanger

- solely based on building heating demands, or
- based on building cooling demands while including in the design a peaking cooling system to be used with the GSHP.

Based on industry standard design assumptions and cost estimates for the capital and operating costs of the systems in Ontario, Canada, it is found in this study that using ground source heat pump systems for residential building blocks in Ontario, Canada, are feasible with a payback period of about 7 to 14 years. It is concluded that the range of payback periods varies depending on the specific heating and cooling demand characteristics of the building. In a broader perspective, this emphasizes the importance of employing smart building coupling strategies in order to maximize financial advantage of using ground source heat pump systems. Strategies could consist of designing geothermal heat pumps to serve buildings of more than one type with various load profiles in order to avoid use of supplementary cooling devices or oversized geothermal heat pumps which negatively impact financial feasibility of geothermal heat pump use.

5.2.Design strategies

Comparison of various GSHP design options in the current study shows that the range of payback periods varies significantly depending on the strategies that are employed in designing GSHPs to meet building heating and/or cooling demands. This emphasizes the importance of employing various design strategies in order to maximize financial advantage of using ground source heat pump systems.

5.3.Component costs

A sensitivity analysis of operating costs and capital costs show that cost of fuel used for heating and cooling in the base case (i.e., electricity and gas in the current case) may have the largest impact on financial feasibility of using geothermal heat pumps. Other costs such as cost of geothermal heat pump or cost of grouting and filling of the ground heat exchanger, while still impactful, may have lower impact on the outcome of the feasibility analysis performed at this level.

Abstract

Large scale heat pumps constitute one of the most important technologies to pursue a future decarbonized heating supply. In this paper a quantitative overview is given for the EU based on Heat Roadmap Europe (HRE4) also referred in the IEA report Annex 47. Based on this future heating challenge it is important that the suppliers and technology developers of the large scale heat pumps take up the challenge and replies to the opportunities and challenges to obtain the best scenarios. The conditions for district heating grids and heat sources for addressing the appropriate heat pump technologies are described. Applications using low GWP refrigerants like CO2, Ammonia and HFO are compared. The paper also considers the opportunities for addressing decentralized heating providers like supermarkets and chillers traditionally intended for cooling only.

Keywords: Large Heatpump; Oil Free systems; Low noise level; Efficiency

1. Introduction

The EU energy targets for 2030 and the long term 2050 decarbonization aspirations call for the most efficient and innovative cross sectorial solutions. Some countries are already moving beyond previous targets e.g. Denmark has now a domestic target of 70% emission reduction by 2030 and more countries will likely follow with strengthened targets to decrease emissions. Heating of buildings is the largest energy consumer and CO2 emission source focus is on planning for a resilient and efficient system which can provide affordable heat for all. To minimize investments the energy demand must be reduced by energy efficiency measures on buildings and performance optimization of technical building systems – the second factor is to establish efficient heating supply system and to make it decarbonized, with focus on renewable electricity The nature of renewable primary energy supply will force the demand and supply sector to become much more integrated and this will ultimately call for new applications and technologies like demand side flexibility and thermal or electrical energy storage. In the Heat Roadmap Europe (HRE) studies [1],[2] it has been shown that increasing the district heating to cover 50% of the total heat demand together with a 40 GW heat pump capacity in average can address up to 15 % of total heat demand. In periods with a surplus of renewable electricity heat pumps are supposed to supply most heat and utilize thermal storage. The large-scale heat pumps are estimated to produce 520 TWh/year with a coefficient of performance (COP) of 3, see figure 1 and 3. Such an increase enables a much larger utilization of alternative sources of heat like ground source thermal heat and waste heat from data centers and at the same time can utilize of renewable intermittent electricity.

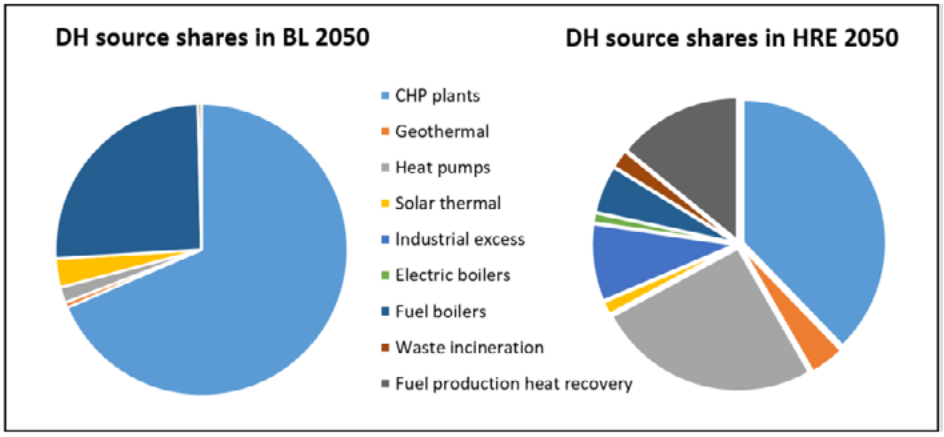

Fig. 1. 2050 DH source share. HRE is the decarbonised scenario [1], likely to increase the HP share with new emission targets

While realized COP in *cooling systems* is important though not a primary business factor (due to existing business models) – it becomes obvious that in heating the 'realized COP' of the heat pumps is a primary business factor for DH operators. The realized COP depends on some basic factors like *temperature lift* and also the *technology* behind the Heat Pump systems. Reported COP values for large heat pumps can be seen in figure 4 [1]. It is obvious that the realized COP values depend on the temperature lift.

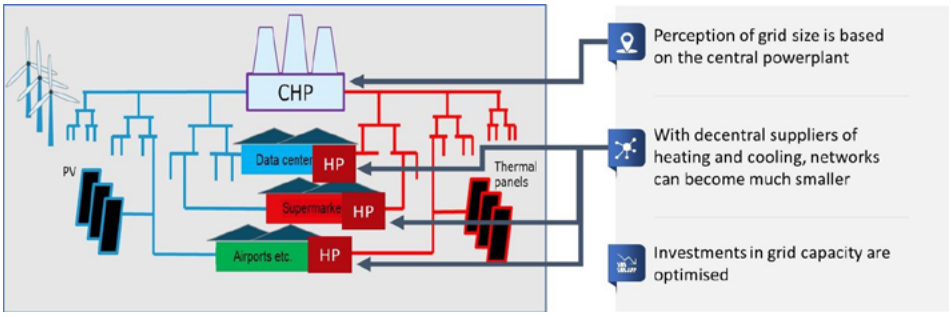

Fig. 2. Decentral large heat pumps can source energy from various utilities. Advantages are listed on the right part of figure

2. Temperature lift

The temperature lift is the difference of the temperature of the heat source inlet and the temperature supplied to the DH system (outlet). DH grids have developed through more than 130 years and can be divided into 4 generations. For simplicity, systems are called by generation names like 3G or 4G. The main parameter characterizing the G-level of the system is the flow line temperature. 3G systems have a flow temperature below 100°C while new 4G systems will go as low as 40°C [4]. The overall system efficiency increases with the lowering of temperature and the opportunities for adding decentral heat sources like heat pumps - or waste heat from supermarkets - can be applied. The first parameter determining how low the flow temp can go is the size of the heating surfaces in buildings. Large surfaces e.g. using floor heating can utilize 40°C water while old radiators in poorly insulated buildings will demand 80°C – at least in cold periods.

Low temp heating is still a rare case for the majority of the building stock in the EU but is expected to grow as renovation of the old building stock takes place. For new city areas low temperature DH is an obvious choice. Specific high temperature needs will then be handled by dedicated heat pumps.

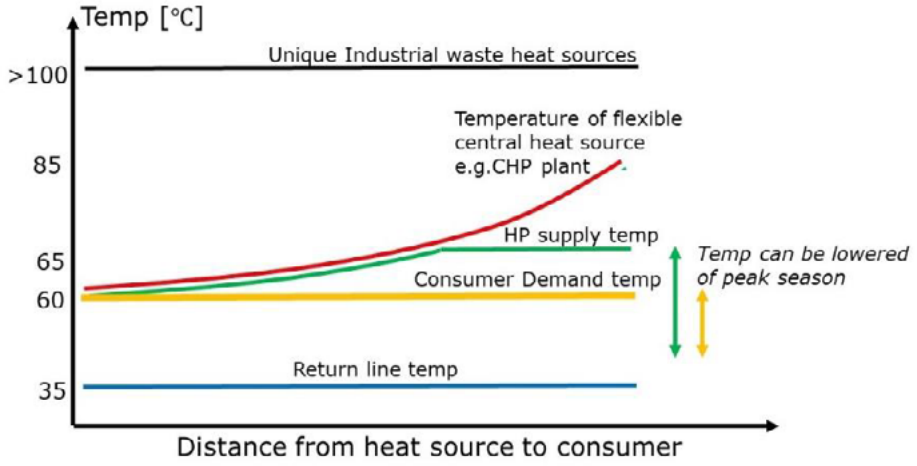

Fig. 3. DH flow line temp compared to demand needs

Another parameter determining the DH flow temperature is the architecture of the DH system layout i.e. pipe diameter, distance between heat supply sources and the density of end consumers. Seasonal variations in heat demand will set the constraints for the flow line temperatures – but the trend is to lower temperatures even during winter. Good practice is to lower the temperature until the most demanding heat consumer will call. Then specific action can be taken towards raising the performance of that specific consumer like better insulation etc. Each City has special opportunities for unique large heat sources i.e. CHP plants, industrial plants, data centers, sea water etc. This will of course reflect the outline of the DH system and likely the flow temperature as some heat sources may have higher temperatures than others. Figure 3 shows a qualitative connection between flow and return line temperatures dependent on distance from heat source and also the heat source type (unique centralized or decentralized heat pumps).

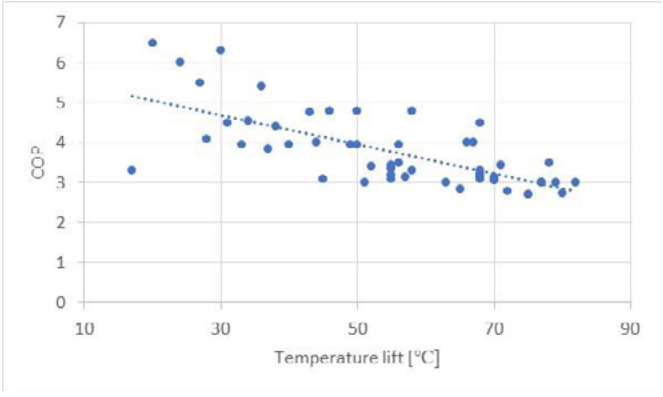

Fig. 4. HP COP versus temperature lift; data from [1]

The flow line temperature is not necessarily reflecting the demand from end consumers but may often be based on the grid piping constraints or specific heat sources. A lower temperature – ensuring sufficient capacity throughout the grid - can be obtained by having multiple and decentralized distributed energy sources like heat pumps. Smaller heat pumps can boost 4G flow temperatures for apartments or multi apartments buildings or

large heat pumps can supply heat to the grid via ground source. Also, the tertiary sector as supermarkets have shown to be able to deliver extra heat to the DH. This issue has already shown to be an important factor to discuss when planning the introduction of heat pumps to the district heating grid and the learning is that the necessary temperature lift may often be smaller than the official flow temperature. This is an important parameter to consider when discussing heat pump heat delivery.

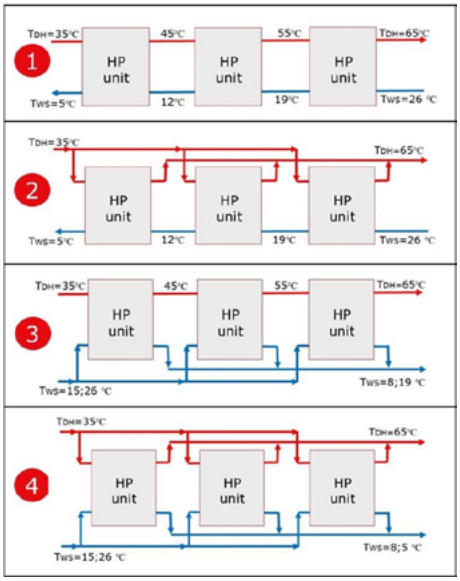

Fig. 5. System type versus refrigerant comparison

3. Technology behind the low GWP heat pump systems

Heat pumps larger than 1 MW are often based on well-known ammonia technology and described in various papers. Also, CO_2 heat pumps can be a good source for high temperature DH but is rarely seen yet. The HFO refrigerant; R1234ze(E), has been introduced to the market during the last years and has a very good HP performance due to its high critical point (165°C). Furthermore, it can be utilized for centrifugal compressors due to its high molecular weight. Assuming a temperature lift of 30-50 °C normally two-three stages of compression are suitable; however, CO2 can due to its transcritical properties, utilize counterflow heat exchanger technology and be effective also for one stage compression. A survey [1] shows COP values from 149 large HP installed in the EU with capacities ranging up to 230 MW and average capacities >10 MW. Looking at figure 6, even with a clear trend line, a high deviation variance of reported COP is evident and can be explained by numerous factors dependent on system architecture, On/off duty cycle or VSD, level of maintenance, etc. As a rule of thumb, the higher the capacity of the system the higher the efficiency due to higher level of complexity and optimization procedures. It should be noticed that potential future rollout of large ground source heat pumps would have capacity limits around 5-10 MW and call for more modular system designs.

4. System comparison

The oil free Air Conditioning chillers using centrifugal compressors have a superior energy efficiency, small size and low noise levels due to high compressor RPM and contact free operation. Even though oil free systems have not yet been used for large scale heat pumps they are notoriously interesting due to high efficiency and the low noise levels which make them suitable to be placed in dense populated areas. To evaluate the efficiency compared to other low GWP refrigerants we did some basic simulations comparing, CO_2 reciprocating

technology and NH_3 screw compressor technology, with the state of art oil free systems for heat pumps around 2 MW capacity. Increased efficiency can likely be obtained in the future due to the ongoing research on utilizing tailor made low GWP refrigerant blends suitable for counterflow heat exchangers [5].
All systems use economizer. The CO_2 and NH_3 system are more complex due to oil management. CO_2 systems evaluated do not use ejectors nor parallel compression. The results in figure 5 show system COP values ranging from 3.5-5.4 depending on the water supply temperatures of 15 °C (high temp level ground source) and 26 °C (Data Center source). The oil free system shows significant good results and the complexity is low which makes it suitable for large scale system production.

5. Conclusion

The energy outlooks for Europe calls for an ambitious increase and investment in district heating networks. District heating will facilitate large scale heat pumps necessary to adopt to the increasing amount of renewable electricity.

The temperature demands of the District Heating grid have continuously decreased during history and it is anticipated that future DH grids will go as low 40°C allowing for decentral heat suppliers like super markets.

Heat pumps can effectively be introduced on a mass scale as decentral zero carbon heat suppliers.

The simplicity of systems and the noise levels and refrigerant safety are qualifying factors to establish MW sized pumps within the cities.

Efficiency of the heat pumps are the business parameter to deliver affordable heat. Efficient, safe and low noise heat pumps can be ensured with oil free heat pump systems.

[c]JAPAN FACILITY SOLUTIONS,Inc, 6-4, Osaki 1-Chome, Shinagawa-ku, Tokyo 141-0032, Japan

Abstract

In this study, we focused on the aging degradation of heat pumps and developed an efficiency evaluation method. From the analysis result of the COP fluctuation factor by the typical CR, it was confirmed that the partial load and the cooling water temperature affected the fluctuation of COP. We developed a method to create a multiple regression equation using these variables as explanatory variables, and analyzed 72 centrifugal refrigerators. As a result, we confirmed the possibility of the efficiency evaluation with this method. Also, it was found that more than 5,000 hours of operation data was necessary to ensure the accuracy of the correction method using the multiple regression equation. In addition, our analysis showed that little aging was observed in CRs under proper maintenance.

Keywords: Long-term Assessment; centrifugal refrigerators; COP;

1. Introduction

1.1. Background of the study

The efficiency of heat pumps for air-conditioning applications, which occupies a large proportion of energy consumption in buildings, should be maintained properly. Therefore, regular inspection and proper maintenance are needed to maintain their initial efficiency. The aging of common equipment is generally represented by a schematic diagram shown in Figure 1. This figure is well known in many fields, however actual investigation on heat pumps are very few. Because, evaluating the changes of actual operation efficiency is not easy. In actual operation, every parameters such as cooling water temperature or partial load change from moment to moment. Complicating things further, seasonal changes also affects to efficiency. According to this background, the evaluation method of heat pumps for stakeholders are demanded.

1.2. Outline of the study

Evaluating efficiency change is worthful for compressing the maintaining cost which to the life cycle management. Considering this issue, the efficiency evaluation method for heat pumps is developed in this study. In particular, focusing correcting the coefficient of performance (COP) of heat pumps against the efficiency fluctuation during operation, long term assessment by maintenance was examined.

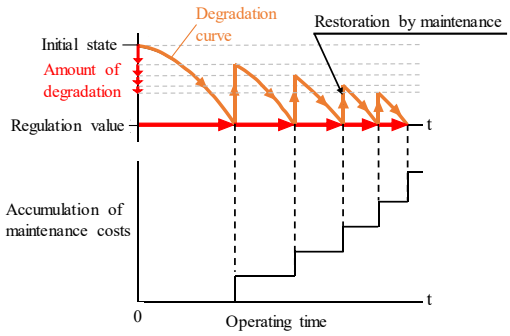

Fig. 1. Schematic diagram of maintenance and costs of recovery from deterioration

1.3. Property of analyzed centrifugal refrigerators

The data of actual operation result used in this study was provided by an energy service company (ESCO) that collaborated in this study and was collected from 73 centrifugal refrigerators (CRs) installed at 30 locations as an ESCO service utilizing thermal energy storage systems. The data was stored on a building automation and control system (BACS) every hour from April 2000 to March 2019. Figures 2 - 5 show outline of the CRs. Many of them have been in operation for more than 10 years. The ESCO includes a maintenance contract for most CRs with the CRs' manufacturers to ensure a supply of chilled water to the users, and it performs satisfactory manufacturer-recommended maintenance at recommended intervals. Since the data contained a large amount of data that was unnecessary for the COP assessment, we had to select the appropriate data before starting the analysis. Table 1 shows the requirement of COP analysis. For this study, not only calculating COP but also functional analysis was main issue, this requirement includes such as the cooling water temperature. In practice, most CRs met this requirement and as a result 72 of CR data was remained.

2. Analysis on COP fluctuation and factors

2.1. Confirmation of the operation trend

Before the development of the correction of COP, the operation result of all the CRs was analyzed to confirm the trend. Figure 6 shows the operation result of NO.19-01 as a typical example. This CR which installed in FY2006, capacity of 2,700kW, had a decade operation data. This time series COP fluctuation plots are distinguished into colour which indicates the cooling water temperature. Focusing on these colors, it was confirmed that COP fluctuation has a strong relationship along to fluctuation of the cooling water inlet temperature (here in after, "cooling water temperature") which depending on a change of season, same as a theoretical behavior. On the other side, COP was enhanced at the point of 3,000 hour after the operation started. Through the other detailed analysis, it was confirmed that this behavior was caused by the set point change of the chilled water outlet temperature. Considering above, the correlation of the COP with factors which selected in Table 1 was investigated.

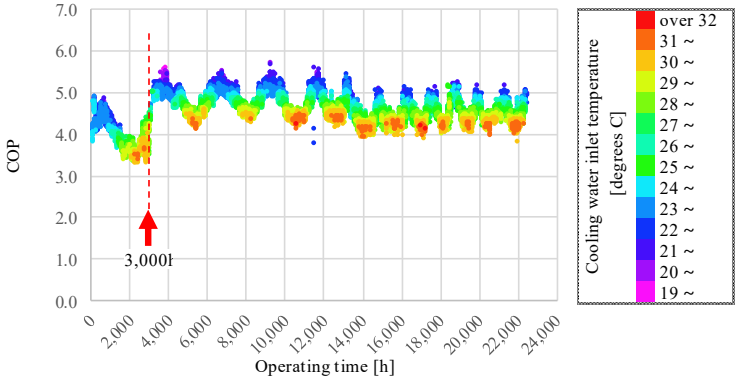

Fig. 6. Operation result of NO.19-01 as a typical example.

Figures 7 - 11 show the correlation of the COP of the CR NO.19-01 over the measurement period for each parameter. The partial load in Figure 8 indicates the ratio of the actual generated heat to the rated capacity of the CR. As shown in Figures 7 - 11, a strong correlation was confirmed between the COP and the partial load as well as the cooling water temperature. On the other side, considering the thermal energy storage system, it is able to be thought that the chilled water temperature is stable in operation except the set point change. Therefore, as the first step of this study, factors which are the partial load and the cooling water temperature were picked up for the correction of COP fluctuation.

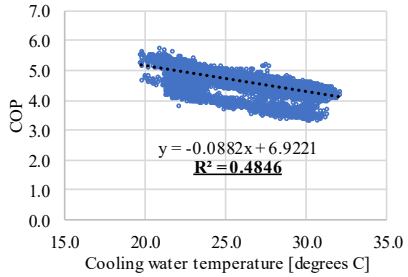

Fig. 7. Correlation between cooling water temperature and COP

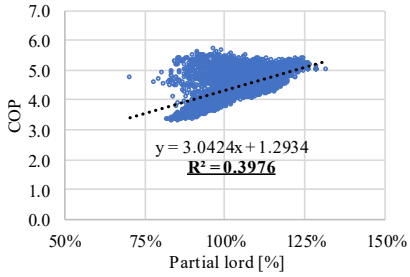

Fig. 8. Correlation between partial lord and COP

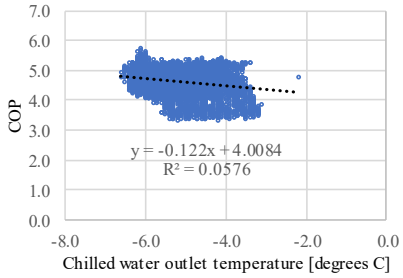

Fig. 9. Correlation between chilled water outlet temperature and COP

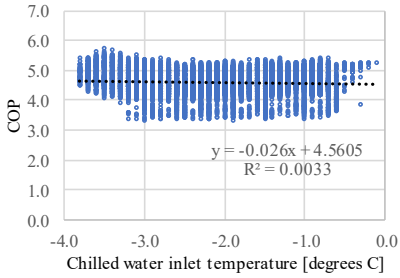

Fig. 10. Correlation between chilled water inlet temperature and COP

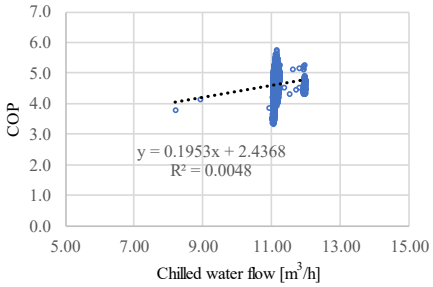

Fig. 11. Correlation between chilled water flow and COP

3. Correction of the COP

3.1. Method of correcting the COP

Table 2 shows the procedure of COP correction. Conception of this method is based on the performance curve generated from an actual operation data. Basically, utilizing the generated curve, the cancellation against fluctuation of factors is realized by correcting the COP of a certain operation state to the data of the reference state. Concrete process utilizing a multiple regression equation is following.

First, to derive a multiple regression equation, a regression analysis of the data for the baseline period is conducted using the partial load and the cooling water temperature as explanatory variables.

The COP obtained by substituting the partial load and the cooling water temperature into the multiple regression equation is defined as the "COP on the performance curve". At this step, we defined the baseline period as three years from the initial fiscal year. If the fluctuation on the cooling water temperature during the

three years is fine degree, another three years with a larger degree of fluctuation were selected to improve the accuracy of the multiple regression equation.

The variability ratio of COP is the value obtained by dividing the actual COP by the COP on the performance curve and subtracting 1 from the resultant value. The multiple regression equation produced in previous step is summarized in the form of equation (1). The coefficients for each variable differ for each CRs. Table 3 shows the coefficients for typical CR.

Figure 12 shows a comparison between the performance curve obtained by the multiple regression equation and the actual operation COP. A few outliers are seen at lower cooling water temperatures, but they are generally similar.

Table 2. COP correction procedure

Step	Contents (Implementation / calculation)
Step.1	Create a correlation diagram between partial lord and COP for each cooling water temperature in the base year
Step.2	Create a multiple regression equation with the partial lord and cooling water temperature as explanatory variables
Step.3	Calculate the COP at each time by substituting the actual cooling water temperature and partial lord every 100 hours into the multiple regression equation * The COP calculated here is defined as COP on the performance curve.
Step.4	The actual COP divided by COP on the performance curve and subtracted 1 is the variability ratio of COP

$$f(x,y) = (C_{11}x^3 + C_{12}x^2 + C_{13}x + C_{14})y^3 + (C_{21}x^3 + C_{22}x^2 + C_{23}x + C_{24})y^2 + (C_{31}x^3 + C_{32}x^2 + C_{33}x + C_{34})y + (C_{41}x^3 + C_{42}x^2 + C_{43}x + C_{44}) \quad (1)$$

$f(x,y)$: COP on the performance curve
x : Cooling water temperature [degrees C]
C_{nm}: Constants
y : Partial lord [%]

Table 3. Coefficient list of typical CR

		m			
		C_{n1}	C_{n2}	C_{n3}	C_{n4}
n	C_{1m}	-8.69283E-02	6.88748E+00	-1.80476E+02	1.56145E+03
	C_{2m}	1.99511E-01	-1.58588E+01	4.17038E+02	-3.62289E+03
	C_{3m}	-1.15261E-01	9.19175E+00	-2.42631E+02	2.12142E+03
	C_{4m}	1.89280E-04	-1.50236E-02	3.92556E-01	-3.36224E+00

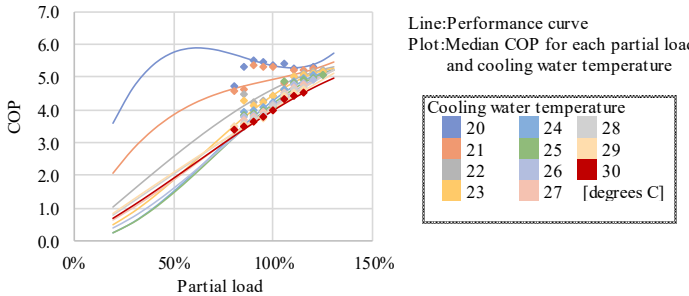

Fig. 12. Comparison of performance curve and actual operation COP

Figure 13 shows the variability ratio of COP for the typical CR (No.19-01). The fluctuation of efficiency concerned with the cooling water temperature and the partial lord was suppressed, effectiveness of this correcting method is confirmed.

On the other side, the variability ratio of COP became a positive value after 6,000 hours. From the point of view of theory, as shown in Figure 13 positive value is not suitable. However, this trend might be caused by the set point change of the chilled water outlet temperature. Also, this trend is able to guess from the correlation of Figure 9. Considering the ordinary circumstances, the chilled water outlet temperature should be involved into the factor of a multiple regression equation. However, all of CRs which picked up in this study are connected to thermal energy storage system, is able to maintain the temperature in stable state, the exclusion effect of the chilled water outlet temperature was estimated not strong issue to evaluate the overview of the trend. Therefore, here in after, two factors which are the cooling water temperature and the partial load were adopted for the correction considering as a first step of this study.

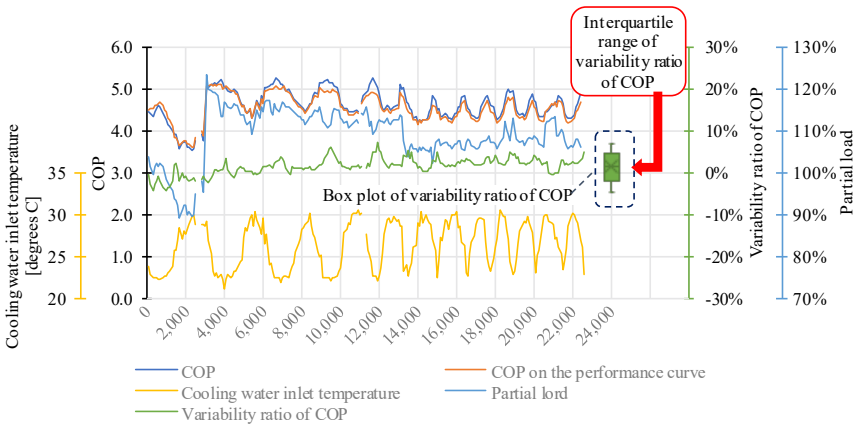

Fig. 13. No.19-01 Changes in variability ratio of COP and COP, etc.

3.2. Correction results of all the COP

Before the evaluation for all the variability ratio of COP, for each CR, it was calculated the interquartile range (the height of the boxplot) of the variability ratio of COP as shown in Figure 13 in previous. This is for the confirmation of the factors that cause a significant fluctuation on the variability ratio of COP.

Figure 14 shows the correlation between the operating (cumulative) time of each CR and the interquartile range of the variability ratio of COP. As shown in the figure, the interquartile range converges after 5,000 hours of the operating time. In other words, a minimum operating time should be decided to maintain the accuracy of the multiple regression equation. Therefore, from point of view of this, these 4 of CRs which are less than 5,000 hours were excluded from the next evaluation.

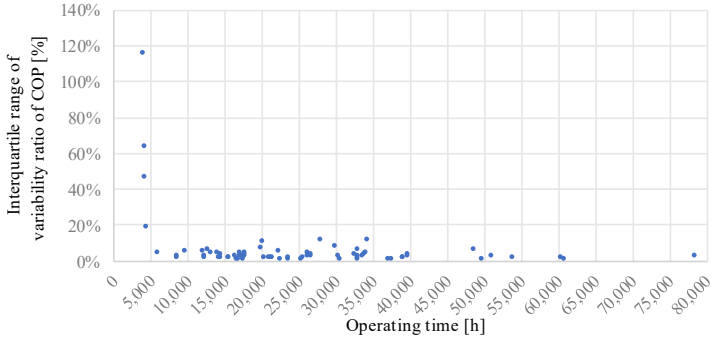

Fig. 14. Correlation diagram of Interquartile range of variability ratio of COP and operation time

Figure 15 shows the variability ratio of COP which averaged in 100 hours for 68 CRs in total, excluding the four CRs mentioned above. Since grasping the overview of the trend was difficult from this figure, statistical processed result was shown in Figure 16. This is boxplot for each 1,000 hours average. Concretely, the evaluation on the variability ratio of COP was performed in the interquartile range to quantitatively determine whether the correction was effective. The range was within roughly ± 5%, indicating that the fluctuation due to the partial load and the cooling water temperature has suppressed by the correction.

Figure 17 shows a comparison between the interquartile range of change in the actual COP for each CR (Red plot) and that of the variability ratio of COP (Blue bar chart). Except for three CRs, the interquartile range is smaller for the variability ratio of COP, it was confirmed that correction method to be effective to almost CRs.

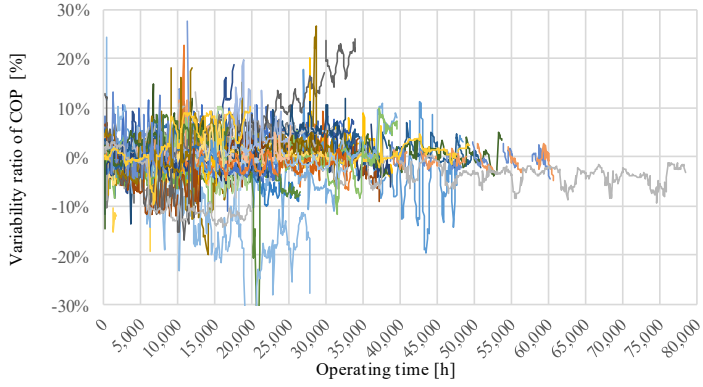

Fig. 15. Trend of variability ratio of COP of 68 units every 100 hours

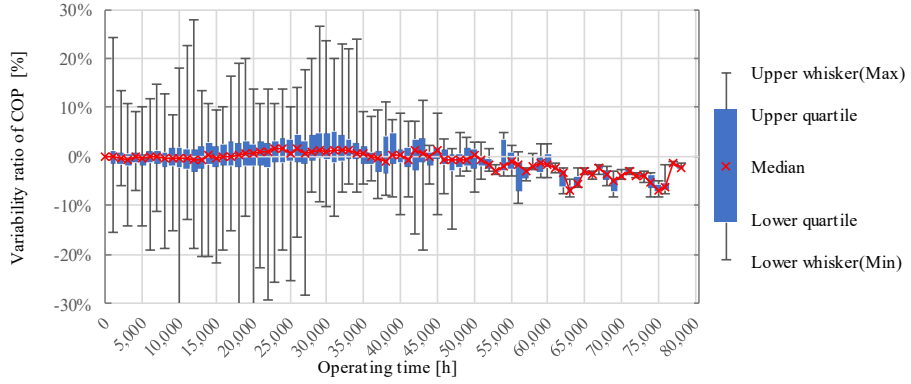

Fig. 16. Box plot for each 1,000 hours

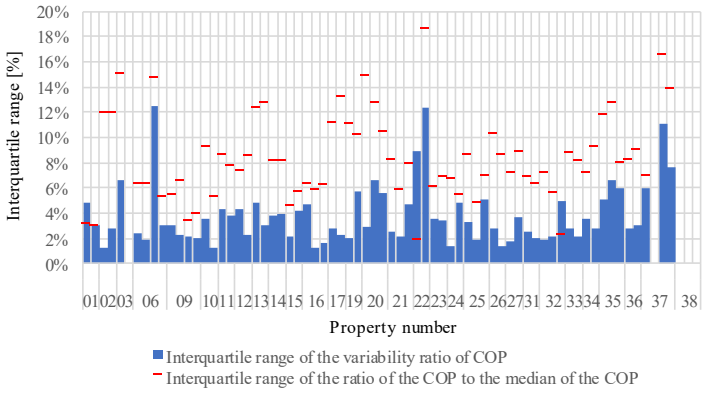

Fig. 17. Interquartile range of the ratio of the COP to the median of the COP and the interquartile range of the variability ratio of COP

4. Conclusions

Focusing on the aging of heat pumps, the efficiency evaluation method is developed in this study. In particular, the correcting COP method against the efficiency fluctuation during operation, long term (longest is 10 years) assessment for centrifugal refrigerators was examined. As a result, following was shown.

- Possibility was confirmed to correct the COP to evaluate the variability COP utilizing developed method which with a multiple regression equation.
- The partial load and the cooling water temperature was explicable factors for the correcting. On the other side, considering other type of refrigerator or HVAC system, it was estimated that the chilled water temperature is one of the effective factor.
- Only in the scope of this study, but more than 5000 hours of operation data is required to ensure the accuracy of the multiple regression equation for the correction method. In addition, from our analysis, almost no aging was observed on CRs under the proper maintenance.

Abstract

The formation of joints is a critical process in HVAC&R component manufacturing and system assembly. Brazed joints are the most commonly used, but there are several alternative methods including mechanical compression, press, and push joints. Adhesive joints have not been widely explored or evaluated for use in HAVC&R systems. In this study, a review of different joint types reveals that adhesive bonding is a promising joining method due to potential benefits in energy use, cost savings, and leakage reduction. In order to demonstrate an application procedure and explore the feasibility of adhesive joints, two proof-of-concept tests were performed. First, tube-to-tube joints were installed in a heat pump dryer system to confirm that adhesive can hold the system pressure without affecting performance. Second, adhesively bonded U-bend joint samples were tested using a shaker table following an ISO standard and benchmarked against brazed joint samples. There was no failure or wear observed for the adhesive or brazed joints. These proof-of-concept tests indicate that there is potential for use of adhesive joints to replace brazed joints in HVAC&R applications, which merits further investigation.

Keywords: ; HVAC&R system, Joints; Adhesive joints; Heat pump dryer; Vibration test

1. Introduction

In heating, ventilation, air conditioning, and refrigeration (HVAC&R) systems, joints are commonly used to connect the refrigerant lines to other system components (such as compressors, condensers, evaporators, and filter dryers) and in the assembly of components such as tube-and-fin heat exchangers. The joints are critical to avoiding system leakage throughout the lifetime of operation. Refrigerant leakage is a direct greenhouse gas emission, but also results in additional indirect emissions by reducing the system energy efficiency and equipment lifetime. Leaks most typically occur at the locations of joints and connections in the system, and are usually caused by fatigue failures associated with temperature cycling, pressure cycling, vibration, or mechanical wear. According to a recent EPA report [1], HVAC&R equipment across many different application categories are facing leakage issues. Several of the common HVAC&R equipment categories shown in Table 1 have leakage rates of 10% per year or more due to faults in joining techniques, system design, and operations/ maintenance practices. Supermarket refrigeration systems can have up to 25% leakage per year due to the nature of field installing long line sets.

In order to address these issues, one of the critical tasks is to investigate, evaluate, and explore both existing and new joining technologies to reduce the leakage of refrigerant from HVAC&R equipment. Currently, brazed joints are the most commonly used, but there are several alternative methods including compression joints, press joints, push joints, and adhesive joints. Among these alternatives, adhesive joints have not been widely explored for use in HAVC&R systems and there has been a lack of evaluation and testing. This paper first reviews and compares different joint types and then reports two proof-of-concept tests performed using adhesive joints.

Commercial Unitary AC	8-9
Packaged Terminal AC / Heat Pump	4
Refrigerated Appliances	< 1

2. Overview of Joining Technologies

A typical HVAC&R system consists of various individual components connected by tubes and joints to form a closed-loop piping system for cycling of the refrigerant. The components usually include compressors, heat exchangers, valves, and additional accessories such as filters, pumps, and sight glasses. In addition to the connections between these components, there are subassemblies consisting of numerous parts that must be joined together. For example, tube-and-fin heat exchangers are manufactured by joining individual tubes and metal sheets together with U-shape bends. In the majority of HVAC&R systems, copper tube-to-tube joints make up most of the connections. The review below focuses on joining technologies for copper, if not otherwise specified.

At each location where two components meet, joining technologies need to provide a mechanically adequate bond between the surfaces without any damage to the original part. These joints must meet structural requirements for load-bearing (if required) and to withstand the operating pressure of the system, allowing refrigerant to flow through unobstructed. Strong and reliable joints provide stable, efficient, and leak-free system operation; failures in joining cause refrigerant leakage having negative consequences including safety concerns, wasted energy due to system efficiency reductions, and pollution to the environment.

2.1. Brazed joints

Brazing is the most common joining technology in the HVAC&R industry. It is a well-established commercial process capable of producing strong joints between most metallic and ceramic materials, which has led to its widespread adoption in industry. Brazing can be performed both manually as well as in automated production processes. As defined by the American Welding Society [2], the term brazing encompasses a group of joining processes that bond materials by heating to a brazing temperature in the presence a filler metal having a melting point above 450 °C (840 °F); the brazing temperature does not cause melting of the base materials. The brazing filler metal becomes molten and is distributed by capillary action within the tight clearance between the two surfaces that are being joined. The assembly is then cooled, and the molten filler solidifies. The filler metal anchors the surfaces together owing to metallurgical reactions that lead to atomic bonding. For most tube-to-tube joints, a separate coupling tube, having a slightly larger diameter than the tube end being joined, is placed so that both tube ends have an overlapping area with the coupling where the bond is established. Alternatively, the two components can be connected directly without an overlapping coupling to form a butt joint.-Strong, uniform, leak-proof joints can be made rapidly and inexpensively with brazing, especially for joints that are inaccessible or for parts and components that may not be joined using other methods.

2.2. Mechanical joints

Mechanical joints can be categorized into several different types including compression joints, press-connect joints, and push-connect joints [3]. Mechanical joints are an alternative for brazed joints when using an open flame is either not desired or impractical. All mechanical joint types form a seal using mechanical

pressure to physically close the leakage path. Mechanical joints are commercially available from several manufacturers.

Compression joints are usually composed of an outer compression nut and an inner compression ring or ferrule made of brass or copper. Ferrules most commonly have a shape of a ring with beveled edges. The longest sloping face of the ferrule usually faces the opposite direction of the nut. In the joining process, the nut is tightened and the ferrule is compressed between the nut and the tube. The ferrule will seal the gap between the tube and nut, producing a tight joint by clamping the end of the ferrule around the tube [3].

Press-connect joints rely on the excellent malleability of copper, forming a seal using a special gasket, usually of an O-ring shape, for joining. Using approved special pressing tools and jaws, the copper fittings are flattened into thin sheet on the tube that are being joined to form a leak-proof connection. [3].

A push-connect joint is another available type of mechanical joint that does not require heating or specialized tools, and can be made by hand. These joints are similar in principle to press-connect joints. On the inner diameter of the fitting, an integral elastomeric gasket or seal and stainless-steel gripping ring help to produce a leak-free joint. Once pushed on, the gripping ring and the gasket together provide a seal on the outer diameter of the insertion tube; the use of the gripping ring avoids the need for a pressing tool as in the press-connect joint.

2.3. Adhesive joints

Adhesive joining processes use an adhesive substance that holds materials together by surface attachment [4]. It is a widely used industrial joining method that has been adopted and proven reliable in several industry sectors, such as in automotive and electronics. While there are many types of adhesives, the ones used for structural bonding are typically cured in order to have adequate strength to transfer the loads through the joints. One-part adhesives need to be heated up before application and two-part adhesives need to be evenly mixed. Based on the application and assembly process requirements, there is freedom to design and develop adhesives with different characteristics such as the curing temperature/time, assembly time, or drying temperature/time.

A review of the scientific literature and survey of available products in the market reveals that adhesive joining (tube-to-tube or otherwise) is not a mature technology for application in HVAC&R systems. There is a lack of research and little information on product development and qualification standards specific to this industry. Most of the existing products focus on quick repair, instead of initial manufacture. Based on our product research, the few examples of adhesives used for HVAC&R joint repairs are two-part epoxies requiring heat curing. Epoxies are widely used as high-performance structural adhesives because of their ability to cure without producing volatile byproducts, high resistance to chemicals, and low shrinkage during curing [5,6]. When employed, the epoxy resin is mixed with hardener at a certain mass ratio to form a homogeneous mixture, which must be applied to a prepared/cleaned surface within a working time before it cures. The strength of the adhesive joint largely depends on the design of the joints, thickness of the adhesive, bonding area, and surface modifications the bonding area.

2.4. Summary comparison of different joint types

A qualitative comparison of brazed, compression, press-connect, push-connect, and adhesive joints are summarized in Table 2. In comparison with the other joining technologies, adhesive joints provide some unique features that are key to overcoming challenges facing the HVAC&R industry. Compared to brazed joints, using adhesive joints can potentially reduce the manufacturing energy and cost, and also avoids the risk of galvanic corrosion between dissimilar metals [7]. In addition, unlike the mechanical joints that are only available for very specialized geometries, the process of using an adhesive material to join between any surfaces is similar in nature to the use of a brazing material. This offers the potential to form adhesive joints in mass production with a similar assembly line as brazing. Being aware that the primary disadvantage of adhesive joints is the lack of established procedures for application and assembly, as well as their unknown reliability, this study aims to demonstrate a joining procedure to explore the feasibility of adhesive joints. A complete joining procedure is developed including surface preparation, adhesive preparation, adhesive application, and curing. Proof-of-concept tests are performed using adhesive joints in a heat pump dryer system and by placing joints on a vibration shaker.

Adhesive	✓	✓	✓	✓	✓	✓	?

3. Heat Pump Dryer System Demonstration

A proof-of-concept test is performed to demonstrate the use of adhesive joints in an HVAC&R system under normal working conditions. In addition to evaluating any potential effects on the system performance, the tests may expose any unexpected issues in the assembly process. The proof-of-concept test uses an adhesive to form tube-to-tube joints in a commercial heat pump dryer test stand, simulating an installation or repair in the field.

3.1. Experimental system

A heat pump system taken from a commercial clothes dryer is selected as the test system. The system components are summarized in Table 3. Fig.1 shows an image of the test stand alongside a schematic diagram of the flow loop with the primary components labelled. The system is a vapour compression cycle: the refrigerant vapour comes out of compressor and is condensed to liquid against ambient air through the subcooler and condenser. A separate fan is used to provide the airflow for the subcooler and to cool down the compressor. The liquid out of the condenser expands through a capillary tube and evaporates in the evaporator which then goes back to the compressor and closes the cycle. There is a blower that provides airflow for both the condenser and evaporator through the same air duct.

Table 3. Component specifications and materials in the heat pump dryer system

Component	Description
Compressor	HIGHLY (Shanghai Hitachi) BSD122DN-H3BDA
Condenser	Tube-and-fin type (Material: Aluminum)
Subcooler	Tube-and-fin type (Material: Aluminum)
Capillary Tube	Material: Copper
Evaporator	Tube-and-fin type (Material: Aluminum)
Filter Dryer	Material: Copper
Tubing	1/4-inch for discharge and 3/8-inch for suction (Material: Copper)

The commercial system introduces various factors that may influence the adhesive joint performance. The system has a relatively high pressure of up to 15 bar at 55 °C with R134a as the refrigerant. The tubing is exposed to sudden pressure changes and random vibrations when the compressor and blower are running. It is an oil-lubricated system with oil passing through the tubing along with the refrigerant. There is tension and torque on the joints caused by thermal expansion and contraction as the system heats and cools as it is cycled on and off. All of these factors simultaneously act on the adhesive joints in a manner that is hard to simulate through standardized testing.

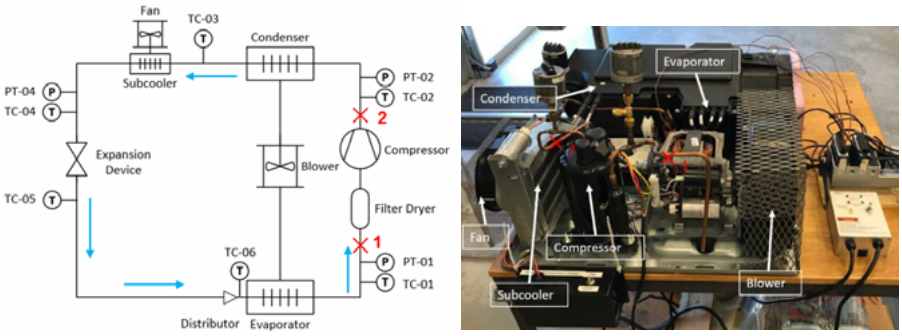

Fig. 1. Schematic drawing (left) and photograph (right) of the custom-instrumented heat pump dryer test stand with the locations of the pressure transducers (P) and thermocouple measurements (T) indicated. The adhesive joints are placed at the locations labelled "1" and "2".

The system was also selected due to its simplicity in system control. The system consists of a single speed compressor, blower and fan with a capillary tube. There is no active control, and hence, the system operating conditions are only determined by the refrigerant charge amount and environmental temperature. Within a lab-testing environment, the temperature stays relatively constant. The operating conditions can thereby be used as an indicator for the system refrigerant charge amount.

The system is custom-instrumented with sensors to monitor the operating conditions. Three pressure transducers and five thermocouples are installed to measure the pressure at several selected locations and the temperatures at the inlet/outlet of each component, as labelled in Fig.1. The pressure transducers measure from 0 – 500 psig with an accuracy of ± 0.65 psig. The thermocouples are copper-constantan (T) type with ± 1 ℃ uncertainty. Two different locations are selected for insertion of the adhesive joint based on the operating conditions of the system, as marked by red crosses in Fig. 1. Location "1" is at the compressor outlet where there is the highest temperature and pressure in the system; location "2" is at the compressor inlet, with the lowest temperature and pressure. At each location, the original tubing is cut with a chip-free tube cutter in the middle, leaving two open ends. A copper coupling is used to form a new tube-to-tube connection using the adhesive, as will be described in the subsequent section.

3.2. Adhesive joining procedure

A structural adhesive two-part epoxy was used as the bonding material for the application process. As suggested by the manufacturer, a manual applicator with a static mixing nozzle were used to evenly mix and apply the adhesive to the surface.

The outer tube surfaces were prepared by a traditional method of acetone cleaning, followed by sanding, and lastly a second acetone cleaning. The coupling is only acetone-cleaned because the inner surface of the small-diameter tube is inaccessible for sanding. Note that the coupling is a standard size for brazing purposes and is not specifically designed for adhesive joining. The gap size between the tube outer diameter and coupling inner diameter at both locations is measured to be 0.85 mm; this is within the recommended working range for the adhesive, which will guarantee a strong adhesive bond. Fig. 2 shows the location "1" tube cut, with the two open ends aligned after preparing the bonding surface; the coupling is shown slid onto the left-side tube end. The difference in color of the copper tube near the coupling indicates that the surface preparation removed the oxide layer and other contaminants. Before applying the adhesive, the two tube ends are aligned coaxially and pressed against each other to decrease the possibility of adhesive leaking into the inner surface of the copper tubing. The adhesive is circumferentially applied on the cleaned tube area to cover a region the same length as the coupling. The coupling is slowly slid along the tube until the cut is at the center of the coupling. It is ensured that the adhesive fills the gap between the tube and the coupling, with no visible openings; the assembled joint is shown in Fig. 2. Because the tube is in a horizontal orientation, the adhesive accumulates at the bottom of the tube due to the effect of gravity. The adhesive is left to cure at room temperature for 24 hours. After curing, an aluminum safety shield is placed around the joints in case of a catastrophic failure. The other adhesive joint in location "2" is manufactured following the same procedure.

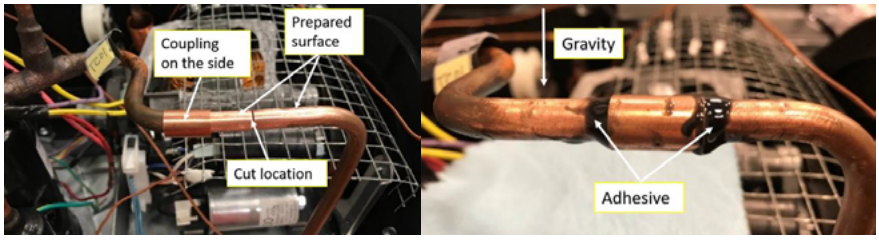

Fig. 2 Photographs of the cut location "1" for the tube-to-tube joint after preparing bonding surface (left) and within the coupling in place over the cut after application of the adhesive (right).

3.3. Testing procedure

Before cutting the tubes, a baseline test was performed to measure the system operating conditions. The system was charged with 428 g of refrigerant R134a, which is recommended by the manufacturer. All of the system components (e.g. the compressor, fan, and blower) were run at a fixed speed that was maintained constant for the duration of the test until steady-state operating conditions were achieved.

After recording the standard operating condition benchmark, the tubes were cut and re-assembled with adhesive joints as described in the previous section. Before recharging the system with refrigerant, a leakage check was performed by charging the lines with high-pressure nitrogen and pulling a vacuum on the system. The system high-side operating pressure is approximately 960 kPa and it was charged with nitrogen to 1900 kPa. After 72 hours, the pressure dropped by ~1% to 1880 kPa and then held steady. When a vacuum was pulled on the system, no pressure increase was observed after 6 hours. These tests confirm that the system was leak-free after the initial adhesive joining and ready for testing.

The system was charged with the same amount of refrigerant as during the baseline testing. After charging, a long-term test plan was followed for the adhesive joints: the system was run for several hours every one or two weeks, similar to the anticipated operation of the device, with the pressure and temperature recorded after reaching a steady operating point. The procedure evaluates whether the prototype adhesive joints can hold the pressure over a long time while being subjected to normal running cycles. The system pressures and temperatures are compared with baseline results, which would differ if there was a significant loss of charge.

3.4. Results and discussion

The operating conditions for the baseline and the case with adhesive joints case are compared in Fig. 3. The baseline condition is defined as the standard operating condition, achieved by the initial charge without any modification with adhesive joints. Several assumptions were made to calculate all state points where there is not a direct measurement, namely: no pressure drop in the condenser, constant enthalpy across the expansion devices, and two-phase operation the condenser and evaporator. Due to the long tubing and distributor before evaporator, there is an additional pressure drop between the capillary tube (point 5) and evaporator (point 6). This was treated as a second expansion device to accurately capture the pressure and temperature at the evaporator inlet.

The data presented in Fig 3. indicates that there is a consistent operation before and after installation of the adhesive joints. In both cases, between state points 5 and 6, there is additional pressure drop with the according temperature decrease. Also, note that the there is pressure drop across the evaporator, which explains the temperature decrease from state point 6 to 1. A small variation in the pressure and temperature, comparing the baseline and adhesive data, are attributed to slightly different charge amounts due to the refrigerant scale uncertainty and difference in the room temperature (21.9 ℃ for the baseline versus 22.4 ℃ in the adhesive case).

In order to further evaluate the feasibility of this concept, the system was operated periodically over the next 6 months per the testing procedure described in the previous section. The corresponding temperature-entropy (T-s) and pressure-enthalpy (P-h) diagrams are shown in Fig. 4, with the adhesive test operating points overlaid on a plot of the baseline condition. As shown in Fig. 4, the system performed consistently with each subsequent test after sealing the joints with adhesive. The consistent pressure level and system performance indicates that there was no leakage over the testing period and that the adhesive joints operate successfully under the temperature changes and vibrations associated with operation of the system using refrigerant R134a. Despite the limitations of testing only two adhesive joints over a moderate temperature/pressure range for a

period shorter than the typical lifetime, as a proof-of-concept test, this suggests that adhesives may be feasible and practical to replace brazed joints in HVAC&R systems. Further testing is recommended to evaluate the performance of adhesive joints in HVAC&R systems to the point of failure or leakage.

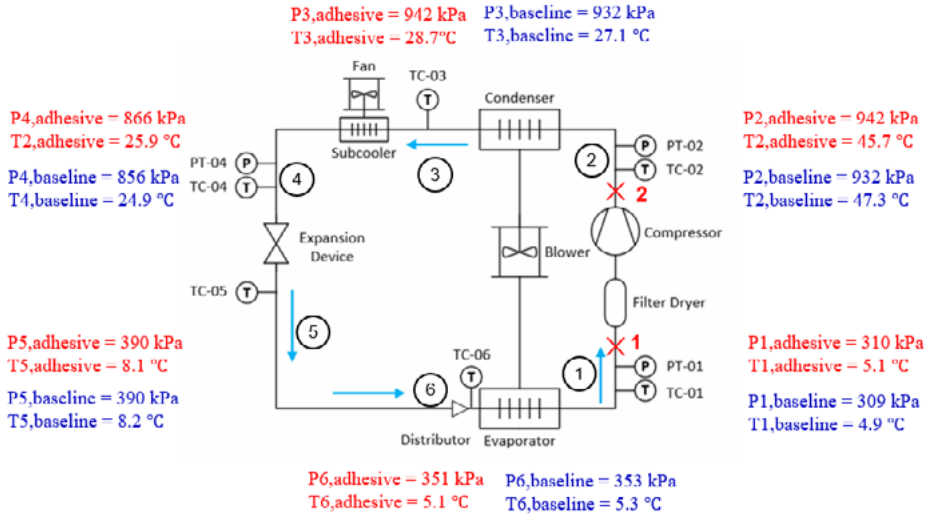

Fig. 3 Schematic diagram of the heat pump system showing the pressure and temperature values measured or calculated at each state point. The baseline data are shown in blue and the data for the tests with the adhesive joints are shown in red.

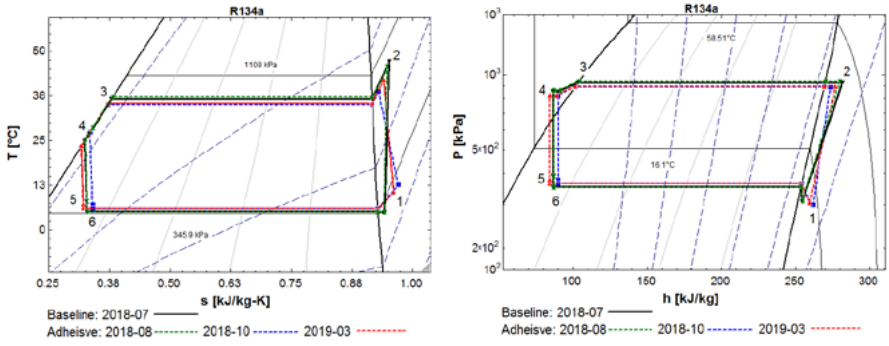

Fig. 4 T-s (left) and P-h (right) diagrams of heat pump system operation conditions at the baseline condition and for three selected tests over a 6-month period after installing the adhesive joints.

4. Vibration Testing

Failure in HVAC&R joints caused by vibration is one of the major concerns. Although the heat pump dryer testing showed that the joints can function in a real operating system under vibrations from the compressor and cooling loop flow, an accelerated test involving more intense and controlled vibrations is performed to evaluate whether a leakage may occur. Vibration testing is performed following the ISO standard 14903 [6], with the test parameters as given in Table 4. The vibration displacement and number of excitations are specified based on the tube size and require precise control.

Table 4 Vibration test parameters from ISO standard 14903 used to evaluate the survivability of the adhesive joints.

Pipe Diameter (mm)	Length (mm)	Displacement (mm)	Frequency (Hz)	Number of excitations
< 10	200	0.30	≤ 200	2 000 000
≥ 10 and < 20		0.25		
≥ 20 and < 30		0.20		
≥ 30 and ≤ 50		0.15		

4.1. Experimental setup

The separate vibration test is performed using a shaker test stand. The test system produces controlled vibrations to evaluate the reliability of components used in various applications.

Due to the large number of U-joints that are present in tube-and-fin heat exchangers, this joint geometry is selected for vibration testing. For this geometry, a U-bend tube is joined at both ends to straight tubes, as shown in Fig. 5. These two tube-to-tube joints are formed by flaring the straight tube for insertion of the U-bend with adhesive, rather than using a coupling. The outer tube diameters are 9.525 mm (3/8 inch) and the straight tube lengths are 152.4 mm (6 inches). A custom adhesive formulation from an industry collaborator (with characteristics similar to the previous one) is used for the joining process, which was performed by the industry partner. Two different sets of U-joints were tested: one set of 8 samples with adhesive joints and another set of 8 samples having brazed joints. Two types of joints are tested simultaneously for comparison.

The vibration exciter generates the vibrations of a specified frequency and displacement to drive the base plate. It is important to firmly clamp the U-joints to the base plate for both safety and accuracy of the testing. For this purpose, aluminum fixtures are custom-designed and fabricated to clamp the extended straight tubes while leaving the U-joints to hang freely at the end, similar to their configuration in tube-and-fin heat exchangers. The 3D drawings of the fixtures are shown in Fig 6. The bottom plate of the fixture is affixed to the shaker base plate using bolted connections through two large clearance holes. The bottom and top fixture plates are attached using bolted connections; eight bolts pass through clearance holes in the top plate and thread into the bottom plate. At the interfacing surfaces between these two plates, there are 16 half cylinder cavities designed to clamp the extended tubes of the samples. Black rubber sheets taped on the extended tubes between the plates and samples provide cushioning and fix the samples in place. The diameter of the cavity is sized to be slightly smaller than the outer tube diameter plus the thickness of the rubber sheet, such that the copper tubes are pushed firmly into place with compression of the black rubber sheets. Fig 5 shows a photograph of the two sets of U-joints with fixtures installed on the shaker test stand.

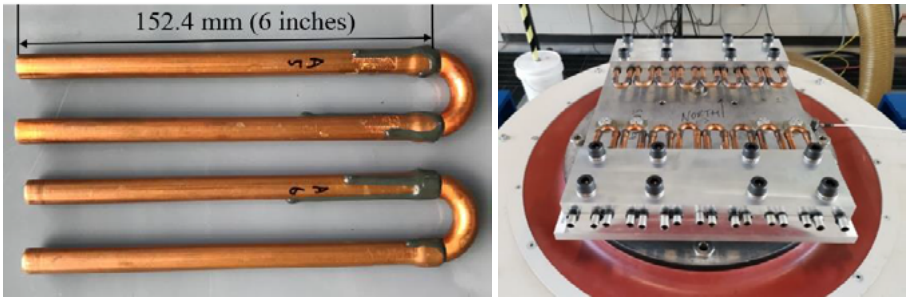

Fig. 5 Photographs of the U-shape joints with adhesive (left) and the fixtures containing a set of 8 samples each installed on the vibration shaker test stand.

4.2. Testing procedure

Following Table 4, the fixtured joints are subjected to vibrations with 0.3 mm displacement at a frequency of 125 Hz. The total number of the excitations is 2,000,000. The displacement and frequency of the test section are monitored and measured throughout the test. The joints are not pressurized with any fluid during the vibration testing in case of failure.

Before and after the vibration testing, the U-joint samples are each visually inspected and checked for leakage. Before vibration testing, fittings are soldered to the open end of the extended tubes to allow charge the samples with high-pressure nitrogen. During the soldering process, the U-joints were cooled using wet cloths to keep the temperature near room temperature. The samples with fittings are charged to 1700 kPa (approximately 250 psi) and immersed in water to observe if there are any air bubbles. The fittings are unsoldered and removed before placing the sample into the fixtures. The same process is repeated after the vibration testing.

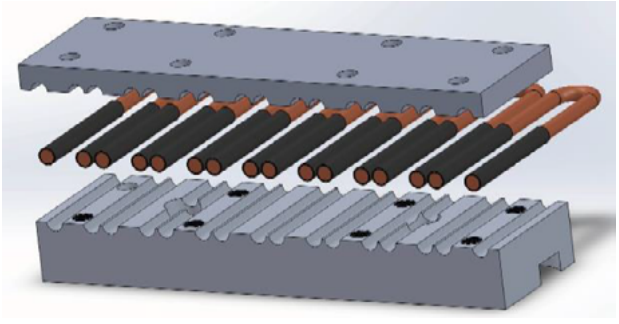

Fig. 6 3D Drawing of the fixture assembly with U-shaped joints wrapped with black rubber sheet.

4.3. Results and discussion

Before vibration testing, there were no cracks or imperfections in the adhesive or brazed joints, and all the samples were leak-free. The in-situ test stand measurements confirmed that the samples were subjected to 0.3 mm displacement vibrations at 125 Hz; the acceleration for the shaker was 21.2 g. The test stand ran continuously for 4.5 hours, which resulted in a total of 2,025,000 excitations. After testing, the rubber sheets used for fixing the samples into place were worn as expected, but the copper surface and the joints appeared the same as before testing for both brazed joints and adhesive joints as shown in Fig. 7. All the samples were confirmed to be leak free after testing. The results demonstrate that the adhesive joints are able to survive these extreme vibration conditions just as the brazed joints without any failures.

Fig. 7 Photographs of the U-shape joints after the vibration test for adhesive joints(left) and vibration joints compared with brazed joints (right).

5. Conclusions

Adhesive joints have the potential to replace brazed joints and improve system efficiencies in the HVAC&R industry. Compared to existing brazed and mechanical joints, the use of adhesives offers lowers cost, increase the ease of manufacturing without an open flame, and provides the flexibility to be applied to various materials and geometries. To demonstrate the application procedure and explore the feasibility of an adhesive joint, two separate proof-of-concept tests were performed using a heat pump dryer system and a vibration shaker test stand. An adhesive joining procedure is presented including surface preparation, adhesive preparation, adhesive application, and curing. For the heat pump dryer system, tube-to-tube adhesive joints were installed

at the inlet and outlet of the compressor. The system was first pressurized to check for initial leaks and then charged with refrigerant for performance testing over a 6-month period. Results showed that the adhesive joints hold the refrigerant pressure without leaks and the system performs consistently before and after the installation of adhesive joints. For the vibration testing, copper U-bend samples were joined to straight tubes using either an adhesive or with a standard brazing method as a benchmark. These joints were fixed on an industrial shaker table and tested following an ISO standard for joints with 0.3 mm displacement at 125 Hz for 2,025,000 vibrations. The joints were leak checked before and after the vibration testing and no failures were observed for the adhesive or brazed joints. These proof-of-concept tests indicate that there is potential for use of adhesive joints to replace brazed joints in HVAC&R applications, which warrants further investigation.

Abstract

In this paper, a series of experimental tests on system coefficient of performance (COP) of air source heat pump water heater (ASHPWH) working with R22 were carried out. ASHPWH equipped the condenser which was wrapped around copper tubes with different inner diameters of 4.5 and 6.4mm and variable types of smooth tube and internal threaded tube. Besides, the economic cost of aforementioned systems were compared and analyzed. The results show that the system performance of ASHPWH with small diameter copper tubes of 4.5mm is improved compared with the large diameter copper tube of 6.4mm, meanwhile the total costs are greatly reduced. Given that the inner diameter is constant, the internal threaded tube has a significant improvement in system COP compared with the smooth tube. Moreover, COP of ASHPWH with internal threaded tubes whose inner diameter is 4.5mm can reach 4.17, therefore the small diameter copper tube has a good application prospect in ASHPWH.

Keywords: heat pump water heater; coefficient of performance (COP); condenser; small diameter copper tubes.

1. Introduction

With the rapid rise of Chinese economy and advancement of urbanization, the "energy bottleneck" problem is becoming increasingly serious. The energy cost of Chinese construction operation was 864 Mtce (million tons of standard coal equivalent) in 2015 excluding biomass energy [1], accounting for about 20% of the total energy consumption in China. As for urban dwelling, the urban residential energy consumption was 192 Mtce in 2015 excluding northern heating, and the energy consumption of domestic hot water was equal to 27 Mtce, accounting for about 14% of total residential energy consumption.

The concentrated supply of urban residential hot water in China mainly depends on electricity, fuel (coal, oil, gas) and solar energy. With increasing awareness of energy saving and emission reduction, the advantages of heat pump water heater, including air source [2-4], ground source [5-6] and solar source [7-8], are significantly obvious in medium-sized centralized hot water supply and small domestic hot water supply. ASHPWH is one of the most widely used style in the market due to its energy-savings, environmental friendliness, flexibility and convenience over the recent decades.

In general, the analysis of the dynamic system characteristics under different working conditions of ASHPWH can be carried out by means of modelling and experiments. Ibrahim et al. [9] proposed a dynamic simulation model to predict the performance of an ASHPWH. The developed model was utilized to assess its performance from the perspective of energy savings and greenhouse gas emissions. Peng et al. [10] developed an ASHPWH model to work under wide operating conditions using different expansion devices, such as electronic expansion valve (EEV), capillary tube and short tube orifice, it was found that the EEV throttling system performed best. Zhang et al. [11] investigated the system performance of an ASHPWH via calculating

* Corresponding author. Tel.: +86-021-65983867, +86 13817847420.
E-mail address: gaonaiping@tongji.edu.cn.

and testing, it pointed out that the refrigerant filling quantity played an important role in heat pump system running.

Some investigations were conducted to compare the different types of refrigerant used in the air source heat pump (ASHP) system. Wang et al. [12] presented a novel frost-free ASHP system working with R134a and R407C as an R22 alternative, the results showed that R134a was more promised alternative than R407C to R22 for the novel ASHP system. Li et al. [13-14] compared the effects of R22, R134a and R744 on the solar-air hybrid heat source heat pump water heater, it was found that the COP of R744 was highest within the ambient temperature of 5~13°C while the COP of R134a was best when the ambient temperature was higher than 13°C.

Moreover, the condenser characteristics were also paid special attention. Yang et al. [15] analyzed the flow condensation heat transfer and pressure drops of R1234yf and R134a in a small circular tube. The results showed that both pressure drop and condensation heat transfer performance depended on the fluid properties, flow conditions and flow patterns. Yan et al. [16] investigated the characteristics of condensation heat transfer and pressure drop of R134a flowing in a horizontal small circular pipe with an inside diameter of 2.0mm, it was found that the condensation heat transfer coefficient of small pipe was about 10% higher than that of large pipe with the inside diameter of 8.0mm. Son et al. [17] experimentally studied the condensation heat transfer of R22, R134a and R410a flowing in the horizontal copper tube of 1.77, 3.36 and 5.35mm inner diameter, respectively. In case of two-phase flow, the condensation heat transfer coefficient for R22, R134a and R410a increased with increasing mass flux and decreasing tube diameter.

The literatures listed above mainly attached importance to the system COP related with expansion devices, refrigerant and its filling quantity. And special attention was paid to the condenser characteristics. But the effects of structural parameters of copper tubes in the condenser on system COP have rarely been investigated. Accordingly, the purpose of this study is to carry out new experimental research on copper tube with different inner diameters, lengths and types used in the condenser of ASHPWH. The effects of aforementioned parameters on system COP are analyzed and these parameters are optimized in order to improve the COP of system. Meanwhile the economic analyses between copper tubes and aluminum microchannel are also taken into consideration.

2. Experimental apparatus and procedures

2.1. ASHPWH experimental system description

The experimental apparatus established in the present study is schematically shown in Fig.1. And the theoretical *P-h* diagram is depicted in Fig.2. The picture of experimental bench is illustrated in Fig.3. The ASHPWH consists of three main loops: the air loop, the refrigerant R22 loop and the water loop. More special attention are paid to the refrigerant R22 circle. As can be shown in Fig.2, its basic components include compressor, condenser, expansion valve and evaporator. The superheated refrigerant vapor is produced in the evaporator, then it flows into the compressor and turns into high temperature and pressure refrigerant vapor via the isentropic compression process 1-2. Next it is sent to the condenser to release heat to the water tank and itself is cooled down to the liquid state, thereby the domestic water at a certain temperature can be obtained through the isobaric cooling process 2-3. Subsequently the liquid refrigerant turns into a gas-liquid mixed state after passing through the expansion valve and then it flows into the evaporator. The refrigerant absorbs heat from the outside air through the isobaric evaporation process 4-1, and enters the compressor again to start a new cycle.

The thermodynamics of ASHPWH can be calculated according to Fig.2. In the actual operation process, the electric energy consumed by the compressor can be expressed by the following equation (1).

$$W = \frac{m_f(h_2 - h_1)}{\eta_o} \tag{1}$$

And the mass flow rate of refrigerant R22 can be calculated according to equation (2).

$$m_f = \frac{NV_{cp}\rho_1\eta_v}{60} \tag{2}$$

Then the released heat from the refrigerant R22 to water in the condenser can be calculated according to equation (3). Equally, this part of heat is absorbed by the water in the condenser.

$$Q_c = m_f(h_2 - h_3) = \frac{\rho_w V_w C_p (T_{out} - T_{in})}{t} \quad (3)$$

Meanwhile the absorbed heat from the ambient air is defined as the equation (4).

$$Q_e = m_f(h_1 - h_4) \quad (4)$$

Finally the system COP can be expressed as the following equation (5).

$$COP = \frac{Q_c}{w} \quad (5)$$

In the above equation (1) ~ (5), m_f represents the mass flow rate of refrigerant R22. The values of rotating speed N, displacement volume rate V_{cp} and volumetric efficiency η_v are 2880rpm, 17cm^3/rev and 91%. h_1, h_2, h_3 and h_4 stand for the enthalpy of point 1, point 2, point 3 and point 4 in Fig.2 respectively. η_o represents the overall efficiency of compressor and the value of it is 0.7 [18] in this study. ρ_w stands for the average density of domestic hot water in the heating process. V_w represents the volume of domestic hot water. C_p represents the average specific heat capacity of water. T_{in} and T_{out} mean the initial temperature and final temperature of water during the heating process. t represents the time of heating process. It is worth mentioning that the enthalpy of refrigerant R22 can be obtained according to the measured temperature and pressure in the corresponding position.

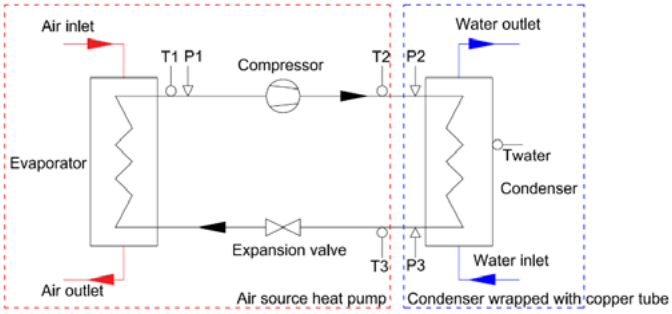

Fig. 1. Schematic diagram of the experimental system.

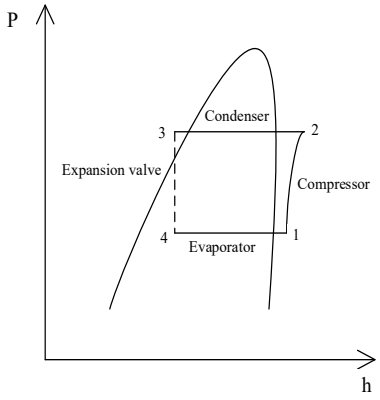

Fig. 2. Theoretical *P-h* diagram of ASHPWH.

2.2. Testing procedure and measuring sensors

The main goal of these experiments is to investigate the effects of different structural parameters of copper tubes on COP of ASHPWH. In this process, 200L water is heated from 15°C to 55°C, and the electric energy consumed by the compressor can be obtained due to the detected voltage and current. Besides, the heat exchange capacity in the condenser can be calculated according to Equation (3). Therefore the system COP can be obtained based on Equation (5). Meanwhile the economic analysis is also taken into consideration for practical application. In this study, the experimental tests are carried out via combining the water tank wrapped around copper tubes in different cases with the host of ASHP system. It should be noted that the dry bulb temperature and the wet bulb temperature of the ambient environment are 20°C and 15°C respectively. The performance parameters of the host are listed in Table 1.

Fig.4 (a) and (b) depict the geometrical and physical diagram of the water tank wrapped around copper tubes respectively. Table 2 illustrates five variable winding schemes of copper tubes outside the water tank in experimental tests. According to Table 2, group A and B study the effects of variable diameters and lengths of copper tubes on system performance. Group B and C pay special attention to copper tube arrangements. Group C and D investigate the effects of length of copper tube and refrigerant charge. Moreover, group D and E compare the effects of type of copper tube on system performance.

Table 1. Performance parameters of host of ASHP system

Parameters	Value
Type	KF35E
Rated heating capacity (kW)	3.5
Domestic hot water output (L/h)	80
Rated input power/current (kW/A)	0.83/4.0
Maximum input power/current (kW/A)	1.3/6.0
Refrigerant/rated charge volume (-/g)	R22/1050
Maximum allowable pressure on high/low pressure side (MPa)	3.0
Allowable working overpressure on exhaust side (MPa)	3.0
Allowable working overpressure on suction side (MPa)	0.7

Table 2. Five winding schemes of copper tubes outside the water tank

Group	Inner diameter (mm)	Type	Length (m)	Arrangement	Refrigerant charge (g)
A	6.4	Smooth tube	60	Two rows in parallel	1050
B	4.5	Smooth tube	80	Two rows in parallel	1050
C	4.5	Smooth tube	80	Four rows in parallel	1050
D	4.5	Smooth tube	100	Four rows in parallel	1130
E	4.5	Internal threaded tube	100	Four rows in parallel	1130

(a) geometrical diagram (b) physical diagram

Fig. 4. Picture of water tank wrapped around copper tubes.

As can be seen in Fig.1, the experimental bench equips 4 thermocouples (T1-T3 and Twater), 3 pressure sensors (P1-P3). They are used to analyze the system characteristics under variable conditions. The specific information about these measuring sensors, such as the instrument type, measuring range and accuracy are given in Table 3.

Table 3. Major measuring sensors used in the experimental system

Parameter	Instrument type	Measuring range	Accuracy
P	diffused silicon pressure sensor	0-2MPa	±0.2% of MV
T	K-type thermocouple	0-1000°C	±1.5°C

3. Results and discussion

3.1. System performance of ASHPWH

The performances of five winding schemes of copper tubes outside the water tank are experimentally investigated using the host of ASHP system. The results of these tests are shown in Table 4. It is found that the COP of group A is 3.95 and it is higher than that of group B (3.66) and group C (3.82). Given that the refrigerant charge and the copper tube type are fixed in these three groups, the heat exchange area of group A is larger than group B and C because of the variable diameters and lengths of copper tube. Besides, comparing

group B and C, the arrangement of copper tubes can also affect the system performance. Obviously the arrangement of four rows in parallel runs better than that of two rows in parallel under the same condition. It can be clearly seen in Table 4 that the values of power consumed by compressor of group B and C are 0.83kW and 0.84kW respectively, which are nearly the same. However, the heating capacity of group C is 3.21kW and it is obviously higher than that of group B (3.04kW). Meanwhile the heating time of group C is a little shorter compared with group B. Furthermore, the type of copper tube is also a significant factor affecting system performance. It can be easily found that the internal threaded tube in group E can make the COP of ASHPWH increase by 5% compared with smooth tube in group E considering other things being equal. This is because the internal threaded tube increases the heat exchange area while also enhancing the heat transfer effect on the refrigerant side, thus increasing the heat transfer coefficient of the refrigerant side. Therefore the heating time required for group E is greatly shortened to 9310s compared with 10160s in group D when heating the same volume of water.

Table 4. Experimental results of five variable winding schemes of copper tube

Group	Volume of water tank (L)	Heating time (s)	Heating capacity (kW)	Power consumption (kW)	COP
A	200	9640	3.47	0.88	3.95
B	200	11000	3.04	0.83	3.66
C	200	10420	3.21	0.84	3.82
D	200	10160	3.29	0.83	3.96
E	200	9310	3.59	0.86	4.17

Further to say, the variation of supercooling degree of refrigerant at the outlet of condenser is also taken into consideration. The variation ranges of five different cases are shown in Fig.5. Moreover, special attention is paid to the flow resistance of refrigerant in the copper tubes. The flow resistance of these five groups are depicted in Fig.6. What worth mentioning is that flow resistance in this paper represents the temperature difference corresponding to inlet and outlet pressure of condenser.

As can be seen from Fig.5, the supercooling degree of refrigerant in group A, B, C and D is basically between 5~10°C while the supercooling degree in group E is much higher. It means that the internal threaded tube makes heat transfer coefficient of refrigerant higher compared with the smooth tube, the heat exchange is so sufficient that energy efficiency of ASHPWH is greatly improved.

As shown in Fig.6, flow resistances of group B and E are larger than 3°C. It indicates that longer length, arrangement of two rows in parallel and internal threaded tube have adverse effects on flow characteristics in the copper tubes. Honestly speaking, although the COP of group E is highest, more attention should be paid to reduce the flow resistance in the future study in order to have a better system performance.

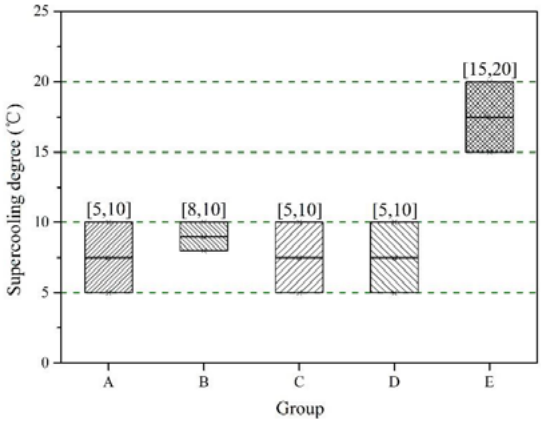

Fig. 5. Variation ranges of supercooling degree of five different groups.

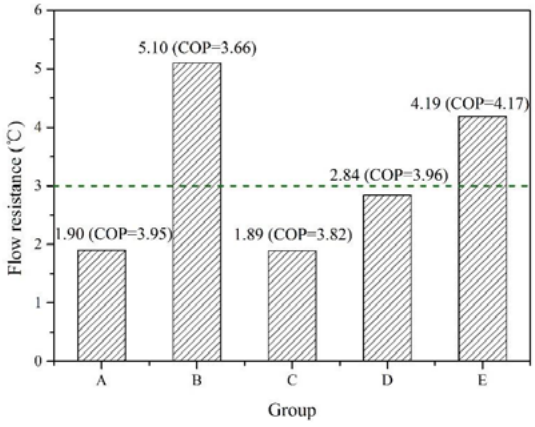

Fig. 6. Flow resistance of these five different groups.

3.2. Economic analysis of tubes

Generally speaking, the total costs of copper tubes consist of material cost and processing cost. And material cost takes a large proportion of total costs, while processing cost only accounts for 10%-20% of material cost. According to the survey, the material cost of copper is ¥45,000 per ton. The processing cost of smooth copper tube is ¥4,500 per ton, and that of internal thread copper tube is ¥6,500 per ton. The total costs of group A, D and E are listed in Table 5. Meanwhile the total cost of aluminum microchannel (group F) is also considered and compared with that of copper tubes.

As for the smooth copper tubes (group A and D), it indicates that copper tubes with smaller diameter can make ASHPWH run better while reducing the total costs. Besides, it is obvious that the total costs of internal threaded copper tubes with the inner diameter of 4.5mm in group E reduce by 17% compared to the smooth copper tubes with 6.4mm in group A. Meanwhile the COP of system increases by 5%. The main reason is that the internal thread copper tubes with smaller diameter can increase the heat exchange area while enhancing the convective heat transfer on the refrigerant side, thereby improving the system energy efficiency. However, what worth mentioning is that the smaller the diameter, the thinner the wall. Considering that the refrigerant pressure is relatively high within high temperature range, if the tube wall is too thin, it is easy to make the D-type copper tube change into O-type, thus reducing the heat exchange area. With regard to the water tank using aluminum microchannel, it is well-known that the unit cost of aluminum is lower than that of copper, but the processing cost of the former is too high. The values of COP in group D and F are 3.96 and 3.95 respectively, the total costs of smooth copper tubes with smaller diameter of 4.5mm reduce by 29% compared to that of aluminum microchannel. Moreover, the internal threaded copper tubes in group E can both increase the system COP and reduce the total costs. In summary, the copper tubes with smaller diameter are relatively more cost-effective, and can also improve the system COP. Thus it has a good application prospect in the area of ASHPWH in the future.

Table 5. Economic analysis of tubes in variable groups

Group	Type	Inner diameter (mm)	Weight per unit length (kg/m)	Length (m)	Total weight (kg)	Total costs (¥)	COP
A	Smooth copper tube	6.4	0.0537	60	3.22	159	3.95
D	Smooth copper tube	4.5	0.0317	100	3.17	157	3.96
E	Internal threaded copper tube	4.5	0.0256	100	2.56	132	4.17
F	Aluminum microchannel	--	--	--	--	220	3.95

4. Conclusions

In this study, the system performance of ASHPWH with variable water tanks using five winding schemes of copper tubes are experimentally investigated. Besides, special attention has been paid to the economic analysis of tubes utilized outside the water tank. The effects of inner diameter and type of copper tubes on system COP have been studied. Moreover, the total costs of copper tubes and aluminum microchannel have been analyzed. The following conclusions can be drawn:

1. As for the smooth copper tubes with different inner diameters (6.4 and 4.5mm), the smaller diameter copper tubes dominate in terms of system performance and economic cost of ASHPWH. Besides, the arrangement of four rows in parallel runs better than that of two rows in parallel considering all other things being equal.
2. With regard to the internal threaded tubes and smooth tubes with same inner diameter, the former can increase the heat exchange area while enhancing the heat transfer effect on the refrigerant side. Therefore the highest COP of ASHPWH can reach 4.17 using the internal threaded copper tubes with the inner diameter of 4.5mm. However, the internal threaded tubes have an adverse effect on system operation, meanwhile the flow resistance increases accordingly.
3. Small diameter copper tube outweighs aluminum microchannel in terms of economic cost of ASHPWH. The total costs of smooth copper tubes with inner diameter of 4.5mm reduce by 29% compared to aluminum microchannel when the system COP of these two cases are almost the same.

Responses to Reviewers' Comments

Dear Editor and Reviewers,

We quite appreciate the comments concerning our manuscript entitled "Experimental investigation of condenser with small diameter copper tube in air source heat pump water heater". Those comments are all valuable and very helpful for revising and improving our paper, as well as the important guiding significance to our researches. We have studied comments carefully and have made correction which we hope meet with approval. Revised portion are marked in red in the paper. The main corrections in the paper and the responses to the reviewer's comments are written in blue as following:

Reviewer #1

1. The description of symbols should add their units.

Discussion: Thanks very much for reviewer's careful suggestion. The "Nomenclature" section has been supplemented in order to describe the symbols in details and marked in red in the manuscript.

2. From the introduction, I can not understand the need of your research. The knowledge gap should be properly issued.

Discussion: Thanks for reviewer's valuable advice. The purpose of this study is to investigate the effects of structure parameters of copper tubes in the condenser on the COP of system throught experiments, which has rarely been studied before. Besides, it can provide the guidance for copper tubes applied in the area of ASHPWH. According to the reviewer's suggestion, we have supplemented the "Introduction" section and the modified texts are marked in red in the manuscript.

3. The overall efficiency of compressor η, how did you calculate it?

Discussion: Thanks for reviewer's question. According to some published literatures[1-3], the recommended range of overall efficicncy of compressor η_o is 0.7~0.75. In our experimental bench, the power consumed by the compressor can be detected directly by the dynamometer, the enthalpy of working fluid R22 at the inlet and outlet of compressor can be determined by the measured pressures and temperatures in the corresponding position. And the mass flow rate of working fluid can be calculated according to the following equation.

$$m_f = \frac{NV_{cp}\rho_1\eta_v}{60}$$

The value of rotating speed N, displacement volume rate V_{cp} and volumetric efficiency η_v are 2880rpm, 17cm^3/rev and 91%. The density of R22 at the inlet of compressor ρ_1 can be obtained through Refprop 9.0 according to T_1 and P_1. Then the average overall efficiency of compressor in our experiments can be calculated accroding to equation (1) in the manuscript and the value of it in this study is 0.7, which is within the recommended range.

According to the reviewer's question, we have modified the section 2.1 and made explanations in the manuscript.

4. There are still some English grammar mistakes in your paper. Maybe a native speaker is needed.
Discussion: Thanks a lot for reviewer's suggestion. We have examined the grammar in details and modified the full paper carefully. There are some minor modifications but they are **not** marked specifically in the manuscript.

5. Some quantitative analysis data should be given in the text of results section, especially when comparing performance.
Discussion: Thanks very much for reviewer's valuable suggestion. We have modified section 3.1 and 3.2 in the manuscript accordingly and the modified texts are marked in red.

Reviewer #2
This paper presented experimental tests on system coefficient of performance (COP) of air source heat pump water heater (ASHPWH) working with R22 in new experimental research of copper tube with different inner diameters, lengths and types used in the condenser. The author clearly shows the experimental apparatus, procedures, system performance and economic analysis. The paper is well-organized and the quality of English is satisfactory. The paper can be accepted.
Discussion: We appreciate for the reviewers' warm work earnestly.

We tried our best to improve the manuscript and made some changes in the manuscript. We appreciate for Editors/Reviewers' warm work earnestly, and hope that the correction will meet with approval.
Once again, thank you very much for your comments and suggestions!

Abstract

In this paper, a series of experimental tests on air source heat pump water heater (ASHPWH) using a novel heat battery module with phase change material (PCM) were carried out. The melting temperature of PCM is 58°C. Meanwhile special attention has been paid to the optimization of heat transfer in heat battery module by means of computational fluid dynamics (CFD). The results indicate that the instant coefficient of performance (ICOP) of ASHP is up to 3.82 but the operation of ASHP is unstable and in poor condition with a 1.3 mm caliber electronic expansion valve. The latest experiment shows that using 1.5 mm caliber electronic expansion valve can not only make ASHP run more smoothly but also increase ICOP to 4.08. During the discharge process of heat battery module, 106.5L domestic water can be heated from 15°C to 40°C. The CFD simulation testifies copper fins applied in heat battery module can greatly enhanced the heat transfer coefficient compared with aluminum fins.

Keywords: Heat pump water heater; phase change material; CFD; system performance

1. Introduction

With the rapid development of the economy to stimulate people's demands for high-quality life, water heaters have become an indispensable device in today's homes. Because of its characteristics of energy saving, high efficiency and comfort, ASHPWH has gradually been favored by domestic and foreign markets. China's ASHP industry has developed rapidly since the beginning of the 21st century. In the latest decade, China has become the world's second largest ASHP producer next to Japan. According to the statistical data in 2015, ASHPWH share in China is only 3%, but with the promulgation of relevant energy conservation policies and the improvement of consumers' environmental awareness, ASHPWH has unparalleled application prospect.

Some researches on ASHPWH have been conducted for several decades. For example, the host of ASHPWH needs frequent start and stop, which not only causes a large amount of energy waste but also greatly affects the life of the heat pump system, which will limit the further development of ASHPWH. However, PCM has the advantages of large latent heat and suitable phase transition temperature, which can replace the bulky water tank and further enrich the application scenario [1] of ASHPWH. Moreover, ASHPWH with PCM can make rational use of electric power cost between on-peak and off-peak, saving the cost of electricity and balancing the grid load.

Moreover, PCM has problems such as low thermal conductivity and unstable heat storage performance [2]. Therefore, strengthening the heat transfer of PCM in the endothermic and exothermic process has become a research focus of PCM. At present, the research on the application of highly conductive nanomaterials [3] coupled with PCM to improve the thermal conductivity of PCM has made significant progress. Motahar et al. [4] experimentally studied the thermal conductivity and viscosity of n-octadecane/TiO_2 nanoparticles [5-6] and found that the thermal conductivity is non-monotonic in both solid and liquid phases. In the solid phase, when the mass fraction of nanoparticles is 3%, the thermal conductivity increases the most. In the liquid phase, when

* Corresponding author. Tel.: +86-021-65983867, +86 13817847420.
E-mail address: gaonaiping@tongji.edu.cn.

the mass fraction of nanoparticles is 4%, the thermal conductivity increases the most. In addition, the maximum average thermal conductivity of the two stages was enhanced by about 5%.

The use of microencapsulated of phase change material (MPCM) [7-8] can be effective in reducing the reactivity of PCM with the external environment, increasing the heat transfer area and the heat transfer rate, which makes MPCM has great application potential in the fields of heat storage, temperature control and heat protection. Luo et al. [9] first applied the miniemulsion polymerization method to the synthesis of nanocapsule phase change materials, and prepared nanocapsules with paraffin as the core material, styrene and methyl methacrylate copolymer as the shell material [10-11]. The obtained nanocapsules have a complete core-shell structure and a particle size of less than 100 nm. Park et al. [12] also synthesized stable spherical nanocapsules with paraffin as core and polystyrene as shell by miniemulsion polymerization. The DSC freeze-thaw cycle shows that it has good thermal stability and exothermic properties, and the latent heat of phase change can reach up to 145 J/g.

When there is an electric current passing through the loop composed of different conductors, the endothermic and exothermic phenomena will appear respectively at the joints of different conductors with the direction of the current. Accordingly, Selvam et al. [13] used the Peltier effect [14] to enhance the heat transfer of PCM. Experiment has shown that the cold junction temperature of a PCM Peltier cooler under pulse operation is significantly reduced from -14.5°C to -17.5°C compared to a Peltier cooler without PCM under pulsed operation. It is also found that, there is no significant reduction in COP of the Peltier cooler under pulse operation with PCM as compared to pulse operation without PCM.

Therefore, the purpose of this study is to explore the feasibility and stability of the combination of ASHPWH and PCM by means of thermodynamic performance analysis. Based on the preliminary experimental work and the test data of the prototype, system performance of ASHPWH is analyzed. Moreover, the heat transfer optimization of heat battery module has been conducted via CFD simulation, the comparison between copper tubes and aluminum tubes is illustrated in this paper.

2. Experimental setup

2.1. ASHPWH with PCM experimental system description

The schematic diagram of present experimental setup is shown in Fig. 1. Its basic components include compressor, heat battery module, expansion valve and evaporator. In order to enhance the heat transfer process in battery module, CFD simulation is applied to optimize the structure of heat battery compared with traditional ASHPWH, the main difference is that the condenser is replaced by a heat battery module. Due to the confidentiality agreement with a partner company, the details of heat battery module are not available in this paper. As can be shown in Fig. 2, the superheated refrigerant vapor, which is produced in the evaporator, flows into the compressor and turns into high temperature and pressure refrigerant vapor via the isentropic compression process 1-2. Then the refrigerant undergoes an isobaric cooling process 2-3 to transfer heat to PCM in the heat battery module. The supercooled refrigerant flowing out from the heat battery is throttled by the expansion valve and turns into a gas-liquid mixed state. The refrigerant then re-enters a new cycle through isobaric evaporation process 4-1 in the evaporator. During the valley electric charge time, ASHPWH starts to work and provide heat. Most of the heat released by the refrigerant is stored in PCM in the form of latent heat. When the hot water is needed, the cold water flows into the heat battery module that absorbs a large amount of heat and becomes hot water that can be used immediately. The time of hot water demand is mostly in peak time period, because of the difference of electric price between the peak and the valley, it can reduce electricity costs.

The thermodynamic performance of ASHPWH with PCM can be calculated according to Fig.2. First of all, the mass flow in ASHP can be calculated through the volume flow of the compressor multiplied by the refrigerant density at compressor inlet. The specific calculation equation is as follows:

$$\dot{m} = \dot{V}_s \cdot \rho \tag{1}$$

In the actual compression process, the electric energy used to compress the refrigerant vapor can be calculated by the following equation (2).

$$W = \frac{\dot{m}(h_2 - h_1)}{\eta_o} \tag{2}$$

Then the released heat from the refrigerant R22 to PCM in the heat battery can be calculated by using the following equation (3).

$$Q_b = \dot{m}(h_2 - h_3) \tag{3}$$

The instant coefficient of performance (ICOP) of ASHP, which is defined as the ratio of heat release of refrigerant in heat battery to power consumption of compressor, can be calculated as follows:

$$ICOP = \frac{Q_b}{W} \tag{4}$$

In the above equation (1) ~ (4), $\dot{m}$ represents the mass flow rate of refrigerant R22. ρ and $\dot{V}_s$ stand for the density and volume flow of refrigerant individually. h_1, h_2, h_3 and h_4 stand for the enthalpy of point 1, point 2, point 3 and point 4 in Fig. 2 respectively. η_0 represents the overall efficiency of compressor. It is worth mentioning that the enthalpy and condensation temperature of refrigerant R22 can be obtained according to the measured temperature and pressure in the corresponding position.

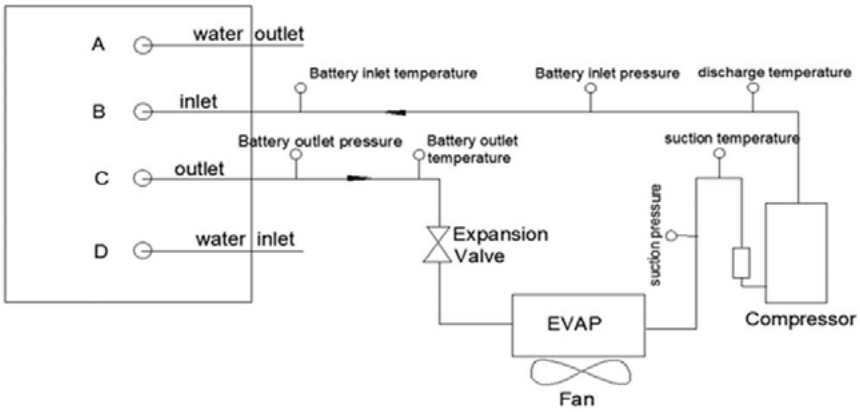

Fig. 1. Schematic representation of experimental setup

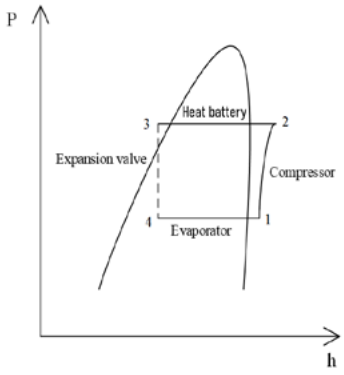

Fig. 2. Theoretical P-h diagram of ASHPWH with PCM

2.2. Testing procedure and measuring sensors

The main goal of these experiments is to test the stability and feasibility of ASHPWH using PCM. During the charge process, the refrigerant R22 releases the heat to the heat battery module whose initial temperature is about 20°C to a fully charged state. It can be measured that the dry bulb temperature and the wet bulb temperature of the ambient environment are 21°C and 19.5°C respectively. During the discharge process, 15°C cold water flows into the heat battery, and the obtained high-temperature hot water is mixed with 15°C cold water at the exit to obtain domestic hot water with 40°C. When the outlet temperature of water has reached 40°C without mixing with cold water, it is considered that the heat battery module is in a completely discharged state. The heat exchange capacity in the heat battery module can be calculated according to Equation (3), and the electric energy consumed by the compressor can be obtained due to the detected voltage and current. Accordingly, the system ICOP can be acquired by using Equation (4).

The performance parameters of the host are listed in Table 1. The experimental bench is shown in Fig. 3. It should be noted that the heat battery module is the most important part of the ASHPWH with PCM and the biggest difference from the traditional ASHPWH.

Table 1. Performance parameters of host of ASHP system

Parameters	Value
Rated heating capacity (kW)	3.2
Rated input power/current (kW/A)	0.88/4.2
Maximum input power/current (kW/A)	1.4/6.5
Refrigerant	R22
Rated charge volume (g)	1700
Caliber of electronic expansion valve (mm)	1.3/1.5

Fig. 3. Picture of the ASHPWH with PCM experimental bench.

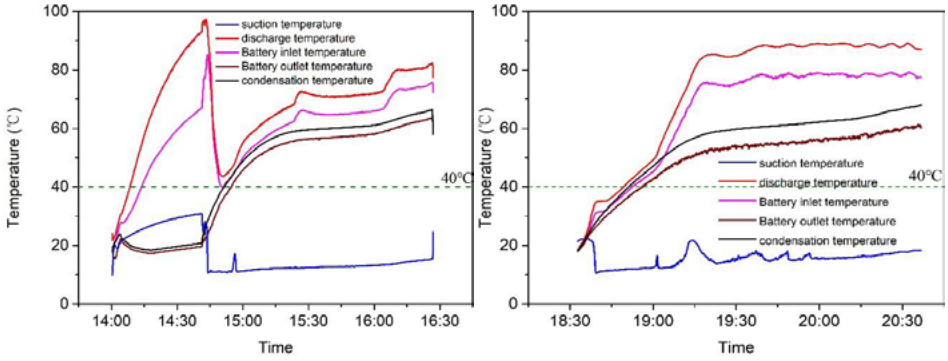
As can be seen in Fig. 1, the experimental bench equips 4 thermocouples (suction temperature, discharge temperature, battery inlet temperature, battery outlet temperature), 3 pressure sensors (suction pressure, battery inlet pressure, battery outlet pressure). These sensors are used to measure the instantaneous change in refrigerant and to analyze the thermodynamic properties of the system. The specific information about these measuring sensors, such as the instrument type, measuring range and accuracy are given in Table 2.

Table 2. Major measuring sensors used in the experimental system

Parameter	Instrument type	Measuring range	Accuracy
P	diffused silicon pressure sensor	0-2MPa	±0.2% of MV
T	K-type thermocouple	0-1000°C	±1.5°C

3. Results and discussion

3.1. Experimental optimization



In the experimental investigation, the effect of two different calibers of expansion value on system performance has been studied, as shown in Table 3. The main performance parameters of the two experiments are shown in Table 4. The system thermodynamic performance of these two experiments are illustrated in Fig. 4 and Fig. 5. Due to the property of PCM, the temperature will not change when it is in a phase change state. Therefore, when the temperature of the refrigerant is constant, the PCM is approximately considered to be in a molten state. According to Fig. 4(a), in the first 45 minutes, the mass flow rate of the refrigerant is small and unstable, resulting in a sharp rise in discharge temperature and battery inlet temperature. When the PCM melts, the temperature and enthalpy of the heat battery inlet are 65°C and 423.3 kJ/kg respectively, and the enthalpy of heat battery outlet is 273.15 kJ/kg. The mass flow rate of refrigerant is calculated as 26 g/s, so the heat exchange capacity in the heat battery is 3.89 kW. The ICOP of the first experiment can reach 3.82. After the previous electronic expansion valve with a caliber of 1.3mm is replaced by that with a caliber of 1.5mm, the second experiment shows that using the electronic expansion valve with a caliber of 1.5mm can not only make ASHP run more smoothly but also substantially increase discharge temperature and battery inlet temperature. It can be calculated that the ICOP of the system is improved by 6.8% to reach 4.08. During the exothermic process of heat battery module, PCM heats 106.5 L water from 15°C to 40°C. It can be concluded that ASHPWH with PCM is feasible.

Table 3. Main parameters of the ASHP after the expansion valve is replaced

Case	Host	Refrigerant	Rated charge volume (g)	Caliber of expansion valve (mm)
1	Haipu (1p)	R22	1700	1.3
2	Haipu (1p)	R22	1700	1.5

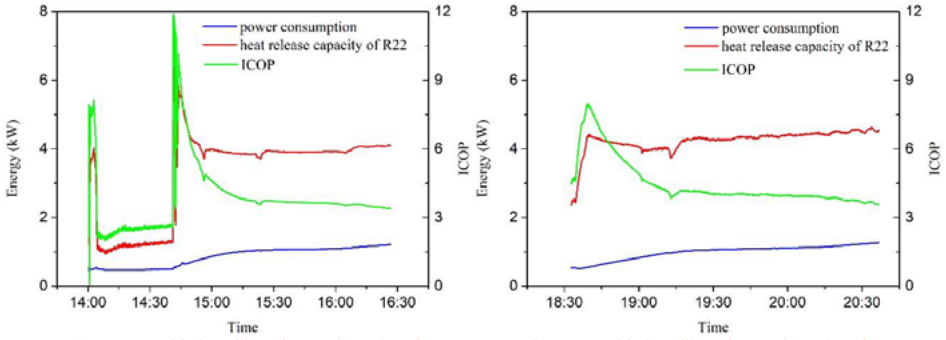


Table 4. Main performance parameters of the two experiments

Parameters	Case 1	Case 2
Discharge temperature (°C)	71	88
Battery inlet temperature (°C)	65	78
Battery inlet enthalpy (kJ/kg)	423.3	437.8
Battery inlet enthalpy (kJ/kg)	273.5	270.8
Mass flow rate (g/s)	26	25.8
Heat release capacity of R22 (kW)	3.89	4.34
ICOP	3.82	4.08
Hot water supply (L)	100	106.5

(a) system with the caliber of expansion valve of 1.3 mm (b) system with the caliber of expansion valve of 1.5 mm

Fig. 5. System performance variation with different expansion valves

3.2. Numerical simulation optimization

At present, one of the main problems of heat battery module is poor heat transfer effect, so enhancing the heat transfer between the PCM and refrigerant/water is the major optimization object. The structure of heat battery module used in this experiment is a fin-and-tube heat exchanger, in which the material of the fin is aluminum, and the material of the heat exchange tube is copper. Aluminum has a relatively good thermal conductivity with an acceptable price. It is one of the most commonly used materials for fin materials. However, when it is connected with a copper tube in heat exchangers, the contact thermal resistance between the two is not conducive to the heat exchange between the PCM and refrigerant/water. Therefore, the simulation analysis of the effect of using copper fins instead of aluminum fins on heat transfer in a heat exchange unit was carried out. The two center sections, as shown in Fig. 6, are selected for observation.

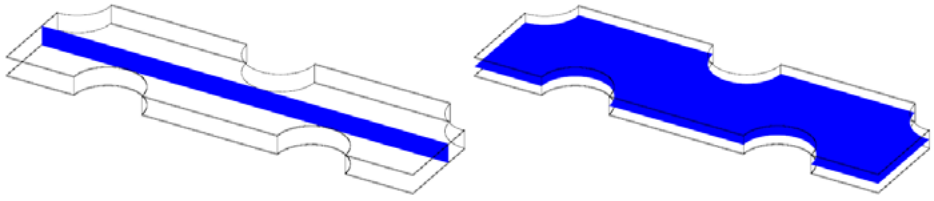

Fig. 6. Two center sections for observation

In the process of simulating the endothermic melting of PCM, in order to simplify the model, the boundary condition on the refrigerant side is set to a constant temperature of 346K, and the initial temperature of the phase change material is 293 K. The CFD simulation results are shown in Fig. 7 and Fig. 8.

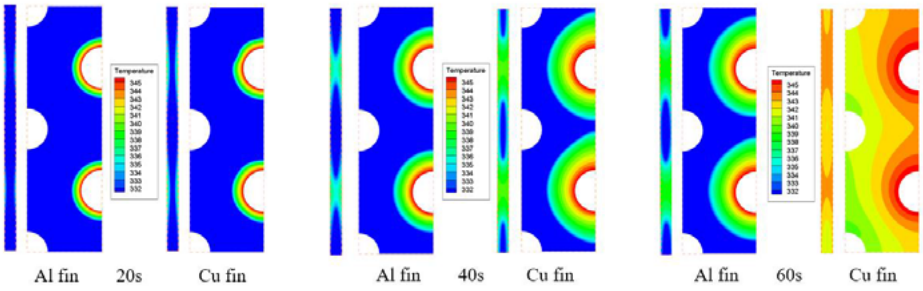

Fig. 7. Temperature distribution of two kinds of fins at different times

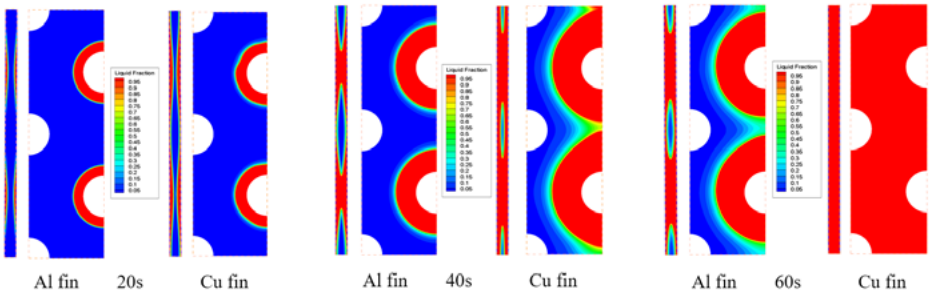

Fig. 8. Liquid fraction distribution of two kinds of fins at different times

It can be seen that the heating rate of PCM increases significantly when using copper fins in the heat battery module. When the heating time reaches 60 s, PCM in heat battery with copper fins almost turned into a liquid state, while a considerable part of PCM of that with aluminum fins was still in solid state. On the one hand, the copper fin can be completely welded together with the copper tube to effectively avoid the adverse effect of contact thermal resistance in heat transfer process; on the other hand, the thermal conductivity of copper is much higher than that of aluminum. Therefore, the use of copper fins can further reduce the thermal resistance of heat transfer and enhance the heat transfer coefficient between the fins and PCM. However, the price of copper is higher than that of aluminum. It is conceivable to replace some of the fins with copper fins to reduce the cost burden.

4. Conclusions

In this paper, a series of experimental tests on a novel heat battery module with PCM applied to ASHPWH were carried out. Based on the preliminary experimental work and the test data of the prototype, the integrated system performance is analyzed. In order to enhance the heat transfer process in battery module, CFD simulation is applied to optimize the structure of heat battery. The following conclusions can be drawn:

1. From the theoretical analysis and experimental results, in the first experiment, the ICOP of ASHP is up to 3.82 but the operation of ASHP is unstable and in poor condition. After the previous electronic expansion valve with a caliber of 1.3 mm is replaced by that with a caliber of 1.5 mm, the latest experiment shows that using 1.5 mm caliber electronic expansion valve can not only make ASHP run more smoothly but also increase ICOP by 6.8% to 4.08. It indicates that ASHPWH with PCM system has a good application prospect and is feasible for practical application in production activities.
2. Copper fins can effectively avoid the adverse effect of contact thermal resistance and greatly enhance the heat transfer coefficient between PCM and refrigerant/water according to the CFD simulation. Considering that copper is more expensive than aluminum, it is conceivable to replace some of the fins with copper fins to balance the cost burden and heat transfer efficiency of heat battery module.

Responses to Reviewers' Comments

Dear Editor and Reviewers,

We quite appreciate the comments concerning our manuscript entitled "Investigation on system performance of air source heat pump water heater with phase change material". Those comments are all valuable and very helpful for revising and improving our paper, as well as the important guiding significance to our researches. We have studied comments carefully and have made correction which we hope meet with approval. Revised portion are marked in red in the paper. The main corrections in the paper and the responses to the reviewer's comments are written in blue as following:

Reviewer #1

This paper made experimental tests on air source heat pump water heater (ASHPWH) using a novel heat battery module with phase change material (PCM), and CFD simulation testifies copper fins applied in heat battery module. It is a good topic to explore the feasibility and stability of the combination of ASHPWH and PCM. The content of the paper is well-organized and the quality of the English is satisfactory. The author clearly explains the experimental setup, analysis of experimental and simulation results. Acceptance of this paper after minor revision is reasonable.

1) Would you please add some detailed description of the specifications of heat battery module with PCM used in the paper?

Discussion: Thanks very much for reviewer's suggestion. We deeply agree with the reviewer. However, the detailed information of heat battery module with PCM is inconvenient to provide in the paper due to the confidentiality agreeement with a partner company. Accordingly we have made the explanation in section 2.1.

Reviewer #2

1) In Table 1 and 3, Has caliber of electronic expansion valve unit? It's better to supply it.

Discussion: Thanks very much for reviewer's careful suggestion. The unit of caliber of electronic expansion is **mm**. According to the reviewer's advice, we have supplemented the unit of caliber of electronic valve in Table 1 and 3. Moreover, the corresponding text has also been modified and marked in red.

We tried our best to improve the manuscript and made some changes in the manuscript. We appreciate for Editors/Reviewers' warm work earnestly, and hope that the correction will meet with approval.

Once again, thank you very much for your comments and suggestions!

Experimental investigation of heat transfer coefficient of R1234yf during condensation inside multiport mini-channel tube

Quang Vu Pham[a], Jong-Taek Oh[b*]

[a] Faculty of Energy Technology, Electric Power University, 235 Hoang Quoc Viet, Hanoi 10000, Vietnam
[b] Dept. of Refrigeration and Air-conditioning Engineering, Chonnam National University, Yeosu 59626, South Korea.

Abstract

R1234yf is an Hydrofluro-Olefins (HFO) that is used as a good candidate for replacing R134a in automotive air conditioning, and it has a low global warming potential of 4 and zero ozone depletion potential (ODP). R1234yf has cooling performance that is 5 % less than R134A but is significantly better for the environment. This research report measured and analyzed the heat transfer performances of R1234yf in the condensation process inside two different multiport mini-channel tubes. Experimental data was obtained for mass fluxes from (50 to 500) kg/m2s, and heat fluxes from (3 to 12) kW/m2 at a fixed saturation temperature of 48 °C. The flow distribution of the R1234yf effect on the heat transfer coefficient was analyzed. Finally, a new heat transfer coefficient correlation was developed from the experimental data.

Keywords: R1234yf, heat transfer coefficient, condensation, multiport tube.

1. Main text

The R-1234yf refrigerant is a low global warming potential of 4 and zero ODP; it has physical properties similar to R-134A and also has the potential as a retrofit refrigerant in existing HFC-134a systems. R-1234yf is classified as slightly flammable., so it is carefully to ensure safety during operation and maintenance of the system included that. R-1234yf has a cooling performance 5% less than R-134A, but significantly better for the environment.

Many available experimental studies compare the heat transfer performance between R134a and R1234yf. Yang and Nalbandian [1] measured the condensation heat transfer and pressure drop of R1234yf and R134a in a 4 mm inner diameter (ID) circular tube. They found that for high vapor qualities, the heat transfer coefficients of R134a are higher than those of R1234yf, but for low vapor qualities, almost the same. Moreover, the authors concluded that the effect of two-phase flow patterns shows strongly on the condensation heat transfer coefficient. [2]'s experimental study on the condensation of R1234yf inside 0.96 mm circular tube compared it with that of R134a at the same test conditions. They found that R134a showed higher performance than R1234yf by about (15–30) % of heat transfer coefficients, and (10–12) % of adiabatic two-phase pressure drop. The experimental data were compared with the correlation of Cavallini et al.[3] . Wang et al. [4] also measured the condensation heat transfer coefficient of R1234yf inside a 4 mm ID tube, compared it with that of R134a and R32, and concluded that strong effects of the mass flux and vapor quality on the heat transfer coefficient are observed in the shear force dominated flow regimes. Also, due to the differences in density ratio, viscosity ratio, and thermal conductivity, the heat transfer coefficients of R1234yf are lower than those of R134a. Illán-Gómez et al. [5] investigated the condensation heat transfer coefficient and pressure drop inside a multiport tube with R1234yf and R134a with large ranges of mass flux and saturation temperature. They

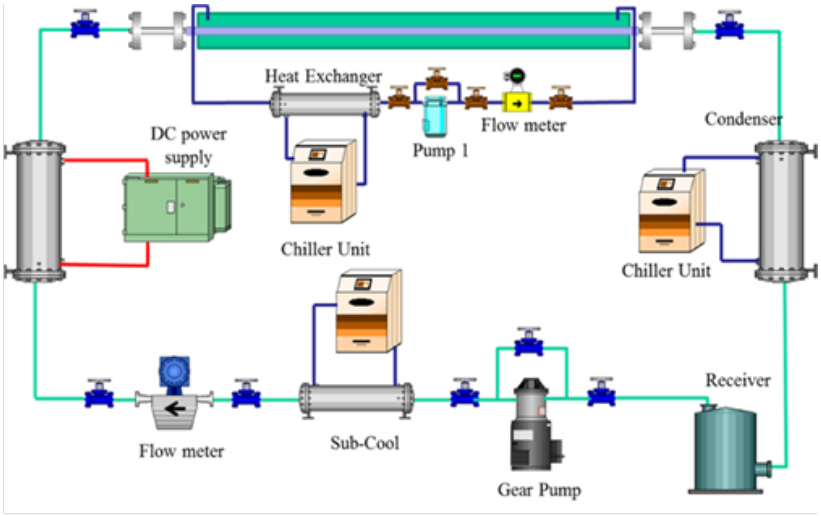

Figure 1 Schematic of the experimental apparatus

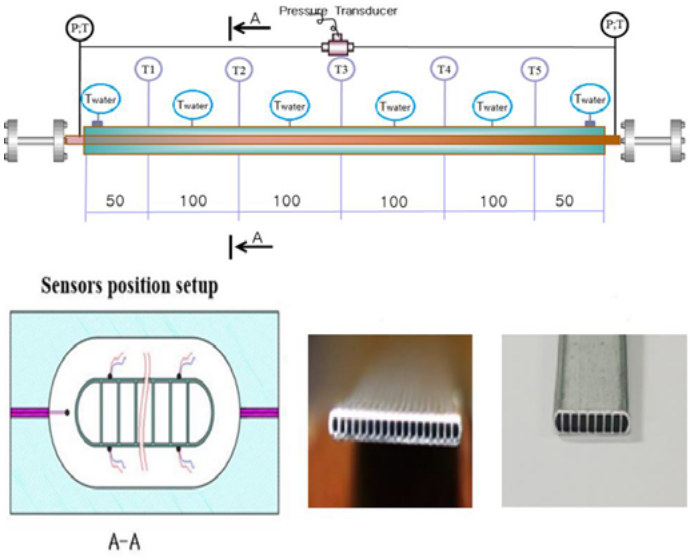

Figure 2 Detail of the test sections setup

compared the experimental data with some heat transfer coefficient and pressure drop models available in the literature, which showed good agreement. Based on the model proposed by Koyama et al. [6], a readjusted model for the heat transfer coefficient has been proposed to improve the agreement with the original model.

Much of the previous research has been conducted and models developed for limited refrigerants and test tubes, while there is a lack of research in the literature that pays attention to the R1234yf inside the multiport minichanel tube. In this study, the condensation heat transfer coefficients of R1234yf inside two types of multiport minichannel tubes of (0.83 and 0.97) mm of hydraulic diameter are investigated experimentally. The effect of mass flux, heat flux, vapor quality, and the geometry of the test section are analyzed, and compared with some existing models.

Table 1 Specification dimensions of the multiport mini-channel tubes

Parameters	PFC	FME
Number of channels	18	8
Width of channel (mm)	0.58	0.69
Height of channel (mm)	1.3	1.42
Hydraulic diameter (mm)	0.846	0.969
Internal cross- sectional area (mm^2)	28.105	19.46
Wetted perimeter surface (mm)	64.52	36.12

2. Experimental apparatus and data reduction

Figure 1 shows the experimental apparatus, which consists of a refrigerant loop, cooling water loop, and water–glycol loop. The experimental apparatus was designed to measure the heat transfer coefficient and pressure drop during the condensation process of refrigerant inside the test section tubes. The refrigerant loop is composed of four major sections: the sub-cooled, the pre-heater, the test section, and the post-condensers. The sub-cooled includes a sub-cooler, a refrigerant gear pump, and a Coriolis-type mass flow meter. The sub-cooler is a tube-in-tube heat exchanger with refrigerant flow inside of the tube and a cooling water loop; the refrigerant is cooled by a water–glycol loop to achieve a subcooled state. The subcooled temperature of refrigerants is controlled by setting the temperatures of constant temperature baths connected to the sub-cooler. The refrigerant is circulated in the refrigerant loop by a magnetic micro gear pump. A Coriolis-type mass flow meter for a maximum mass flow rate of 80 kg/h is installed to measure the mass flow rate of refrigerant. The mass flow rate of refrigerant is independently controlled by adjusting the rotation speed of the drive for the gear pump. The aims of the sub-cooled part provided for the subcooled state refrigerant and required mass flow rate. The pre-heater is used for the multiport tubes test, which is 4 m long, and of 1/4" outer diameter (OD) stainless steel tube. It is connected with a DC power supply for a maximum capacity of 1,500 W. The refrigerant vapor quality in the test section is determined by the heat applied in the pre-heater, which can be controlled by adjusting the voltage and current in the DC power supply unit.

Figure 2 details the test section setup and test section tubes. The test sections are the tube-in-tube heat exchanger in which the refrigerant vapor condenses inside the inner test tubes, while cooling water flows in the annulus. Two types of aluminum multiports were used to have 8 and 16 rectangular channels in hydraulic diameters of (0.969 and 0.846) mm, respectively. The effective lengths of the test section are 200 mm with mass fluxes of (50, 100, and 200) kg/m^2s; and 500 mm with mass fluxes of (300 and 500) kg/m^2s. The local heat transfer coefficients are calculated from the measurements of average heat flux on the test section and the local tube wall temperatures. Twenty T-type thermocouples were equispaced at fixed 5 points along the test sections length, on both the top and bottom sides, to measure the outside tube wall temperature.

Four high-accuracy resistance temperature detectors were attached at the inlet and outlet of refrigerant side and cooling waterside in the test section. The energy balance in the test section is verified by initial testing with the liquid water–water in the test section; the heat balance between the outside fluid and inside fluid was always less than ±3 %. Table 1 shows the dimensions of the two types of aluminum multiport tube.

The vapor quality at the inlet of the test section was defined from the voltage and current of the DC power supply unit in the preheater, which can be determined as follows:

$$x_{inlet} = \frac{1}{h_{fg}}\left[\frac{Q_{pre-heater}}{m_{ref}} - C_p\left(T_{sat} - T_{p,inlet}\right)\right] \quad (1)$$

where, Q_{pre} is the heating power applied in the pre-heater by the DC power supply. The saturation temperature T_{sat} was computed from the measured saturation pressure at the inlet of the test section. The average heat flux in the test section was determined as:

$$q = \frac{m_{water} c_{p,water} \Delta T_{water}}{A_{external}} \tag{2}$$

where, m_{water} is the cooling water mass flow rate, T_{water} is the temperature difference between the inlet and outlet of the cooling water side, and $A_{external}$ is the external surface area of the test section tube. The cooling water mass flow rate in all cases is fixed at 1 kg/min to maintain the water flow distribution on the annulus side. Two test section lengths were used with different mass flux conditions to control the vapor quality difference in the test section at approximately (0.011–0.16). Therefore, it can be assumed that the variation in vapor quality on the test section is linear over the length of the test section. The following equation calculates the vapor quality in the test section:

$$x = x_{inlet} - \frac{m_{water} c_{p,water} \Delta T_{water}}{2 m_{ref} h_{fg}} \tag{3}$$

The Fourier steady-state one-dimensional heat conduction calculated the inner wall temperatures of the tube through the tube wall:

$$T_{w,i} = T_{w,o} + \frac{q\delta}{k_{aluminum}} \tag{4}$$

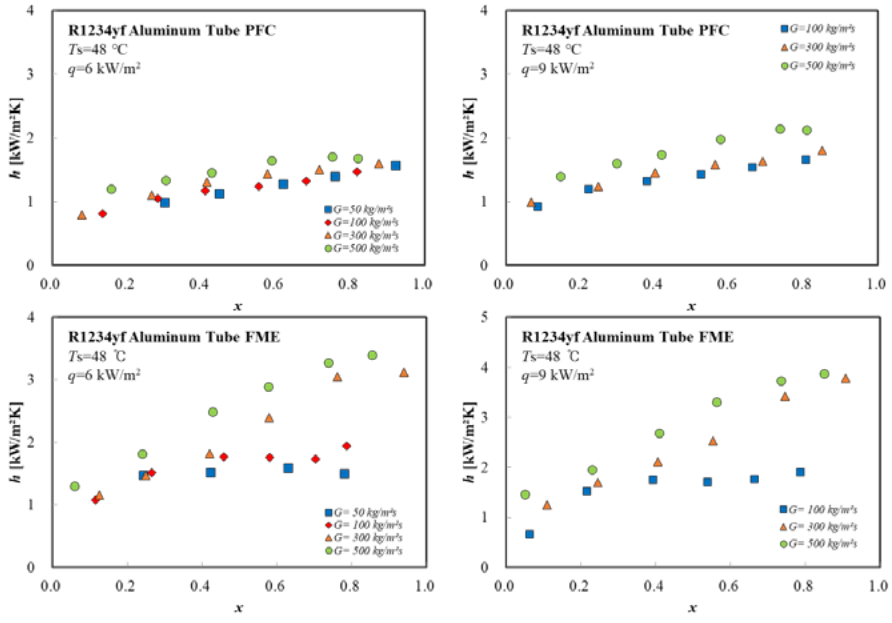

Figure 3 Effect of mass flux on the heat transfer coefficient

where, k is the thermal conductivity of the aluminum. Through all the data reduction processing, the different temperature between inside and outside wall tubes was less than 0.025 K.

The average condensation heat transfer coefficient is obtained as:

$$h = \frac{A_{\text{external}}}{A_{\text{internal}}} \frac{q}{\left(T_{sat} - T_{w,i}\right)} \tag{5}$$

3. Result and discussion

Condensation heat transfer of R1234yf inside the aluminum multiport tubes is carried out at fixed 48 °C, mass flux ranging (50 to 500) kg/m^{2}s, and heat flux ranging (3 to 12) kW/m^2. The vapor quality at the inlet of the test section varied from (0.9 to 0.1), and approximately (0.011–0.16) vapor quality change in the test section, depending on the mass flux and heat flux conditions. The relations of vapor quality, mass flux, and heat flux with the condensation heat transfer coefficient of refrigerant were discussed.

Figure 3 shows the heat transfer coefficient influence of mass flux with both test tubes. The increase of vapor quality and mass flux leads to the rise of the condensation heat transfer coefficient, because of the forced convection mechanism. The effect of vapor quality on the condensation heat transfer coefficient can be explained by flow models. The flow models proposed by Coleman and Garimella [7] show bubbly flow and plug flow in the case of low vapor quality, and annular flow for high vapor quality. Liquid film during condensation is thick in the bubbly and plug flow, and thin in the annular flow. In addition, the effect of liquid film thermal resistance predominates in the condensation heat transfer coefficient, where the heat transfer coefficient increases as the thickness of the liquid film decreases. This effect is more evident in high mass flux and high vapor quality, but weaker in low mass flux and vapor quality.

At low mass fluxes, the results showed that the data of (50, 100, and 150) kg/m^{2}s mass fluxes almost overlap with those figures of (3–12) kW/m^2 of heat flux. Jige et al. [8], Matkovic et al. [9], and Del Col et al. [10] reported that the heat transfer coefficients of (100 and 200) kg/m^{2}s mass velocity were almost similar, which may be explained by the decrease in the shear stress at a certain point and increase at the interface, so that the effect of surface tension in the rectangular channels dominates. The explanation is similar to the theoretical analysis reported by Bortolin et al. [11]. Kim & Shin [12] considered the condensation heat transfer of R134a inside mini channel tubes, and concluded that the low mass flux regime had a weak effect on the heat transfer coefficient. However, at high mass fluxes, the surface tension does not dominate, because the vapor shear stress is much stronger.

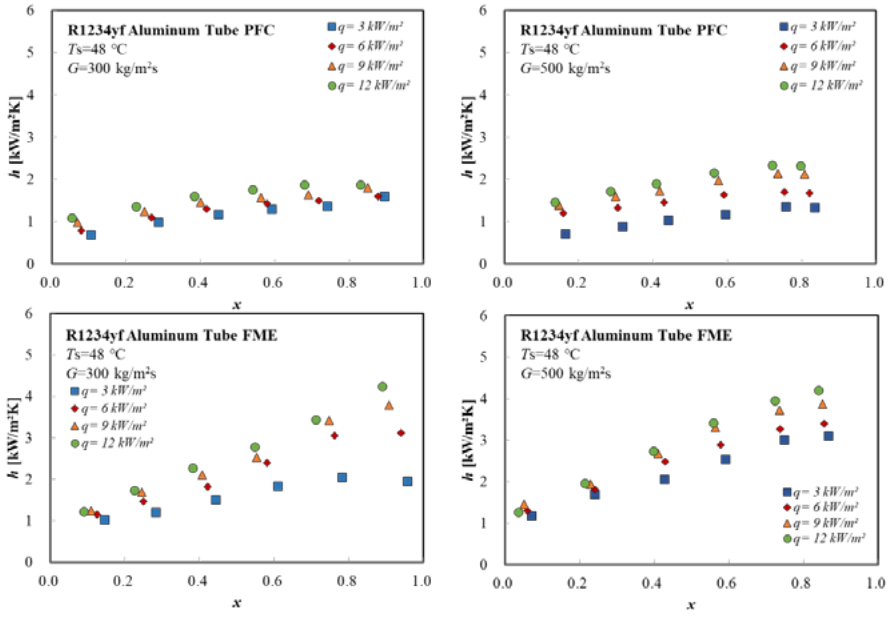

Figure 4 Effect of heat flux on the heat transfer coefficient

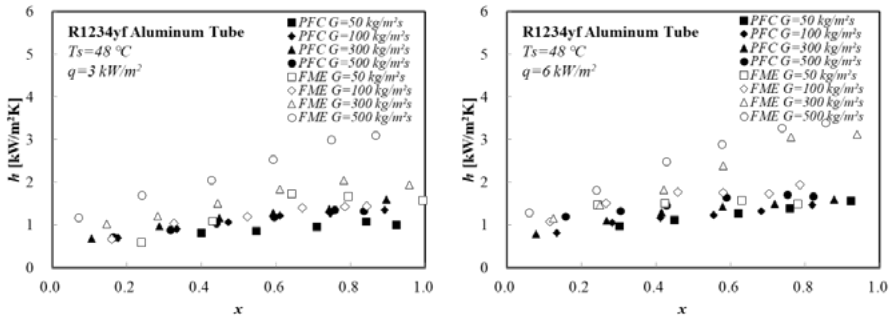

Figure 5 Comparison of the heat transfer coefficient between two types of multiport tubes

Figure 4 shows the effects of heat flux on the measured condensation heat transfer coefficient. The results show that the condensation heat transfer coefficients increase with increasing heat flux. In the present experimental study, the average heat flux approximated uniform heat flux on the test section length, due to keeping 1 kg/min past the cooling water mass flow rate for all test cases. Zhang et al. [13], Sakamatapan et al. [14], and Yan and Lin [15] also reported similar behavior of the heat flux effect. They concluded that the main reasons are the interface temperature between the liquid film and vapor core, and even the effects of the change of momentum of the liquid and vapor phases on the change of heat flux.

Figure 5 compares the condensation heat transfer coefficients of the two types of multiport tube. These show that the heat transfer coefficients of FME are higher than those of PFC at similar test conditions. For conventional round tubes, the heat transfer coefficient increases with decrease of hydraulic diameter of the tubes, but many researchers, such as Pham et al. [16], Kaew-On et al. [17], and Nema et al. [18], suggest that the heat transfer behavior inside multiport rectangular channel tubes is quite different. In the present study, the experimental data show that the heat transfer coefficient is not an observed effect of the hydraulic diameter. However, the widths and aspect ratio of each rectangular channel influence the heat transfer coefficients. Table 1 shows the details of the tube dimension. The condensation heat transfer coefficients of refrigerant inside a rectangular tube are dependent on the surface tension and the shear stress interface of vapor and liquid phases. The condensed liquid film at the top and bottom of the channel is thinner as the width of the rectangular channel increases. These results show that due to surface tension, the condensed liquid drainage to the edges generated a thin liquid film.

4. Conclusions

The condensation heat transfer coefficients of R1234yf inside two types of multiport minichannel tubes were investigated experimentally over a large range of test conditions. The installation and data reduction were described and defined; the results were analyzed and discussed. The condensation heat transfer coefficient increases with increasing vapor quality, mass flux, and heat flux. The effects of cross-section geometry on the condensation heat transfer characteristic are dependent on the surface tension and vapor shear stress.

Energy saving pre-cooling pattern search of an inverter air conditioner using a deep reinforcement learning algorithm

Myung Sup YOON[a,*], Won Sik YOON[a]

[a]Energy Technology Center, Korea Testing Laboratory, 87 Digital-ro 26-gil, Guro-gu, Seoul, 08389, Republic of Korea

Abstract

In this study, we experiment with the energy saving pre-cooling operation of an inverter air conditioner using a deep reinforcement learning algorithm under a fixed going out time duration. An air conditioner with a rated cooling capacity of 6500 W is used. An indoor building load of 4500 W sensible heat and an outdoor temperature of 35°C are continuously applied throughout the study. During the going out time, three remote control temperature options (21, 26, 31°C) are given for simplicity, and a remote controlling pattern (set temperature sequences) that minimizes power consumption upon arrival home while satisfying the arrival target temperature condition is searched using deep reinforcement learning. For a given going out time duration, the power consumptions of the temperature operation pattern found by the computer deep reinforcement learning algorithm and a human are compared. Although the artificial intelligence searches for the power consumption operation pattern over a long period (7 ~ 9 days), depending on the learning environment, it identifies a more accurate and more energy saving and an unexpected operation pattern than by human analysis.

Keywords: Air conditioner; Deep reinforcement learning; Pre-cooling; AI; Energy saving; Smart HVAC; Set temperature sequences

1. Introduction

Due to the development of artificial intelligence (AI) technology, many of us will soon live in more comfortable and energy efficient smart homes, with pre-cooling/pre-heating before returning home that incorporates data from smart vehicles. With the development of high efficiency inverter air conditioners at part-load condition, more energy can be saved by operating an air conditioner gradually before arrival than to operate an air conditioner suddenly on arrival if certain conditions are met [1]. Studies on building energy prediction, management, and heating, ventilation, and air conditioning (HVAC) system control using deep learning technology have been actively conducted [2–20]. However, research that applies deep learning technology to household air conditioners is scarce. Some AI platform companies such as Google Nest and global electronics companies are developing deep learning technology for household air conditioning, but they tend not to publicly release their research findings. Precision temperature control for an air conditioner and optimal operation point search of air conditioner components for maximum energy efficiency (EER) using a deep reinforcement learning algorithm have been conducted in previous research [21–22]. However, there is no air conditioner deep learning research for energy saving pre-cooling operation during the time at which all household occupants are away from home.

Figure 1 shows a conceptual diagram of a comfortable and energy saving HVAC pre-cooling or pre-heating system in conjunction with location information of occupants. The arrival time varies depending on the means of transportation and traffic conditions of the day. Pre-cooling or pre-heating should also vary according to the arrival time of family members, outdoor atmospheric conditions, and the internal building loads of the day. If

sufficient data exist for these variables, or a well-defined environment exists, it seems that optimal operation is possible using a deep learning algorithm.

2. Experimental Approach

2.1. Problem setup

In this study, in order to minimize the AI learning time, a deep reinforcement learning algorithm is applied under certain assumptions in a well-defined test chamber environment [23–24]. First, cases where the fixed going out time is 2.5 and 3.5 hours are calculated. Second, the building load (q_{build}) during non-occupancy is assumed to be constant at 4500 W of constant sensible heat, and the outdoor side temperature is assumed to be constant at 35°C. Third, it is assumed that there is no latent heat consideration. Fourth, in order to minimize learning obstacles in the dead band zone, which is a feature of the product control, only three signals of set temperature (21, 26, 31°C) are considered. Fifth, the initial temperature (T_0) of the indoor room temperature (T_{in}) in most of the learning episodes is near 26°C. Sixth, temperature variations are considered only when a single agent (actor) exists as one resident (Fig. 2(a)). Seventh, linear distance movement is assumed in all episodes during learning (Fig. 2(b)).

Figure 2(a) shows the temperature change of a room (dashed lines) over the going out time duration ($t_2 - t_1$). Three set temperatures (T_{set}) of the remote controller (21, 26, 31°C) can be given in various sequences over the going out duration at about every 2 minutes. If T_{set} is fixed as 26°C throughout the problem, then the indoor room temperature will ideally be horizontal. To simplify the problem, two cases of the going out time duration (2.5 h and 3.5 h) are scrutinized. Figure 2(b) shows the remaining distance to the destination over time. Linear approximation for the simplicity of the problem is assumed regardless of the various paths according to the traffic and traffic conditions (Fig. 1). A non-linear remaining distance (Ls(t)) pattern also can be considered if there is time-dependent GPS information of multiple agents (family members). Here, only linear profiles are assumed, and $t_{arrival(1)}$ corresponds to 2.5 h and $t_{arrival(2)}$ to 3.5 h, respectively.

The purpose of this study is to find T_{set} sequences over the going out time duration to minimize energy consumption (kWh) using a deep reinforcement algorithm. Of course, T_{in} should be in the target temperature (24 ~ 28°C) on the arrival time (t_2), regardless of the temperature variations during the going out time.

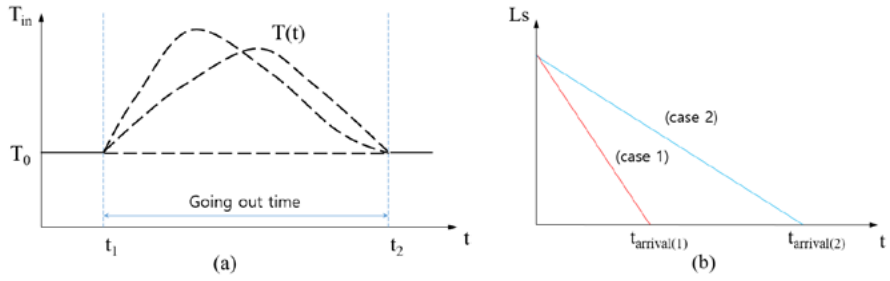

Fig. 2. Variations of (a) indoor temperature (T_{in}) and (b) remaining distance (Ls)

2.2. Air conditioner selection

Air conditioners differ in precision control from model to model and from brand to brand [1]. Minimized dead band zone and precision controlled products are good for reinforcement learning (RL), but unfortunately, the latest models are locked from obtaining IR signals for controlling remote signals using Arduino [21]. Therefore, the old inverter products of Fig. 3 and Table 1 are used throughout this study.

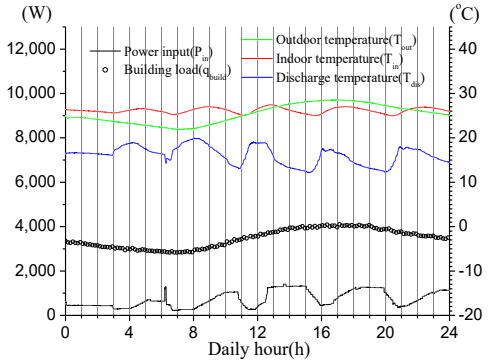

Fig. 3. Operating characteristics of the air conditioner under test (reproduced from Yoon et al. [1, 21])

Table 1. Specifications of test air-conditioner (reproduced from Yoon et al. [21])

Contents	Name plate values
Air-conditioner type	Split wall mount
Compressor type	Inverter type
Electricity	Single phase, 220 V, 60 Hz
Rated cooling capacity	6500 W
Rated power input	1750 W
Max. power input	2900 W
Min. power input	500 W
Refrigerant	R410a, 2 kg

3. Methodology

3.1. Artificial neural network (ANN) model

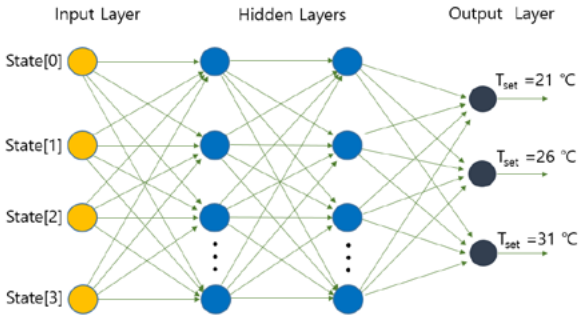

Fig. 4. ANN model for the inverter air conditioner pre-cooling

For the deep reinforcement learning (RL) algorithm, we use one input layer of four nodes, two hidden layers of 24 nodes each, and one output layer of three nodes. The input layer consists of four elements of state [(T_{in}(t) –26), dT_{in}/dt, Pws(t), t]. Each element represents indoor temperature (T_{in}), indoor temperature derivative (dT_{in}/dt), and cumulative power consumption (Pws(t)) at time t, and time t. Here, Pws is same as the Pwh divided by 3600 seconds (Pws = Pwh / 3600). If the movement change due to traffic is non-linear, the above state variable t can be changed into the distance state variable of Ls(t), or it can be replaced with x(t) and y(t), that is, GPS coordination information.

3.2. Reward strategy

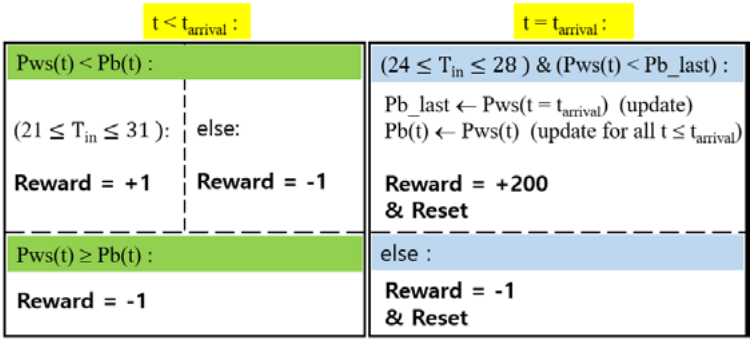

Fig. 5. Regions for the rewards

Figure 5 shows the reward strategy for this problem set-up. Pws(t) is the cumulative power consumption [Ws] measured at each time step, Pb(t) is the cumulative power consumption as a baseline at time t, and Pb_last is the baseline cumulative power consumption at the last time step. If the indoor room temperature (T_{in}) satisfies the target temperature (24–28°C) at the arrival and the Pb($t_{arrival}$) records the minimum power consumption, then a big reward (+200) is given and Pb(t) and Pb_last are updated as new data in this episode, that is, baseline information is updated as the minimum power consumption case. In the first episode (episode = 0), Pb_last starts with 1.e+25, and Pb(t) starts with null values. Before arrival ($t<t_{arrival}$), the target temperature is looser as (21–31°C) under the Pws(t) < Pb(t) condition at each time step, and reward is 1 if satisfied. The reward +1 region induces an air conditioner operation pattern that consumes less power than the previous episode in each time step and consequently induces the reduced cumulative power consumption at the last time of arrival. In other regions, except for the reward +200 and +1 regions, –1 reward is given. Every time, steps have real time progresses according to the linear movement of Fig. 2(b).

3.3. Deep reinforcement learning algorithm coding

The problem definition is:

- State: [(T_{in}–26), dT_{in}/dt, Pws(t), t]
- Action: [21°C, 26°C, 31°C]
- Reward: +200 pt, when T_{in} in the range of (26 ± 2.0)°C and Pws is reduced than ever existing minimum power consumption value (Pb_last) at the arrival time
- Reward: +1 pt, when T_{in} in the range of (26 ± 5.0)°C and Pws(t) is reduced than Pb(t)
- Penalty: –1 pt, in other regions except positive reward regions
- Each episode ending and reset: when t = $t_{arrival}$

The coding flow is shown in Fig. 6. The basic algorithm is the same as established deep Q-learning, with experience replay [25], but it differs by the addition of the reward and reset condition according to Figs. 5 and 6. In Fig. 6, time progresses as real time (t = t + dt) until t = $t_{arrival}$. The initializing condition of T_{in} = (26 ± 0.05)°C is specially applied only to Section 4.4 to compare with the Section 4.3 case of non-exact temperature initializing (fixed time initializing case). The simulation time end is judged by human sense when it seems impossible to achieve more energy saving even with enough repetitive episode training.

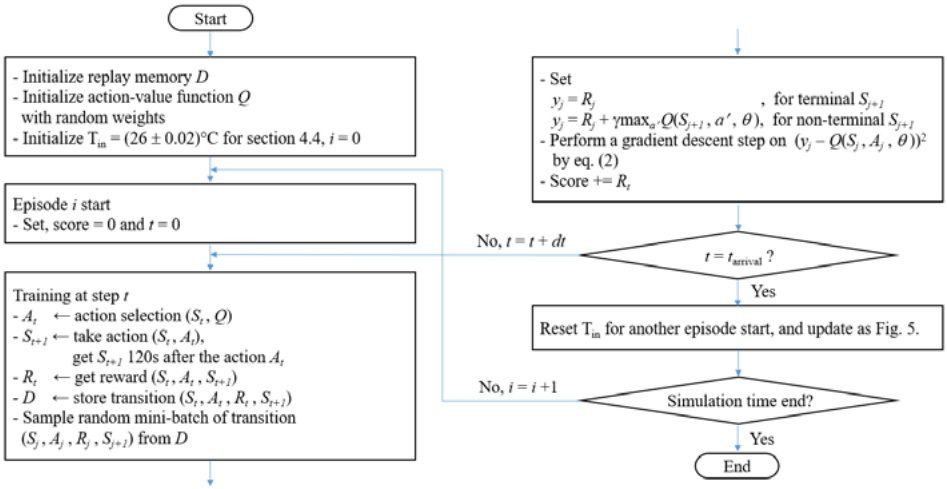

Fig. 6. Deep reinforcement learning coding flow

4. Experiments and results

4.1. Without machine learning (human operation)

Before operation using RL, the amount of minimum power consumption is checked during 2.5 hours and 3.5 hours of going out time by a human. Half an hour is initialized to a set temperature of 26°C before going out at 2.5 hours. Each case of Figs. 7(a), (b), and (c) shows a slightly different T_{in} initializing graph even though the T_{set} temperatures are the same at 26°C. This is generally due to the rough control behavior of air conditioning products, including dead band control. Table 2 summarizes the manual control method. In Fig. 7(b), in order to bring the temperature at t = 3.0 to the target temperature of exactly 28°C, the target range is (24–28°C), T_{set} = 31°C is extended to t = 1.83 h as opposed to 1.33 h in the case of Fig. 7(a). As a result, in Fig. 7(b), the power consumption is reduced to Pwh = 2930 Wh rather than Pwh = 3441 Wh in Fig. 7(a). In Fig. 7(c), instead of lowering the temperature by T_{set} = 26, it is lowered to T_{set} = 21°C. But there is no difference in how the product actually cools due to the (T_{set} –T_{in}) difference detection control.

Figure 8 shows the manual control pattern when the going out time is 3.5 hours. An hour is initialized to a set temperature of 26°C before going out. In Fig. 8(c), T_{set} = 26°C is continuously maintained and changes to 31°C at t = 4.1 h, so that the temperature is near T_{in} = 28°C at the arrival point. Figure 8(c) shows a relatively large electric consumption of 4761 Wh due to poor air conditioner operation.

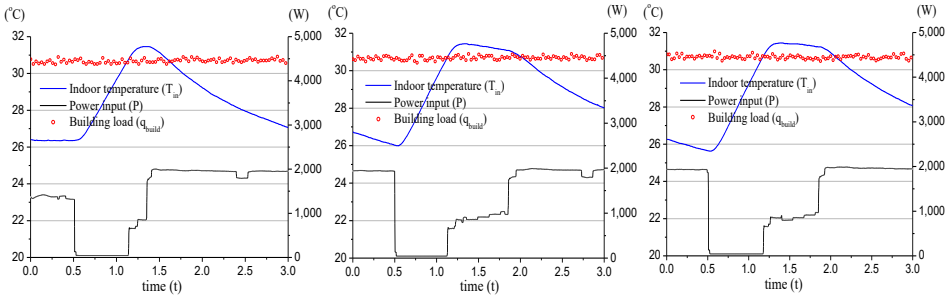

Fig. 7. Human operation during 2.5 h (power accumulation starting at t = 0.5 h): (a) Pwh = 3441, (b) Pwh = 2930, (c) Pwh = 2951

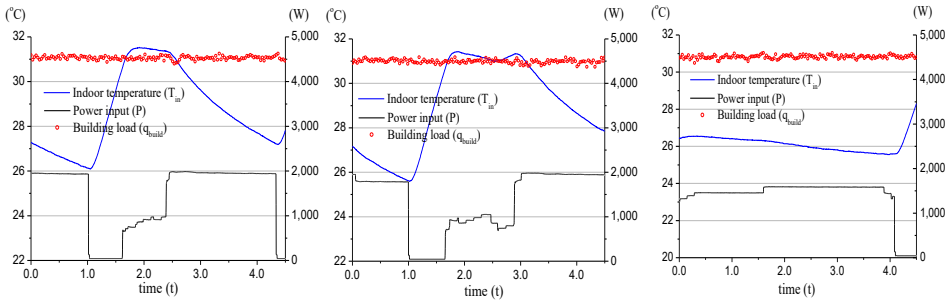

Fig. 8. Human operation during 3.5 h (power accumulation starting at t = 1.0 h): (a) Pwh = 4520, (b) Pwh = 4318, (c) Pwh = 4761

Table 2. Human operation case results

Going out time	Operation case	Operation method	Pwh during going out
2.5 h (Fig. 7)	Fig. 7(a)	26°C(t=0), 31°C(t=0.5h), 26°C(t=1.33h)	3441 Wh
	Fig. 7(b)	26°C(t=0), 31°C(t=0.5h), 26°C(t=1.83h)	2930 Wh
	Fig. 7(c)	26°C(t=0), 31°C(t=0.5h), 21°C(t=1.83h)	2951 Wh
3.5 h (Fig. 8)	Fig. 8(a)	26°C(t=0), 31°C(t=1.0h), 26°C(t=2.5h) , 31°C(t=4.3h)	4520 Wh
	Fig. 8(b)	26°C(t=0), 31°C(t=1.0h), 26°C(t=3.0h)	4318 Wh (4437 Wh)
	Fig. 8(c)	26°C(t=0), 31°C(t=4.1h)	4761 Wh

In the case of Fig. 8(b), due to the manual operation error of the initial temperature adjustment, the initial temperature at the beginning of the power measurement (t =1.0) starts at 25.6°C, which is advantageous for calculating the accumulated power consumption. The time of 430 seconds, which is 26.0°C after t = 1.0, is compensated for the power consumption under the part-load operation assumption (see the power consumption around t = 2.0 in Fig. 8(b)) of 1 kW (430 × 1000 / 3600 = 119 Wh). The 4437 (= 4318 + 119) Wh in the parentheses is a reasonably minimally compensated value for the human operation error.

4.2. Deep reinforcement learning (2.5 hours going out)

The air conditioner operation of 2.5 hours' going out time is solved by RL. It is operated throughout 7.5 days of 59 episodes (Figs. 9 and 10). When we see the entire results graphs (Fig. 9) of 7.5 days, it is difficult to see what the meaningful results are. Therefore, the scores and the cumulative power consumption at each episode are taken by a quick glance from Fig. 10. The red dots in Fig. 10 refer to the results where the episode acquired a +200 reward at the arrival time. The red dots of power consumption decrease until episode 42 and no more episode cases, which gains a +200 reward, appear until the last episode (episode 59).

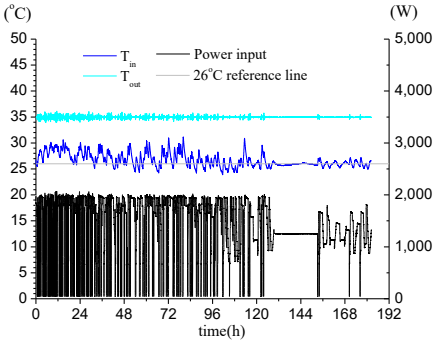

Fig. 9. Total of 7.5 days' deep reinforcement learning for the 2.5 h going out problem

Among the red dot episodes, a representative of three episodes cases (episodes 6, 34, 42) are carefully analyzed (Fig. 11). Commonly, an episode is forcibly stabilized by the 26°C remote control setting during the initial 0.5 hours. However, in the case of Fig. 11(a), the initial value of 26°C is not stably reflected because 0.5 hours are insufficient to stabilize in some cases. In Fig. 12(a), the action outputs for the 21, 26, and 31°C settings are even. In the case of episode 34 (Fig. 12(b)), however, most of the action output maintains the set temperature of 21°C or 26°C, with the exception of the 31°C action output at the 51st time step. In episode 42 (Fig. 12(c)), only the remote control signal of 26°C is continuously maintained. This means that it is more effective to keep the air conditioner at the same initial temperature for a relatively short going out time, which is 2.5 hours in this case. When we compare the human operation case of Table 2, episode 42 of deep reinforcement learning finds smaller power consumption (Pwh = 2766 Wh) than the human (Pwh = 2930 Wh). A human is prone to missing the idea of maintaining the same temperature, but AI finds the answer exactly.

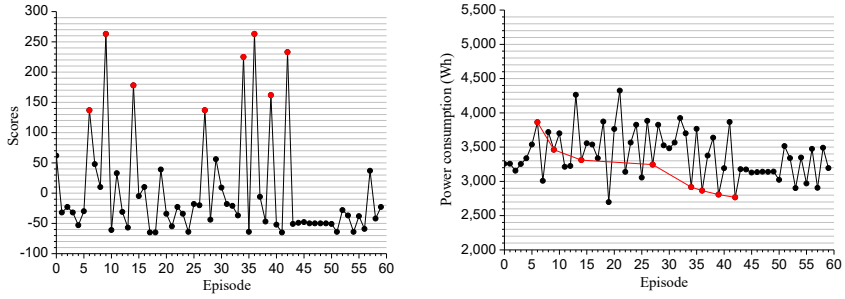

Fig. 10. Variations of (a) scores and (b) power consumption at each episode for the 2.5 h going out problem

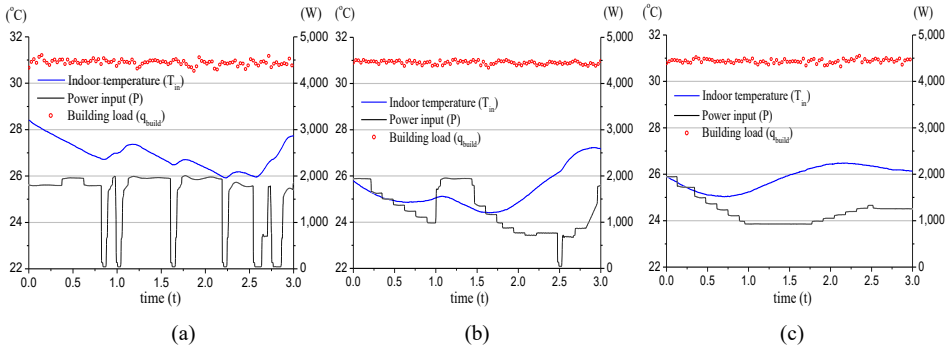

Fig. 11. The RL operation during 2.5 h (power accumulation starting at t = 0.5 h): (a) episode 6, (b) episode 34, (c) episode 42

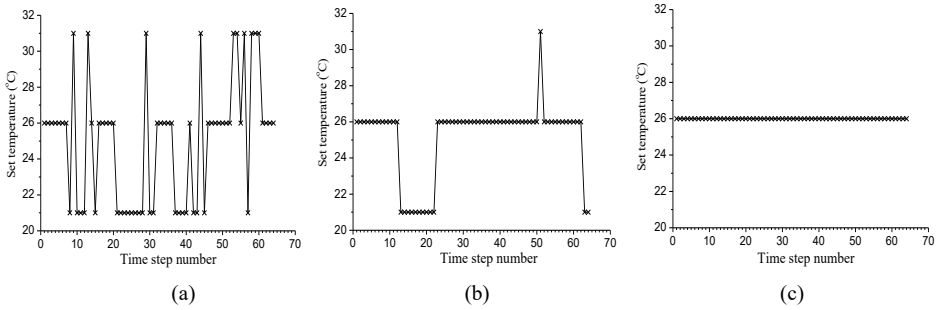

Fig. 12. Set temperature sequences for: (a) episode 6, (b) episode 34, (c) episode 42

4.3. Deep reinforcement learning (3.5 hours going out)

The air conditioner operation of 3.5 hours' going out time is solved by RL. It is operated throughout nine days of 47 episodes (average 0.19 days per one episode, that is, one hour initializing and 3.5 hours training). Because the going out time is longer than the 2.5 hours' going out case, it takes more training time (nine days) than Section 4.2 described (7.5 days of 59 episodes, average 0.127 day per one episode, that is, 30 minutes' initializing and 2.5 hours' training).

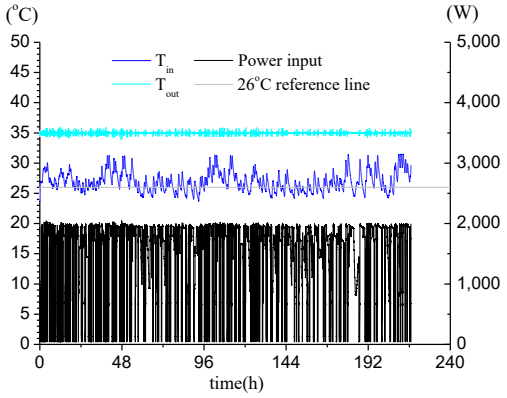

Fig. 13. Total of nine days' deep reinforcement learning for the 3.5 h going out problem

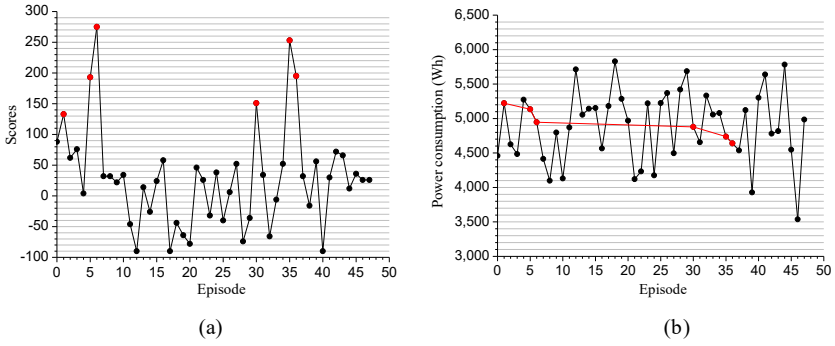

Fig. 14. Variations of (a) scores and (b) power consumption at each episode for the 3.5 h going out problem

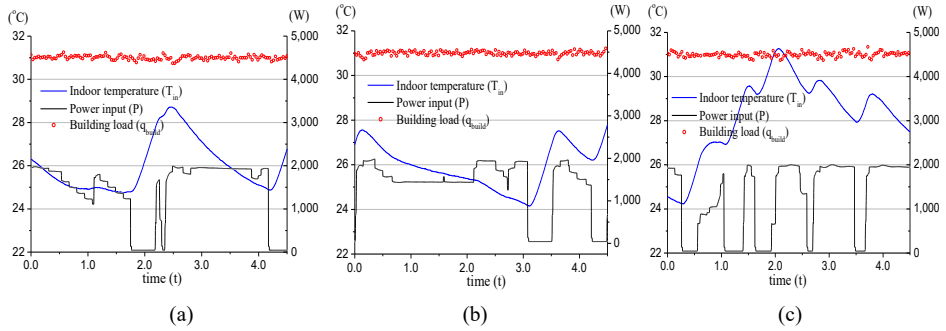

Fig. 15. The RL operation during 3.5 h (power accumulation starting at t = 1.0 h): (a) episode 35, (b) episode 36, (c) episode 42

The RL finds red dots, which satisfies minimized power consumption and in the range of target temperature on the arrival, at episodes 1, 5, 6, 30, 35, and 36 until episode 47. Figures 15 and 16 show the power consumption and remote control signal analysis at episodes 35 and 36 of the energy saving red spot and at episode 42, where there is no energy saving effect. Episodes 35, 36, and 42 record the power consumption of 4739, 4639, and 4780 Wh, respectively. Compared with the results of human analysis in Fig. 8 and Table 2, the cases of human operation (4437 or 4520 Wh) save more energy than the result of RL (4639 Wh). Considering the time it took (9 days), the RL results look comparatively poor.

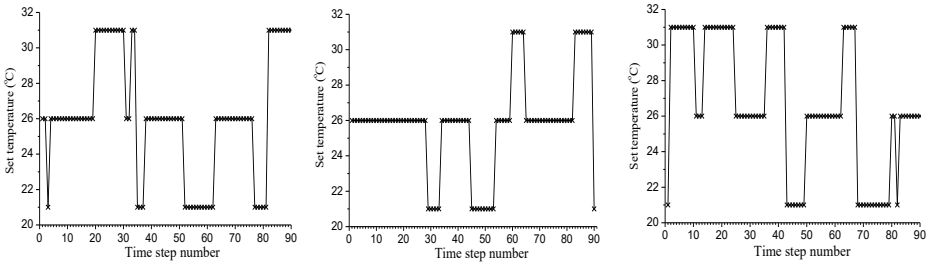

Fig. 16. Set temperature sequences for: (a) episode 6, (b) episode 34, (c) episode 42 (no red dot position of Fig. 14)

4.4. Deep reinforcement learning (3.5 hours going out) with accurate initial condition (T_0 =26 ℃)

The former RL work of Section 4.3 (3.5 hours going out) does not fare well compared with the RL case of Section 4.2 when the going out time is 2.5 hours. The reason for the difference can be guessed by comparing Figs. 11 and 15. In Fig. 11, as the episode progresses, it converges to the 26°C remote control setting value at the arrival time, and in the next episode the learning starts stably at the initial temperature around 26°C. However, in Figs. 15(b) and (c), learning starts slightly away from the initial value of 26°C. The importance of a consistent initial value for RL is well known in the grid world problem or in Atari games [25–26].

With this in mind, 3.5 hours' going out problem is re-solved by modifying the program to start the RL in each episode when the indoor room temperature (T_{in}) is within (26 ± 0.05)°C. If the initial value is under 26°C, then the 31°C remote signal is sent. In the opposite case, a 21°C remote signal is transmitted before starting each episode of learning. The RL is operated fully throughout seven days of 39 episodes, as in Fig. 17.

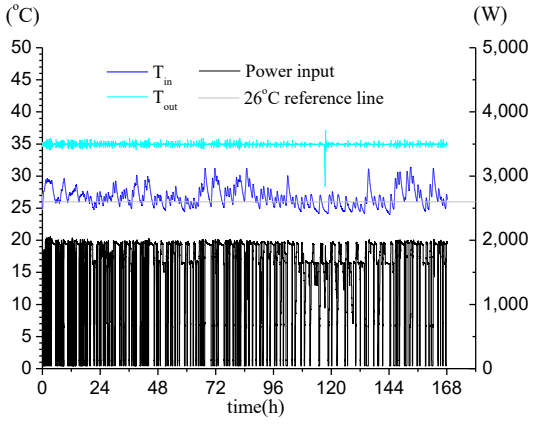

Fig. 17. Total of seven days' deep reinforcement learning for the 3.5 h going out problem

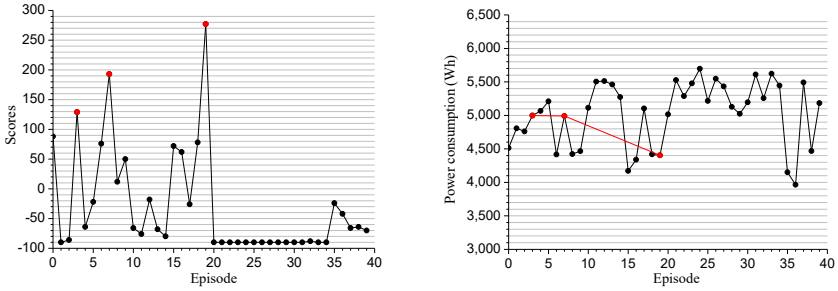

Fig. 18. Variations of (a) scores and (b) power consumption at each episode for the 3.5 h going out problem with accurate initial condition of T_{in} = 26°C

Although learning is performed for seven days, the meaningful RL practically ends within 3.6 days of 19 episodes, as in Fig. 18. At episodes 3, 7, and 19, a reward of +200 (Fig. 5) is recorded, and the power consumption is 4998, 4991, and 4405 Wh, respectively. When compared with the former case of Fig. 14, Fig. 18 converges fast (episode 19) and finds less power consumption (4405 Wh) than the Fig. 14 case (episode 36, 4639 Wh). In Fig. 18(a), it is not easy to get even a smaller reward of +1 (Fig. 5) after episode 19, since the results of episode 19 seem to be optimal.

Compared with the manual result of 4437 Wh in Table 2 and Fig. 8(b), the RL result of 4405 Wh in episode 19 saves more energy. What is more noticeable is that unlike the common sense used in the air conditioner operation method in the operation case of Fig. 8(b) in Table 2 (minimize operation of the air conditioner when going out and then drive again before arrival), RL finds an energy saving method that cannot be found by a human (Fig. 19(c)). Conversely, by comparing the results of Fig. 19(c) and Fig. 8(b), the strategy of RL is analyzed from a human point of view. In Fig. 8(b), after the room temperature reaches 31°C or higher at t = 1.7 h, the air conditioner runs with a part-load of 1 kW to satisfy the 31°C set temperature. After t = 3.0 h, in order to satisfy the final target temperature 28°C (the target range is 24–28°C), the temperature starts to drop by full-load operation. On the other hand, in Fig. 19(c), since the temperature must drop after reaching 31°C anyway in some moment, the temperature drops immediately without delay at the point of 31°C. In addition, energy saving is achieved by aiming for the effect of turning off the air conditioner in (1.8 ~ 2.0) hours and (3.25 ~ 3.5) hours.

In summary, this kind of RL approach is surely useful to find an energy saving operation method when we run an air conditioner. However, we also need more studies about when such an algorithm should be stopped, because in this problem there is no determined answer like the grid world problem or the precision temperature control problem. The grid world problem [26] has a clear goal of reaching the target position, and the air conditioner precision temperature control problem [21] also has an obvious target range of temperature. However, this study has no deterministic minimum energy consumption value. If we have found an energy saving operation method such as in this study, we need to think carefully about how to verify that this minimum solution is a real optimum.

5. Conclusion

Reinforcement learning (RL) using a DQN (Deep Q-learning Network) method is applied to a household inverter air conditioner energy saving operation pattern search while occupants are out. Four state variables of [(T_{in}(t) −26), dT_{in}/dt, Pws(t), t] and three actions of 21, 26, 31°C remote control are used in the DQN model. To simplify the problem, some assumptions are made. The indoor building load (q_{build}) and outdoor temperature (T_{out}) are set to be constant at 4500 W and 35°C. Then, assuming that the moving path of the mover (person going out) is linear, only the going out time ($t_{arrival}$) is involved in the problem. For the two going out times of 2.5 and 3.5 hours, the case of manual operation by a human and the case of artificial intelligence operation using RL are compared. The objective of this problem setup is to find remote controller signal sequences during the going out time that save electricity and satisfy the target temperature (24 ~ 28°C) on arrival. In applying RL, it is important to maintain a fixed initial room temperature (T_0 = 26° C) at each episode for fast and stabilized RL results. For the 3.5 hours' going out time problem, two cases of initial condition treatments are given: i) fixed stabilization time as one hour regardless of the start temperature, and ii) accurate initial temperature condition. The latter identifies the energy saving pattern twice as fast as the former, and the result is also better (less energy consumption).

Compared to manual operation based on human judgement, RL finds an exact method that is easy for humans to miss. When the going out time is 2.5 hours, RL derives continuous operation of the air conditioner by fixing the remote controller temperature as 26°C. And when going out time is 3.5 hours, RL shows an operation strategy that induces longer periods of off-mode or part-load mode. In the future, this work can be expanded by merging non-linear movement information with multi-agents and more realistic environmental conditions.

[a] Institute of Low-Carbon Industrial Processes, German Aerospace Center, 03044 Cottbus, Germany

Abstract

This paper studies the part load behavior and capability of a high temperature heat pump that operates with the Brayton cycle. A novel concept of a high temperature heat pump which is currently under construction in Cottbus (Germany) is presented. It goes far beyond temperature levels of current high temperature heat pumps and will provide process heat at above 250 °C. The heat pump uses a closed Brayton cycle driven by axial turbomachinery and provides up to 200 kW of thermal energy. The thermal output can be adjusted by variation of compressor shaft speed, use of internal recuperation and additionally by variation of the fluid inventory. The latter allows operation of our prototype within a broad part load range down to 25 % of the nominal power at nearly constant efficiencies and output temperatures. Brayton cycle heat pumps can be adapted to a wide range of industrial processes and enable highly efficient thermal energy storage systems to balance grid fluctuations.

Keywords: high temperature heat pump; reverse Brayton cycle; fluid inventory control; process heat; electrification

1. Introduction

Industrial processes account for about 25 % of the primary energy used and 20 % of greenhouse gas emissions in the EU-28 countries. Two thirds of this energy are used to meet the process heat demand [1]. Together with space heating in domestic and industrial applications heating and cooling account for 51 % of the final energy consumption in Europe [2]. Current technology relies mainly on fossil fuels such as coal, natural gas and petroleum products [3]. In order to transition to a climate-neutral economy by 2050 which is the declared goal of the European Union [4] all these heat requirements must be met by net zero carbon technologies within 30 years. Heat pumps have been identified as a key technology towards this goal [5].

When using electricity from conventional fossil sources, power to heat technologies are only interesting if either highly efficient or in applications where combustion and emissions are undesired. Otherwise, the losses and the complexity of two conversions from fuel to electricity to heat can hardly be justified. Therefore, conventional heat pumps for low temperature applications such as domestic warm water and space heating are the only field where heat pumps find widespread use as of now [6].

Heat pumps are an important component in energy storage concepts and a possible power-on-demand tool in a more flexible energy system [5, 7, 8]. Efficient part load operation increases the grid balancing capability of heat pumps and is also a selling point for heat pumps in industrial processes where they compete with boilers. Variation of the working pressure is a common tool for changing the power level of a thermodynamic cycle process without having to adapt the geometry [9, 10]. In this paper, the part load capability of a closed loop Brayton cycle heat pump using fluid inventory control is analyzed.

Table 1 shows different technologies to electrify process heat demand. They all rely on renewable electricity which must be generated emission-free in order to reach a climate-neutral economy.

ρ	Density [kg/m³]

Using resistance heating one unit of electrical power is converted to the same amount of thermal energy. When burning substitute natural gas (SNG) or green hydrogen, conversion losses cannot be avoided [11]. Less than one kWh of process heat is generated per kWh of renewable electricity used. With heat pump technology, it is possible to convert one unit of renewable electricity into several units of usable thermal energy. In order to decarbonize process heat demand efficiently, heat requirements at low temperature levels should be met with emission-free technologies first. Process heat at high temperature levels needs a larger investment of renewable electricity per energy unit of heat which can be seen from the low conversion ratio in high temperature applications (see Table 1). Rehfeldt et al. [3] show that a relevant portion of process heat is required at temperature levels from 100 °C to 500 °C.

Heat pumps for sink temperatures of up to 160 °C are already available on the market [6]. The feasibility of heat pumps with sink temperatures as high as 280 °C [12] and 465 °C [7] has been proven utilizing currently available compressor technology. Zühlsdorf et al. [12] suggest a reverse Brayton or Rankine cycle for heat-pumps with very high sink temperatures (> 250 °C) and suggest that coefficients of performance (COP) of nearly two are possible. The German Aerospace Center's (DLR) Institute of Low-Carbon Industrial Processes is currently constructing prototype heat pumps with sink temperatures above 250 °C researching both Rankine and Brayton cycle technology. This paper focuses on the reverse Brayton cycle.

Table 1: Overview of power to heat technologies for process heat demand

Technology	Temperature level	Conversion ratio from net electrical power (COP for heat pumps)	Heating demand for industrial processes in Europe [3]**
Green hydrogen	only material limit	70% [11]	3726 PJ (> 500 °C)
Green gas (SNG)	only material limit	55% [11]	
Resistance heating	At least 850 °C [13]	<100 %	
Ultra-high temperature heat pump	250-500 °C	130-200 %* [7] [12]	2542 PJ (100 – 500 °C)
High temperature heat pump	100-160 °C	200-500 %* [6]	
Conventional heat pump	20-100 °C	300-600%* [6]	821 PJ (<100°C)

* Conversion ratio strongly depends on heat source temperature

** numbers for EU-28 plus Norway, Switzerland and Iceland in 2012, heat demand for space heating not included

2. Thermodynamics of high temperature heat pumps

The reversed Brayton and Rankine cycles are the thermodynamic models of the most commonly used closed cycle compression heat pumps. The Rankine process is preferred in refrigeration and heat pump processes in

the temperature range from -40 °C to 160 °C [6, 14]. It makes use of the phase transition of its working fluid (refrigerant) but is for this reason limited by the physical properties of the refrigerant. The Brayton-process has no phase transition and no temperature limit if air or noble gas is used as a working fluid.

2.1. Brayton process

The Brayton process models a gas turbine process. Operating it reversely (counterclockwise) turns it into a heat pump [14]. Isentropic compression ($T_1 \rightarrow T_2$) happens at a higher temperature level than isentropic expansion ($T_3 \rightarrow T_4$). Sensible heat q_h is provided during an isobaric state change between temperatures T_2 and T_3. The cycle absorbs sensible heat q_c from the environment in an isobaric state change from T_4 to T_1. T_1 is therefore limited to the temperature of the heat source T_0.

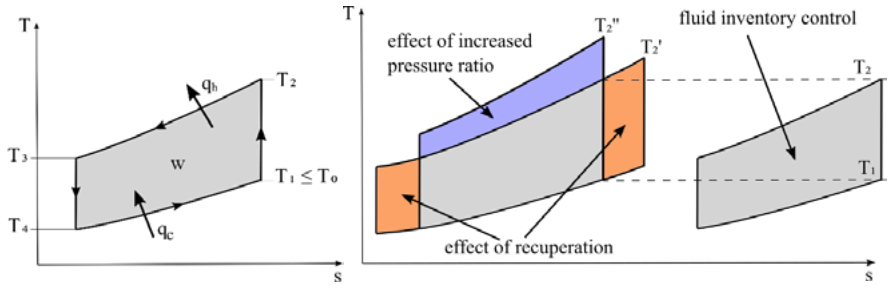

Figure 1: Temperature-entropy diagram of the Brayton cycle (left) and effect through variation of pressure ratio, recuperation or fluid inventory control adapted from [9, 14] (right)

The power turnover of a Brayton cycle can be changed in two ways. By changing the similarity parameters of the cycle and thereby the specific work w or by varying the amount of working fluid exercising the thermodynamic process. Changing the pressure ratio or introducing recuperation affects the temperature levels and the area inside the loop process which represents the specific work w (see Figure 1). With means of fluid inventory control, the process can be shifted sideward in the T-s diagram. When shifted to the right to lower pressure isobars the specific work and temperatures remain constant but the amount of working fluid is reduced. The total power as product of specific work and mass flow is also decreased. Fluid inventory control therefore enables part load operation at constant process temperatures.

2.2. Coefficient of performance

The coefficient of performance (COP) of heat pumps is defined as the ratio between heat delivered from the cycle to the heat sink q_h and work consumed in the thermodynamic cycle process w. The COP is the inverse of the thermal efficiency η_{th} of the equivalent thermal engine [14].

$$COP = \frac{q_h}{w} = \frac{1}{\eta_{th}} \tag{1}$$

For the ideal Brayton cycle with constant isentropic exponent κ the specific work w can be expressed as the difference between heat provided q_h and heat absorbed q_c and $\mathrm{COP_{Brayton}}$ is a sole function of the compressor inlet temperature T_1 and the compressor outlet temperature T_2 [14].

$$COP_{Brayton} = \frac{q_h}{w} = \frac{q_h}{q_h - q_c} = \frac{T_2}{T_2 - T_1} \tag{2}$$

High values of T_1 increase $\mathrm{COP_{Brayton}}$, but T_1 is limited to the temperature T_0 of the available heat source which can be ambient temperature or an exhaust air stream. It is visible from Eq. (2) that the COP

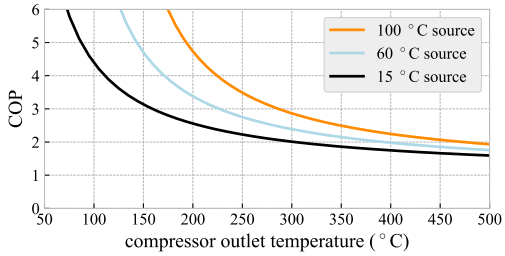

Figure 2: Brayton-cycle COP for high compressor outlet temperatures T_2

decreases with a rising heat sink temperature level and approaches the value of direct electrical heating $COP_{deh} = 1$ for very high T_2.

Figure 2 shows the COP levels of an ideal Brayton cycle heat pump as a function of T_2 for different heat source temperatures $T_0 = T_1$. It shows clearly that the use of exhaust streams is an important aspect when increasing the energy efficiency of industrial processes. The trend of low COP for high sink temperatures also holds for Carnot or Rankine cycle heat pumps [6] and explains why high temperature heat pumps tend to have a lower COP than heat pumps for domestic purpose and low temperatures (see Figure 2 and Table 1).

3. Technical specifications of the DLR-CoBra prototype

With the construction of the prototype 'CoBra' (**Co**ttbus **Bra**yton-cycle heat pump) the German Aerospace Center (DLR) aims at researching the key parameters of a high temperature heat pump with air as working fluid. The high temperature heat pump is designed to provide up to 200 kW of useful heat at temperature levels above 250 °C [15]. Figure 3 shows a model of the heat pump with its most important components. The heat pump has a conditioning unit to control the amount of working fluid in the system consisting of a buffer storage and vacuum pump. Dry air will be used for safety reasons in the research environment. It is non-toxic and has zero global warming potential unlike other common refrigerants [6]. The air in the heat pump must be dried in order to prevent condensation and icing of the turbine at low temperatures.

3.1. Working principle

The compressor increases the pressure and temperature of the working fluid which is the equivalent to state change 1 → 2 of the reverse Brayton cycle (see Figure 1). The high temperature heat exchanger (HTHE) transfers heat to the secondary process which is simulating the industrial process that requires heat. In the turbine, the working fluid is expanded 3 → 4 and power is recovered. The low temperature heat exchanger (LTHE) simulates the heat source which can be ambient air or an exhaust gas stream at higher temperatures. The inlet temperature of the cooling cycle is set to T_0=15 °C for all simulations. The low temperature secondary cycle can also be used for refrigeration at temperatures below 0 °C. The recuperator increases temperature lift at the cost of increased power consumption as shown in Figure 1. It allows to research different operation modes and temperature levels of the heat pump.

Red lines indicate high pressure, blue lines indicate low pressure. Both are fully independent of the ambient air pressure. By filling more working fluid from the buffer storage into the primary circuit the overall pressure level, mass flow and power can be increased. This technique is called fluid inventory control and can be used in closed cycle Brayton engines without combustion [9]. The air buffer also accounts for leakages of the working fluid in the turbomachines and ensures a constant pressure level for repeatable operating conditions.

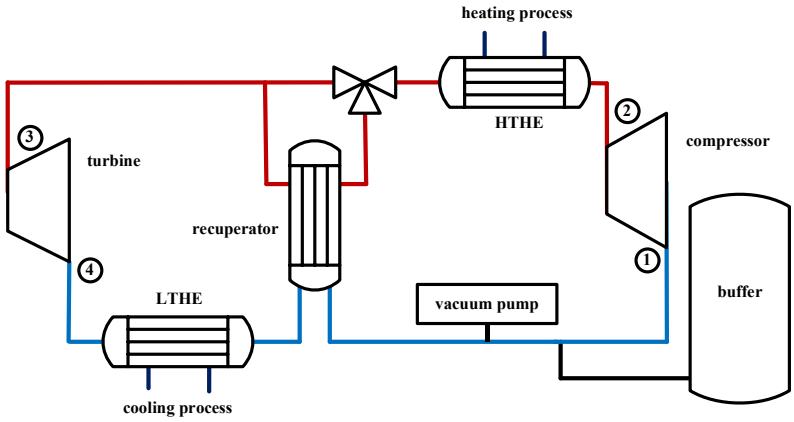

Figure 3: Simplified piping and instrumentation diagram of the Brayton cycle heat pump of the DLR Institute of Low-Carbon Industrial Processes in Cottbus (Germany)

3.2. Part load strategy

In order to meet a reduced heat demand below nominal load, the heat pump can adjust the thermal output with two different control strategies:

- Shaft speed control (SSC)
- Fluid inventory control (FIC)

Reducing the compressor shaft speed yields lower pressure and temperature ratios, lower mass flow and reduces the heat delivery of the heat pump. The compressor outlet temperature T_2 is reduced (see Figure 1). Using fluid inventory control the temperature levels of the thermodynamic process can be kept constant at different load levels. Pradeep Kumar et al. [9] have shown for a closed Brayton cycle gas turbine that fluid inventory control as a part load strategy allows much higher efficiencies than changing temperature levels or bypassing parts of the gas stream.

4. Methodology

In order to simulate the part load performance of the heat pump, a thermodynamic performance model of the system has been developed. The performance model accounts for the effects that occur during part load operation of a closed-cycle heat pump system. The following subsections outline the methods used for the analysis.

Simulations were mainly carried out on a system level. Detailed component simulations are not required to assess the system behavior and were left out of the present work. As the development of the heat pump and simulation tools progresses, higher-fidelity methods will be developed for more in-depth analyses.

4.1. Heat pump cycle simulation

The steady-state heat pump model on which the present analyses are based was created using the DLR in-house performance code GTlab-Performance developed by Becker et at. [16]. In the 0D thermodynamic cycle simulation, the main components of the heat pump are represented as modules, which in turn model the changes of thermodynamic state in the working medium.

For off-design calculations, a performance map of the compressor particularly developed for the CoBra prototype heat pump was used. The map is the result of detailed 3D CFD simulations of the flow in the compressor stages, which used the exact geometry of the blades. The turbine performance map was generated by scaling an existing turbine map of a gas turbine to match the turbine performance of the CoBra prototype based on 3D CFD simulation data computed with the preliminary turbine geometry.

In order to estimate the transferred heat of the shell-and-tube heat exchangers, an approach based on the Number of Transfer Units (NTU) method has been implemented using correlations from VDI Heat Atlas [17].

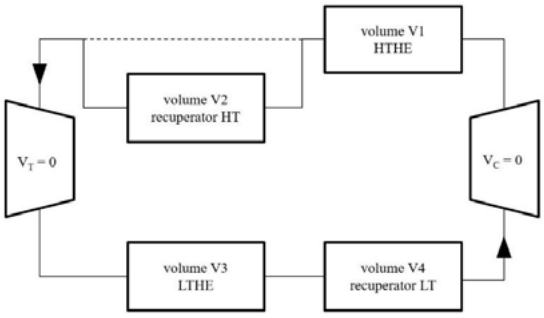

Figure 4: Heat pump component volumes for calculation of pressure levels

The heat transfer is calculated from the two inlet flows and the heat exchanger geometry and accounts for variations in similarity parameters such as Nusselt and Reynolds number. The thermodynamic cycle simulation is coupled with the heat transfer simulation in order to model the system behavior under different operating conditions.

4.2. Pressure level estimation depending on fluid inventory

A simplified heat pump model is used to calculate fluid mass on the high and low pressure side of the heat pump under stationary operating conditions. The volumes are mainly determined by the geometry of the heat exchangers and piping. The pipe volume is lumped to the heat exchangers. According to this, four volumes represent the heat pump components as shown in Figure 4. Due to their small size turbomachine volumes are neglected. Fluid mass is calculated using the semi-ideal gas model of GTlab-Performance, which provides values for density at the inlet and outlet stations of these volumes.

$$M_{Fluid} = \sum_{i=1}^{n=4} V_i \, \bar{\rho}_i \tag{3}$$

M_{Fluid} is approximated with the approach shown in Eq. (3) by using the arithmetic mean value of densities $\bar{\rho}_i$ for each volume V_i. This method is coupled with the GTlab-Performance solver by an iterative correction of lower pressure level for a user-defined fluid inventory. At nominal load the total pressure at compressor inlet is set to the design value of $p_{1,nominal} = 101325\ Pa$.
Part load operating conditions lead to a variation of compressor inlet flow conditions. Reducing compressor shaft speed shifts the operating point to lower pressure ratios, which in most cases induces rising lower pressure levels in hermetic systems. For system level simulations of Brayton cycle heat pumps, it can be important to consider this effect to correctly predict power input and operating limits.

4.3. Pressure drop approximation at partial load

In addition to the isentropic efficiency of turbomachines, pressure drop is a significant factor for the overall heat pump performance. In Brayton cycle heat pumps, the energy recovery of the turbine strongly depends on the pressure losses in the system. This effect is taken into consideration by a pressure loss coefficient ζ_i for each component:

$$\Delta p_i = \zeta_i \frac{\rho_i}{2} c_i^2 \tag{4}$$

Pressure drop is mainly driven by friction losses in heat exchangers, valves and piping. As the heat pump is still under development, not all component geometries and no experimental data are available. Therefore, a simplified approach is used to approximate part load pressure drop in this work. A reference pressure drop for the high and low pressure side of the heat pump is calculated for design operating conditions based on data from the component manufacturers. Pressure drop coefficient ζ is considered to be constant because relevant Reynolds numbers are sufficiently high in all operating conditions (see Moody chart e.g. [17]).

$$\frac{\zeta}{2\,A^2} = \Delta p_{ref}\,\frac{\rho_{ref}}{\dot{m}_{ref}^2} = const. = C_\zeta \tag{5}$$

Off-design pressure drop is estimated by deriving the part load value from the reference state depending on actual mass flow and fluid density. This approach allows a calculation with the parameter set of the GTlab-Performance model:

$$\Delta p = C_\zeta\,\frac{\dot{m}^2}{\rho} = \Delta p_{ref}\,\frac{\dot{m}^2}{\dot{m}_{ref}^2}\,\frac{\rho_{ref}}{\rho} \tag{6}$$

According to the method introduced, pressure losses are approximated for each stationary operating point. On the high pressure side the resulting pressure drop is applied upstream of the turbine inlet and on low pressure side upstream of compressor inlet.

4.4. Reynolds number effect on efficiency of turbomachinery

In compressor and turbine maps, the effect of Reynolds number on the performance of turbomachinery is usually neglected. However, the increased kinematic viscosity at low Reynolds numbers results in additional losses or lower efficiencies. Multiple efficiency scaling correlations have been proposed to account for the Reynolds number effect. The general form of the efficiency correction follows [18]:

$$\frac{1-\eta}{1-\eta_{ref}} = a + (1-a)\left(\frac{Re}{Re_{ref}}\right)^n \tag{7}$$

In Eq. (7), the coefficient a denotes the fraction of the losses that are independent of the Reynolds number. The exponent n is a measure for the Reynolds number dependence of the losses. The effect of Reynolds number on turbomachine efficiency is shown in Figure 5 for three commonly used correlations taken from Wiesner [18] .

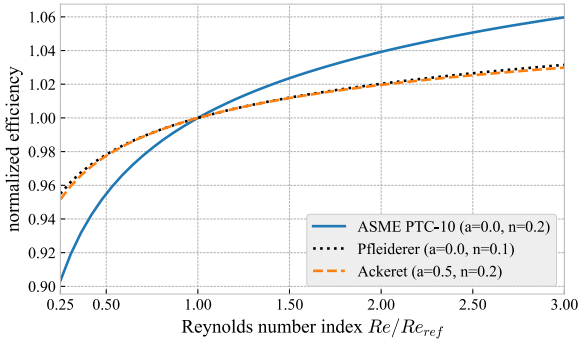

Figure 5: Effect of Reynolds number on turbomachine efficiency based on selected correlations [18]

The ASME Performance Test Code 10 [19] provides Reynolds number correction correlations for axial and centrifugal compressors. Axial compressor efficiencies are assumed to scale only with the Reynolds number ratio, resulting in values of $a = 0$ and $n = 0.2$. Since experimental data of the turbomachines were not available at the time of this study, the coefficients proposed in ASME PTC-10 were applied for the present analyses.

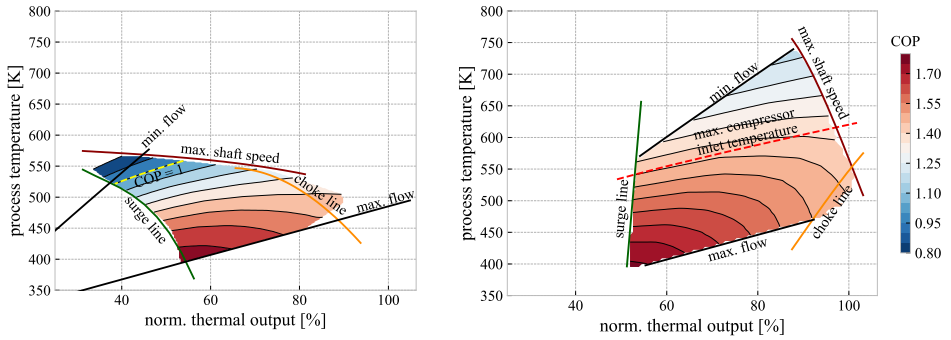
5. Results and discussion

To investigate the part-load capability of closed-cycle high temperature heat pumps two strategies are evaluated (see section 3.2):

- Shaft speed control (SSC): Operating areas of HTHP for non-recuperated and recuperated cycle
- Fluid inventory control (FIC): Comparison with SSC for a scenario with constant temperature requirement and load reduction by 75%

5.1. Operating limits of Brayton cycle heat pumps controlled by shaft speed

The permissible operating range of the CoBra prototype heat pump is bounded by several operating limits:



- Compressor surge: The surge line marks the operating limit beyond which no stable flow can be sustained in the compressor due to flow separation at the blades. A certain safety margin must be kept during operation.
- Maximum shaft speed: The absolute shaft speed is typically limited by the mechanical strength of the rotor blades.
- Secondary mass flow: The secondary mass flow rate at the heat exchanger's secondary side is bounded by the minimum and maximum delivery rate of the fan.
- Maximum compressor inlet temperature: Due to the used instrumentation, the compressor inlet temperature must not exceed a maximum value.
- Compressor choke: At high corrected mass flow rates, the flow reaches sonic velocities, preventing further increase of mass flow rate.

Using the methods presented in section 4, the operating envelopes have been calculated for the CoBra prototype heat pump in non-recuperated and recuperated operating mode. The results are shown in Figure 6 (a) and (b), respectively.

The COP used for the following analysis is defined in Eq. (8) and computed with consideration of pressure drop and component efficiencies as described in section 4:

$$COP = \frac{\dot{Q}_{HTHE}}{P_C - P_T} \tag{8}$$

A comparison of the operating modes shows that the recuperated cycle allows for operation at higher process temperatures and thermal output. In accordance with the assessments in section 2.2, both envelopes show a decrease of COP when higher temperatures are demanded. It should be noted that the non-recuperated cycle shows an operating area where the COP drops below 1: At these operating points, the turbine outlet temperature exceeds the temperature of the heat source level $T_0 = 15\,°C$. Therefore, heat is rejected at both heat exchangers and the system is not working as a heat pump. When comparing the operating envelopes, the recuperated cycle shows higher COPs at the same delivered heat flows and temperatures.

(a) Non-recuperated (b) Recuperated

Figure 6: Operating envelopes with COP

Figure 7 illustrates the heat pump's permissible operating range with the current instrumentation for a given fluid inventory in a single diagram. The achievable temperatures are currently limited by the instrumentation at the compressor inlet. Higher delivery temperatures may be achieved by modifying the installed sensors. It is noticeable that the delivered heat flow cannot be reduced below a minimum value by shaft speed control.

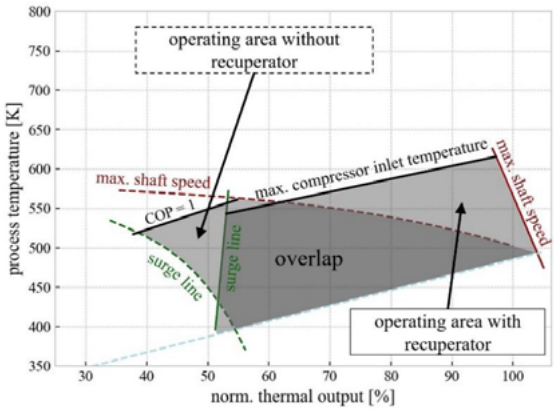


Figure 7: Comparison of operating areas depending on process architecture

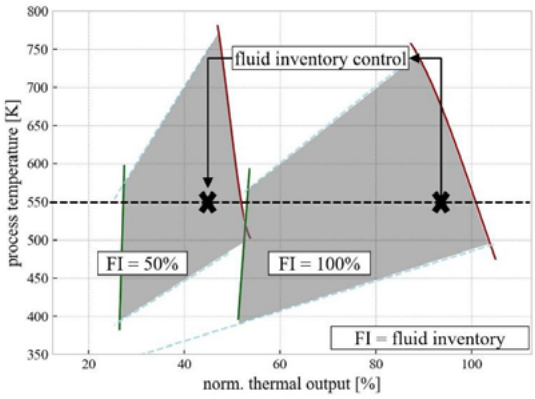
Consequently, if a process requires a wider operating range, additional control options are necessary. This is shown in the following section, where the limitations of the recuperated process with fixed amount of working fluid are compared to a system with fluid inventory control.

5.2. Fluid inventory control

As discussed in section 5.1 load reduction of shaft-speed-controlled high temperature heat pumps is limited e.g. due to instability of the compressor. Fluid inventory control has the potential to significantly expand the operating range with little variation in engine efficiency (see section 3.2).



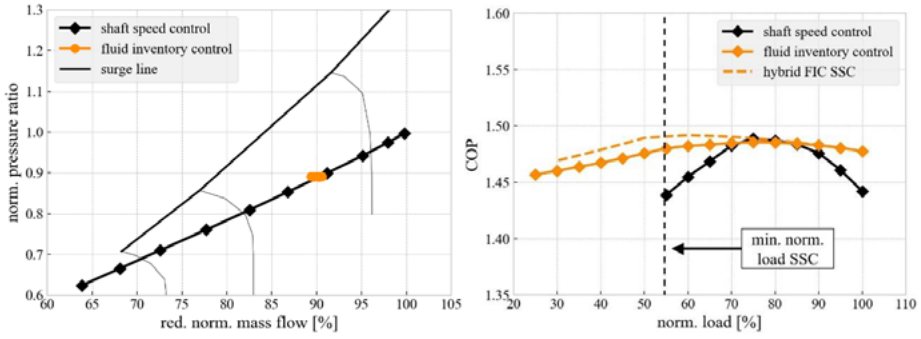


Figure 8: Effect of fluid inventory variation on operating limits of recuperated cycle

Figure 8 shows the effect of a variable fluid inventory on the operating envelope of a HTHP. Altering fluid mass shifts the resulting operating area to corresponding power outputs. When reducing the fluid inventory from a reference state to 50% as shown in the example, the thermal output scales almost linearly with the fluid mass while the temperature range remains almost identical.
For the investigations presented in this paper, a required process temperature of 550 K is assumed. The thermal output range extends from the nominal load to a reduction of 75%. However, the recuperated process architecture only allows a reduction to approx. 55% of nominal load via control of compressor rotational speed.

(a) Compressor map (b) COP

Figure 9: Fluid inventory control vs. shaft speed control for load reduction

If the process requires greater flexibility, the fluid inventory must be adjusted accordingly. This is demonstrated in this figure by shifting an operating point through FIC to low thermal output, which could not be reached by reduction of shaft speed.

Figure 9 demonstrates the advantages of part load operation with fluid inventory control. Figure 9 (a) shows a section of the compressor map. The black working line connects the operating points in the case where part load operation is controlled by varying the compressor rotational speed. For each operating point, the required process temperature is set to 550 K. The inlet temperature of the secondary side of both heat exchangers (HTHE and LTHE, see Figure 3) is 15 °C. The amount of working fluid is optimized for best COP in this range.

When thermal output is controlled by adjusting the fluid inventory, the operating conditions in the turbomachines remain almost identical for the requested performance range. The resulting operating point has been determined by optimization of COP near nominal load conditions and is highlighted in orange in Figure 9 (a).

Figure 9 (b) compares the COP for the entire operating range of shaft speed control and FIC. It becomes clear, that an adjustment of fluid inventory is not only able to extend the operating range but also leads to only minor deviation of heat pump performance even for very low thermal output. The decreasing COP is mainly evoked by Reynolds corrections (see section 4.4) which lead to lower efficiencies of the turbomachines for low-power operating conditions. This trend coincides well with the results by Pradeep Kumar et al. [9], who investigated fluid inventory control for closed cycle gas turbines. There is also some optimization potential by introducing a hybrid method where fluid inventory is controlled as well as compressor shaft speed. This is shown by the dotted orange line. Therefore, fluid inventory control should be considered to increase flexibility of future high temperature heat pumps and extend the scope of their potential applications.

6. Conclusion and outlook

High temperature heat pumps can cover a wide range of industrial process heat requirements. They highlight a very efficient decarbonization strategy for process heat temperatures up to at least 500 °C. Closed cycle Brayton heat pumps capable of thermal output regulation by fluid inventory control provide high flexibility while operating with almost constant efficiency. It is shown that heat pumps are limited to a certain operating range depending on the available methods to control part load operation. Maximum output is mainly determined by thermal and mechanical load capacity of the components.

Two strategies for load reduction have been investigated in the scope of this work. If the heat pump is solely controlled by variation of shaft speed, the permissible minimum load is limited e.g. by compressor stability. The overall operating range for non-recuperated and recuperated process architecture is demonstrated by the introduction of HTHP envelopes. For the CoBra prototype heat pump the recuperator invokes higher output temperatures and better COP.

In order to demonstrate the field of application for fluid inventory control, a scenario with constant output temperature and a load reduction down to 25% has been investigated. The simulation results indicate that fluid inventory control incurs only minor reduction of heat pump performance over the entire operating range. On the other hand, the shaft speed controlled heat pump with fixed amount of working fluid can only operate down to 55% load with varying operating conditions and efficiency.

Fluid inventory control is a promising method to control thermal output of highly flexible future heat pumps. It offers an effective mechanism to react to heat demand changes and address grid fluctuations. Its effect on the transient stability of the compressor will be researched during the operation of the CoBra. In order to investigate fluid inventory control in more detail, studies based on this work with a higher-fidelity model base and experimental examinations are planned.

Abstract

This study was aimed at evaluating the technological feasibility of an absorption refrigeration system using heat from the exhaust gases to cover the needs of air conditioning in automobiles. In the first step, architecture of a single-stage ammonia-water absorption cycle was designed for a case study with a standard 2.0L gasoline turbo-engine vehicle. Then, a new dynamic model of the absorption cycle was built based on the TIL Modelica library to simulate the transient behaviour of the cycle during start/stop and change in driving regime. The simulation results show two major limitations of the absorption refrigeration: insufficient cold production for low wheel power (urban cycle); and slow start up compared to a conventional compression system. The dynamic of the absorption cycle is slow enough to make the engine speed fluctuations (including the stop & start function) imperceptible by the users. Analysis of the ammonia mass flow rate in the system exhibits that the inertia of the absorption cycle mainly depends on high-pressure components such as generator and condenser. This study provides some insight to optimize the performance and the dynamic of the absorption refrigeration system for automobile application.

Keywords: absorption refrigeration; dynamic simulation; heat recovery

1. Introduction

Today, compression refrigeration system (CRS) is the most used refrigeration system in automobiles, requiring approximately 8% to 12% of the engine rated power for air-conditioning. As a result, the average fuel oil consumption increases approximately 16% to 20% when driving automobile with air-conditioning in operation [1]. As automobiles have 35% to 40% thermal efficiency rate, the remaining primary energy is consumed for cooling liquid/lubricant, and in exhaust gases [2]. Nowadays, studies focus on the improvement of thermal efficiency by achieving a better fuel consumption. While utilization of the heat dissipated in exhaust gases for turbo charging and cabin heating has been browsed, more and more studies [3 – 4] focus on air-conditioning by waste heat refrigeration system (WHRS). However, WHRS is a crucial topic still not at a maturity state, because of specific technical requirements. WHRS should be compact and light to fit the narrow space of automobiles. They need to be cooled by air directly and must operate whenever the vehicle runs, under any road/driving conditions. Furthermore, the working fluids should be low toxic, low flammable, able to work under the operating pressure and provide good heat and mass transfers [3]. Ammonia-water absorption refrigeration system (ARS) is a promising solution, with the ammonia filling all the working fluids constraints.

Horuz [5] experimentally proved the possibility of using absorption refrigeration system (ARS), feed by the waste heat in exhaust gases from a 6L diesel vehicle. The prototype is a 10kW commercial single-stage NH3-H2O system. The author shows ARS can replace both the internal combustion (IC) system and the compressor of the CRS. Kaewpradub & al. [6] investigate a single-stage LiBr-H2O absorption refrigeration system. Experiments are led at different engine speeds, expansion valve openings, condenser-outlet temperatures and solution flow rates. The coefficient of performance (COP = Cold produced power/Sum of thermal and electricity input powers) and cooling load increase with the engine speed, and the drop of condenser outlet temperature. The cooling load and COP reach maximal values of 700W and 0.28 respectively, at 1400 rpm and 25°C at condenser outlet. When the solution mass flow rate increases, the cooling load capacity increases

E-mail address: haitrieu.phan@cea.fr.

too, but the COP drops. Koehler & al. [7] developed a detailed model and designed a breadboard prototype of a single-stage NH3-H2O absorption system for truck refrigeration. The heat is provided from the exhaust-gases, at a temperature of around 460°C and a mass flow rate of 360 kg/h. The evaporation temperature varies between -20°C and 0°C, while ambient temperature is from 20°C to 30°C. The prototype COP is from 0.23 to 0.30 with a cooling capacity of 6-10kW.

Charate & al. [4] provide a literature review on air-conditioning in a car, using absorption refrigeration supplied by exhaust heat. Chandrakar & al. [8] designed a NH3-H2O absorption refrigeration system for a 4-cylinder car. Evaporator can produce 2.6 kW of cold, from 4.5 kW of heat; with a COP of 0.57. Rixon & al. [9] designed and built a NH3-H2O absorption refrigeration system from pieces recovery. COP reaches 0.14, with exhaust gases temperature between 100°C and 180°C. Vicatos & al. [10] conducted a theoretical analysis, and developed a unit tested in a laboratory and on road. COP reaches only 0.09. Talom & Beyene [11] led an experimental study on a 10.6 kW absorption chiller, modified to be supplied by a 2.8L V6 IC engine. Results show the concept feasibility and the increase of the system performances.

Most of the authors [5, 4; 8-10] highlight that the use of exhaust gases for air-conditioning allow to reduce IC, fuel consumption, noise and atmospheric pollution, while maintaining efficiency of the engine. However, in most of the studies, the COP is low, about 0.1 to 0.3, which means that further researches for cycle improvement are necessary. According to [5], some points need to be strengthened: pressure variations, and fluctuations of cooling capacity regarding the vehicle speed. An important issue, underlined by [5, 7, 8], is when the vehicle is parked or move slowly: ARS is not sufficient, an alternative solution or a complementary heater is needed. In [7], the authors insist that this system is promising for long distance driving, but is not robust when exhaust gases are low. In [4; 8-10], the authors show that NH3/H2O is the best working fluid couple compromise, being environment friendly and efficient enough.

Xu & al. [3] propose an interesting alternative solution for stationary problem: a novel absorption–compression hybrid refrigeration cycle (ACHRC) driven by gases and power from vehicle engines. R124–DMAC mixture is used as a working fluid. The ARS is powered by exhaust gases; and the CRS, driven by power, runs only if ARS cannot supply enough cooling capacity. For ambient and evaporator temperatures of 35°C and 3°C respectively, the maximum air-conditioning power is 30 kW, while rated generator load in the ARS is 58.68 kW. When the waste heat load recovered by the generator reaches its rated value, air-conditioning is fully supplied by ARS and the maximum integration COP is 0.5. Otherwise, CRS operates to cover the lack of cooling capacity and the COP is reduced. Ambient temperature greatly affects the operating characteristic of the ACHRC: when it rises, the maximum value of the integration COP reduces significantly.

The previous studies focus on the feasibility of ARS process for automobile applications. This process has been proved efficient for monotonic driving at a cruise speed, but an important lock remains to be lifted: the good operation of the ARS during stationary immobile period, start/stop and fluctuations of the vehicle speed. Most of the studies about ARS system for automobile do not consider the dynamic performance of the chiller, which is yet significant for the whole system performances. Indeed, stabilization is deeply affected by transient processes [14]. Even though they are not focus on automobile applications, some studies about dynamic modelling of absorption chiller have been led so far.

Kim and Park [12] and Cai & al. [13] presented dynamic simulations of single-effect NH3-H2O absorption refrigeration system. The numerical model of [12] was applied to a 10.5 kW commercial chiller, to observe the behaviour of several parameters during start-up operation, and find the best conditions for the shortest time constant, with optimal cooling production. A low mass of solution in a large generator volume, combined with a stepwise turn-up/turn-down flue of gas flow rate seems to be the ideal solution for start-up operation. In [13], the authors studied the dynamical response to a pressure step change, and showed that mass flow and heat rates as well as COP oscillated during approximately two loops circulation times before reaching a steady state. Wang & al. [14] analysed the performances of a dynamic model of a single-effect H2O-LiBr absorption chiller, under different parameters. The time required to reach steady-state increases when generator inlet temperature widely change, when cooling water inlet temperature rises, and when evaporator inlet temperature drops. Viswanathan & al. [15] developed a model able to simulate the transient behaviour of an absorption chiller, exploring the entire start-up and shutdown processes for step change of several parameters. Flow rates, pressures and concentrations were stable after 3 minutes. Evaporator and condenser took longer times to reach steady state conditions.

As a continuous of the literature studies, this work aims at bringing further investigation to evaluate the performance of an absorption refrigeration in automobile. A new dynamic model of an absorption cycle feed by exhaust gases was developed to simulate the transient behaviour of the cycle during start/stop and change in driving regime. The simulation results gave the dynamic profiles of hydrodynamic and thermal parameters in different component as well as the system characteristic times. Analysis of the refrigerant mass flow enabled us to identify the key processes and components affecting the dynamic of absorption refrigeration system. Based on this, some ideas are suggested in order to improve the system performance and inertia.

2. Case study and architecture

The present study focuses on evaluating the feasibility in term of the dynamic performance of an absorption refrigeration in order to respond to a given cold request. The other constraints related to the integration of the machine into the vehicle such as vibration, acceleration, deceleration, geometrical layout, weight, fluid charge, etc. are not considered. The case study is a standard 2.0 L gasoline turbo-engine vehicle, which requires a maximum cold production of 5 kW at 5°C of air temperature in the passenger compartment. The driving cycle presented in Fig. 1 corresponds to FTP-75 cycle [16], which has been used for emission certification and fuel consumption testing of light duty vehicles in the United States. This cycle is interesting for this study because of level of acceleration and number of start/stop phase. The first step of thermal system design suited for transient heat sources is to select the power design point, which is important to size all the components, especially heat exchangers. To support design point selection, we have developed a methodology based on analysis of exhaust energy distribution on the cycle. Main output of this methodology are the time fraction, exhaust energy fraction, and average values of parameters such as exhaust temperature and mass flow, on given exhaust power range, as shown in Table 1. It is observed that the available power of the exhaust gases strongly depends on the exhaust-gas flow rate, which depends directly on the engine power. During 62% of time, the vehicle stops or runs at low speed (Point 0 and Point 1), giving low exhaust-gas power.

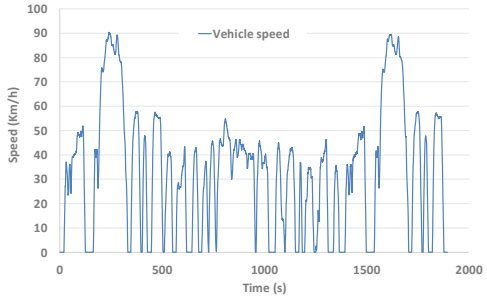

Fig. 1. Typical profile of the vehicle speed

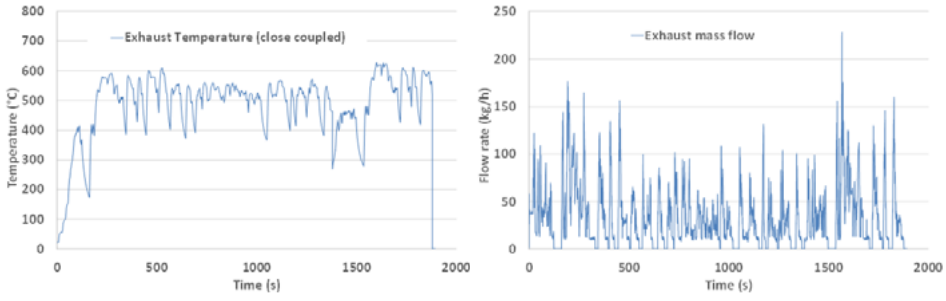

Fig. 2. Evolution of the temperature and flow rate of the exhaust gases

Table 1. Time fractions and average parameters of different range of exhaust power. T_{air} is the ambient temperature.

Point	Range of Available Exhaust Power with T_{air} = 20 °C [kW]	Time fraction	Exhaust Energy Fraction	Average of Vehicle speed [km/h]	Average of Exhaust mass flow [kg/h]	Average of Exhaust Temperature [°C]	Average of Available Exhaust Power with T_{air} = 20 °C [kW]

7	]30-35]	0,04%	0,24%	50,6	202,1	526,6	32,2
8	]35-40]	0,02%	0,11%	50,0	224,8	525,8	35,8

Fig. 3 shows the architecture of the absorption refrigeration of this study. It contains a generator, directly heated by the exhaust gases; an absorber, a rectifier and a condenser, which evacuate heat to the ambiance; an evaporator directly produces cold air; a solution heat exchanger (also called economiser); two expansions valve (one for the refrigerant and one for the weak solution) and a solution pump. The system also includes several tanks: T2 and T3 for liquid-vapour separation, T1 for solution storage and T4 for refrigerant storage. Using a standard air heat exchanger with a difference temperature between the air and the fluid of around 10K. The production of cold air at 5°C requires a negative evaporation temperature of the refrigerant. That is the reason why we investigated the absorption refrigeration using the couple NH_3/H_2O as working fluids.

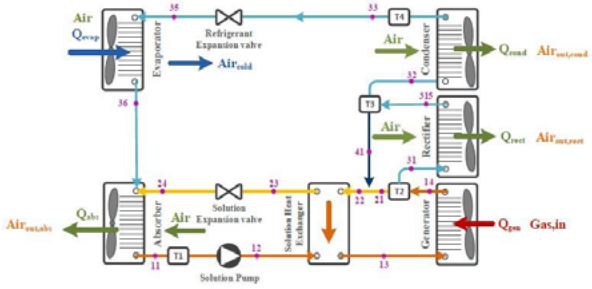

Fig. 3. Schematic view of the architecture of the absorption-refrigeration system

3. Dynamic model

A dynamic model of the above architecture was developed based on Modelica language using the commercial TIL library of TLK-Thermo GmbH, which contains a number of pre-set components and fluid property (based on REFPROP). The component diagram of this model is shown in Fig. 4.

We considered the following hypothesis in different components:

- Heat exchangers:
  - ✓ Air heat exchangers (generator, absorber, rectifier, condenser and evaporator) are fin-and-tube type with tube wall in stainless steel and fins in aluminium;
  - ✓ Liquid-liquid heat exchanger (economiser) is plate type with wall in stainless steel;
  - ✓ The heat exchange coefficients in the exchangers are imposed. On the gas side, the heat exchange coefficient is in the order of magnitude of 100 W/m²/ K on design point. On the liquid side, the heat exchange coefficient is in the order of magnitude of 1000 W/m² K. On the two-phase side, the heat exchange coefficient is in the range of 2000-4000 W/m²/ K;
  - ✓ The geometries of the heat exchangers were previously determined by static calculations to target heat exchanger efficiencies around 0.85 at Point 2 (see Table 1);
  - ✓ The pressure drops are not calculated;
- Expansion valves: a linear relationship between the pressure drop and the mass flow rate is used: $\dot{m} = open \times \Delta P$, *open* is the effective valve opening;

- Tanks: only tanks T2 and T3 where there are separation of liquid and vapour phases are simulated. An artificial pump is used to impose a stable liquid level in tank T3 as observed experimentally with the absorption-chiller prototypes in our laboratory. In reality, the liquid in tank T3 returns to the poor solution due to gravity;
- Air flow: the inlet temperature of air is fixed at 30°C. The air-flow rates were previously determined by static calculations to target a variation in temperature of about 15°C from inlet to outlet for absorber, condenser and rectifier;
- Regulation parameters: pump flow rate and expansion-valve openings;
- Initial conditions: the initial conditions of dynamic simulations are set as below:
  - ✓ Pressures : 10 bar (based on experimental data);
  - ✓ Wall temperatures : 30 °C (equal to the ambient temperature);
  - ✓ NH_3 mass fractions in different components given by static simulations.

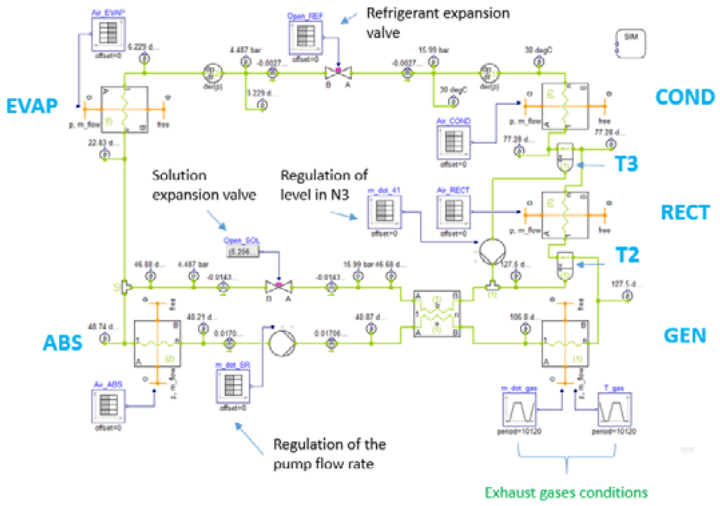

Fig. 4. Component diagram of the dynamic model of the absorption-refrigeration system

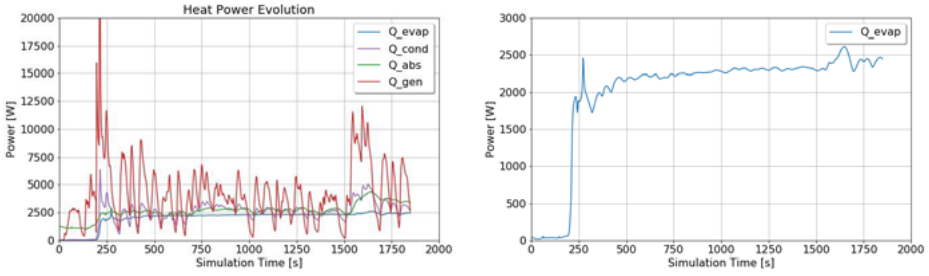
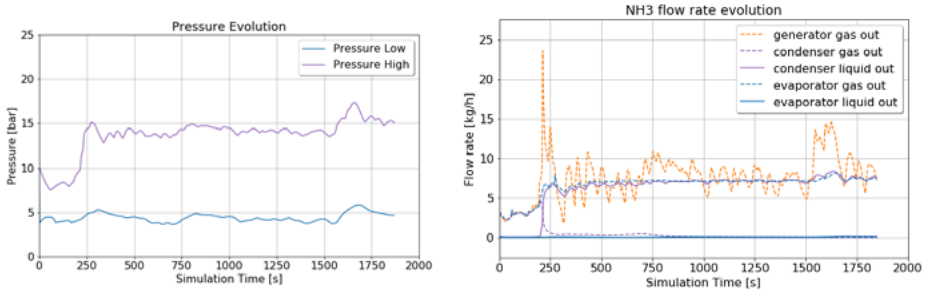


4. Simulation results

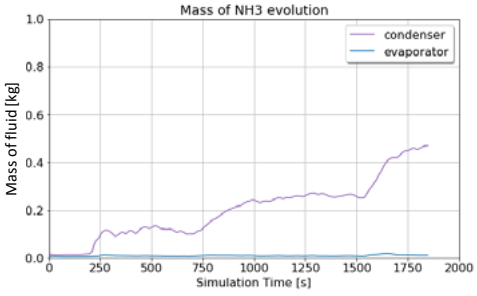
4.1. Constant pump flow rate and valve openings

For this case, we set the pump flow rate to the average value given by static simulations (45 kg/h) and fixed the valve openings to obtain the target difference of the pressures in the system. We performed simulations with the exhaust inputs as shown in Fig. 2 and obtained the evolutions of the power in different components: evaporator, condenser, absorber and generator. As shown in Fig. 5, the power at the generator fluctuates significantly due to fluctuations in the exhaust conditions. Since the condenser and the generator are connected at the same pressure level (high pressure), they show similar dynamic behaviour. At the low-pressure side, the absorber and the evaporator show smoother curves. After 250 s (~ 4 minutes), we observe a sudden increase of the cold power to 80% of the stabilized value, mainly due to the highly increase of the generator power. The cold production is maintained even when the vehicle stops. The system dynamic is slow enough to make imperceptible by the customer the fluctuations in engine speed/load. The stabilized cold power is around 2.3 kW, significantly lower than the maximum power required of 5 kW.



For a better understanding of the main factors affecting the system dynamic, we analyse the evolution of the pressure and the ammonia flow rates in different components. As shown in Fig. 6a and Fig. 6b, there is high peak of ammonia-vapour production at the generator outlet between 200s and 250s, leading to a sudden increase of the high pressure. At 250s, the high pressure approaches 15 bar, generating condensation inside the condenser. Then, the liquid flow rate remains stable at the condenser outlet due to hydrodynamic constraint.

The rest of the produced ammonia liquid is accumulated in the condenser (see Fig. 6c). In reality, this amount of ammonia liquid is stored in tank N4 (see Fig. 3) to do not degrade the condenser performance. Passing through the expansion valve, the ammonia liquid enters the evaporator at nearly saturated condition and therefore it is rapidly evaporates. That is the reason why only a small amount of ammonia-liquid presents in the evaporator.



a) b)

Fig. 5. Evolutions of power: a) Q_evap at evaporator, Q_cond at condenser, Q_abs at absorber and Q_gen at generator; b) a zoom on power at evaporator

a) b)

c)

Fig. 6. Evolution of a) pressures; b) ammonia flow rates and c) ammonia mass in the heat exchangers

The above analysis shows that the absorption refrigeration dynamic strongly depends on hydrodynamic in the system. Different from a mechanical-compression machine, during the starting phase, the pressure in an absorption chiller increases by ammonia-vapour production from the generator. The starting time corresponds to the time required for the high pressure to reach the saturation value so that condensation occurs in the condenser. Once ammonia liquid is generated, cold power can be rapidly produced since the ammonia liquid enters the evaporator at nearly saturated condition.

4.2. Regulated pump flow rate and valve openings

To investigate the impact of the regulation parameters, we perform simulations with the following conditions for pump flow rate and valve openings:

- The pump flow rate is regulated to maintain a constant temperature of the weak solution at the generator outlet with the following laws (as illustrated in Fig. 7):
  - Start (t < 250 s) : $\dot{m}_{pump} = \dot{m}_{pump,\,mean} = 45\ kg/h$
  - After start (t ≥ 250 s) :
    - ✓ $\dot{m}_{pump} = \frac{\dot{m}_{pump,mean}}{\dot{m}_{gas,mean}} \dot{m}_{gas} = 1.4 \times \dot{m}_{gas}$ if $\dot{m}_{gas} > \frac{\dot{m}_{gas,mean}}{2} = 16.2\ kg/h$
    - ✓ $\dot{m}_{pump} = \frac{\dot{m}_{pump,mean}}{2} = 22.5\ kg/h$ if $\dot{m}_{gas} \leq \frac{\dot{m}_{gas,mean}}{2}$
- The valve openings are regulated to maintain a constant difference between high and low pressures :
  - Refrigerant valve : $Open_{ref} = k1 \times \dot{m}_{pump,\,mean}$ with $k1 = 160 \times 10^{-9}$ [1/Pa]
  - Solution valve : $Open_{sol} = k2 \times Open_{ref}$ with $k2 = 5.26$

Fig. 8 shows comparison of cold production with constant and variable pump flow rates. After the start-up, the cold production reacts rapidly with the change in pump flow rate. Because the regulation of the valves is fast enough (~ 1s) to adjust the pressure levels in the system so that condensation and evaporation of the refrigerant occur continuously. At high exhaust gas power, an increase in the pump flow rate will lead to an increase in the refrigerant flow rate and thus improve the cold production. For future works, better regulation laws can be developed to optimize the machine performance.

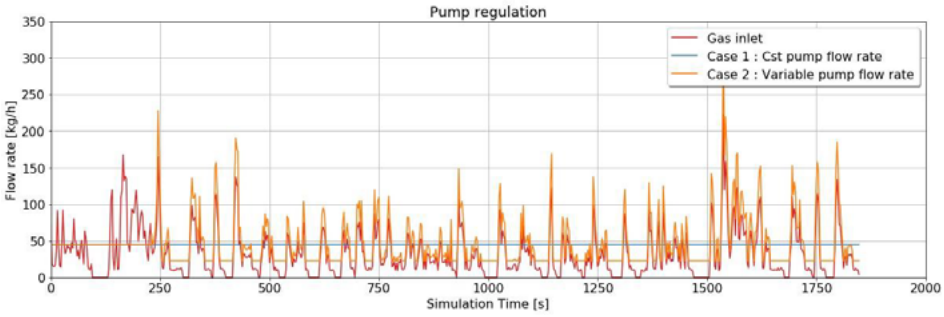


Fig. 7. Pump regulation with case 1: constant flow rate and case 2: variable flow rate

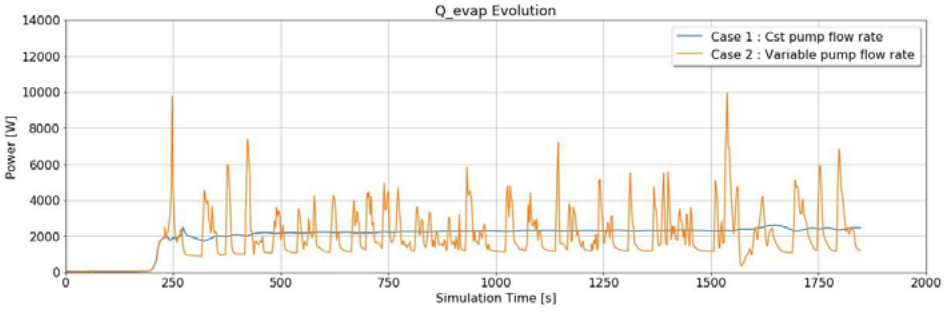

Fig. 8. Cold power productions with constant and variable pump flow rates

5. Conclusions

This study investigates the dynamic performance of an absorption refrigeration heated by exhaust gases. The case study is a standard 2.0L gasoline turbo-engine vehicle running on FTP-75 driving cycle. In agreement

with the literature, dynamic simulations confirm insufficient cold production when the vehicle runs at low engine power (low speed and/or low torque). Another technological limitation is the high inertia of the system that causes long start-up time, around 4 minutes in the present case study. The key factor affecting the absorption refrigeration dynamic is the high-pressure level, which mainly depends on the vapour generation at the generator. For the system to start, the high pressure should reach the necessary value allowing condensation in the condenser. Boosting the generator power (for example by adding complementary heat) for fast vapour production could be a solution to reduce the start-up time. After the start-up, the cold production reacts rapidly with the regulations of pump flow rate and valve openings. Smart regulation law could be a solution to improve the machine performance.

Experimental Investigation of Parameters Affecting Drying Time and Power Consumption of a Heat Pump Tumble Dryer

Mehdi Rasti[a], Ji Hwan Jeong[a,*]

[a]School of Mechanical Engineering, Pusan National University, Geumjeong-Gu, Busan 46241, South Korea

Abstract

A heat pump clothes dryer comprises of two closed loops, namely, the heat pump cycle and the air cycle. Clothes dryers are among the most energy-intensive home appliance. This study experimentally investigated how the textile type, textile size, textile weight, fan speed, and compressor frequency influence the drying time and power consumption. A heat pump tumble dryer with a 9 kg rated capacity was selected for experimental investigations. The following values were selected for experiments: textile weight: 3, 6, 9 kg; textile type: sheet, pillowcase, towel; fan speed: 2850, 3150, 3450 rpm; and compressor frequency; 27, 35, 40 Hz. Results showed that the drying time and power consumption were increased by increasing the textile weight and the textile size. The drying time of 9 kg sheets was 42.2% and 22.5% higher than that of pillowcases and towels, respectively. Moreover, the drying time was decreased by increasing the fan speed and compressor frequency.

Keywords: Heat pump clothes dryer; drying time; experimental study; textile weight; textile size.

1. Introduction

Clothes dryers can be categorized as open-loop such as vented dryers or closed-loop such as heat pump dryers and condenser dryers depending on exhausting drum outlet air outdoors. Condenser clothes dryers and vented clothes dryers use an electric heater to heat up the air entering the drum while heat pump clothes dryers use condenser heat rejection to heat up the air. Shrinkage of clothes as a result of high air temperature and high energy consumption are disadvantages of clothes dryers that use an electric heater. Because energy consumption of heat pump clothes dryers is almost half of conventional dryers, their market share has grown rapidly [1]. It should be noted that drying time of heat pump clothes dryers is longer than conventional clothes dryers because of lower drying air temperature [2].

In 2019, the worldwide sale market of clothes dryers was $7.3 billion and it is expected to reach $10.8 billion by 2023 [3]. In 2015, the Energy Information Administration reported that total electricity consumption of clothes dryers were 57.4 billion kWh [4]. The number of clothes dryers in Northern Europe and North America is increasing because of small space requirement and dry clothes regardless of weather conditions [5]. It is expected to reach number of clothes dryers to 105.8 million by 2025 in the US [6]. Since the energy consumption of clothes dryers is considerable, energy efficiency enhancement of clothes dryers is crucial. Stawreberg and Nilsson [7] established a mathematical model for energy efficiency enhancement of drying small loads. Their results showed that by reducing the heat supply and the airflow rate, it is possible to improve the clothes dryer's specific moisture extraction rate by 6% when drying small loads. Braun et al. [8] experimentally compared performance of a heat pump tumble dryer with conventional electric dryers. They reported that energy consumption of a heat pump tumble dryer was 40% and 14% lower that an electric clothes dryer and a conventional electric dryer using heat recovery heat exchangers, respectively. Bengtsson et al. [9] reported that by increasing the cylinder volume of compressor by 50%, drying time of heat pump clothes dryer decreased by 14% without increasing in energy consumption. Erdem [10] developed a model to investigate effects of evaporator geometry on the energy consumption and drying time of heat pump clothes dryers. Their

E-mail address: jihwan@pusan.ac.kr.

simulation results showed that energy consumption reduced by 12% and 8% by increasing number of evaporator rows and columns from 2 to 4, respectively. Moreover, energy consumption increased by 18% and 21% by increasing tube outer diameter from 6 to 10 mm and increasing the longitudinal tube pitch from 10 to 30 mm, respectively.

The purpose of this study was to investigate the effect of a wide range of textile type, textile weight, fan speed, and compressor frequency on the drying time and power consumption of heat pump tumble dryers.

2. Experimental study

A heat pump tumble dryer with 9 kg rated capacity was selected for experimental investigations. The heat pump tumble dryer was equipped with twenty-three thermocouples with the uncertainty of ±0.3 °C, and three "SHT85 model" relative humidity and temperature sensors with the uncertainties of ±1.5 %RH and ±0.1 °C. The schematic of heat pump tumble dryer is shown in Fig. 1.

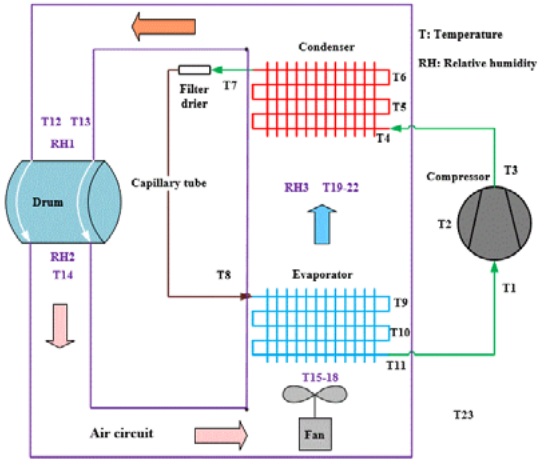

Fig. 1. Schematic of equipped heat pump tumble dryer

All experiments were conducted at the ambient temperature of 23±2 °C. According to IEC 60456 [11], the bone dry method was used for the conditioning of textiles to define the nominal mass of textiles at the start of experiments. The conditioned weight of textiles was defined as:

$$m_{cond,t} = m_{bd,t} \times F_{bd} \tag{1}$$

where $m_{cond,t}$ is the conditioned weight of textiles, $m_{bd,t}$ is the bone dry weight of textiles and the bone dry factor F_{bd} is bone dry factor which experimentally was found equal to 1.072. The difference between $m_{cond,t}$ and $m_{bd,t}$ is equal to the amount of moisture absorbed by textiles from surrounding for more than 15 hours at the ambient temperature of 20±2 °C and relative humidity of 65±5 %. All experiments started at the initial moisture content (IMC) of 60%. The initial moisture content "IMC" can be calculated as below:

$$IMC = \frac{m_{add,w}}{m_{cond,t}} \times 100\% \tag{2}$$

where $m_{add,w}$ is the weight of water added to the conditioned textile. In the present study, the effect of textile weight (3, 6, 9 kg), textile type (sheet, pillowcase, towel), fan speed (2850, 3150, 3450 rpm), and compressor frequency (27, 35, 43 Hz) on the drying time were experimentally investigated. To examine the effect of textile size on the drying time, three cotton base textiles were selected according to IEC 61121 [12]. Specifications of sheets, pillowcases, and towels are given in Table 1.

Table 1. Specifications of textiles used in the experiments.

Parameter		Unit	Sheets	Pillowcases	Towels
Length		mm	2400±150	800±50	1000±50
Width		mm	1600±40	800±20	500±30
Area		m^2	3.84±0.342	0.64±0.057	0.5±0.056
Weight per piece		g	725±15	240±5	110±3
Mass per unit area		g/m^2	185 ± 10	185 ± 10	220 ± 10
Substrate		---	Long staple pure cotton	Long staple pure cotton	Long staple pure cotton
Yarn		---	Ring spun	Ring spun	Ring spun
Weave			Plain weave linen 1/1	Plain weave linen 1/1	Huckaback
Water uptake in		%	138 ± 10	138 ± 10	250 ± 15
Yarn twist	Warp	T/m	600 ± 20	600 ± 20	610 ± 20
	Weft		500 ± 15	500 ± 15	490 ± 15
Yarn Count	Warp	tex	33 ± 1	33 ± 1	36 ± 1
	Weft		33 ± 1	33 ± 1	97 ± 1
Pick count	Warp	pick/cm	24 ± 1	24 ± 1	20 ± 1
	Weft		24 ± 1	24 ± 1	12 ± 1

A list of experiments is shown in Table 2. It should be noted that the heat pump tumble dryer was comprised of a fan-drum motor for rotating both the laundry drum and drying air fan. The drum rotation speed was 49.12 RPM when the fan rotational speed was 2850 RPM and it was 54.29 RPM for the fan rotational speed of 3150 and 3450 RPM.

3. Results and discussion

Drying time and total power consumption for cases 1 to 12 are presented in Figs. 2 and 3, respectively. It should be noted that the fan speed and compressor frequency were the same for cases 1 to 12 while the textile weight and textile composition were different. Results showed that the drying time and power consumption increased by increasing the weight of textiles. The shortest and longest drying time was related to towels and sheets because of the smallest size and largest size, respectively. Due to rolled up or rolled inside another, thus trapping moisture, the drying time of sheets was significantly more than towels and pillowcases. In other words, the stagnant core of sheets in the drum was bigger than pillowcases and towels. Therefore, the molecular diffusion which is slower than convection diffusion in the sheets was dominant. Results showed that the drying time of 3, 6, and 9 kg sheets was 7.2%, 28.4%, and 52.3% higher than that of a mix of textiles, respectively. Moreover, the total power consumption of 3, 6, and 9 kg sheets was 11.2%, 34.2%, and 56% higher than the total power consumption of a mix of textiles, respectively.

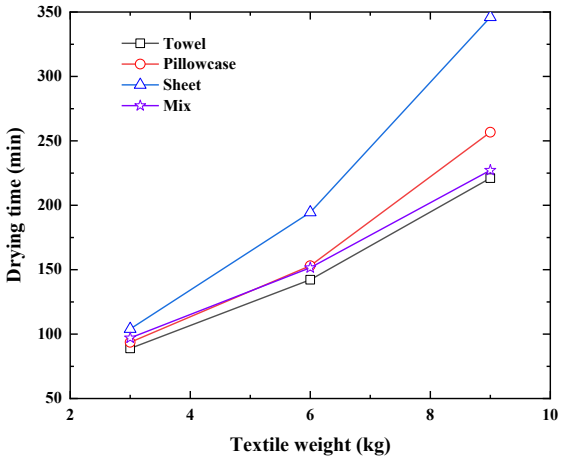

Fig. 2. Effect of textile weight and textile composition on the drying time

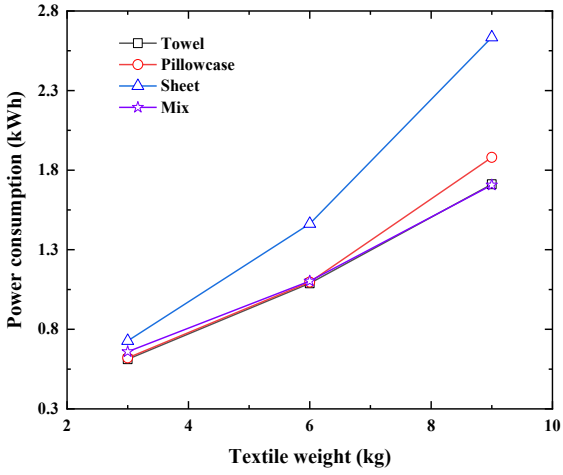

Fig. 3. Effect of textile weight and textile composition on total power consumption

Figs. 4 and 5 present the drying time and total power consumption for cases 13 to 21, respectively. The textile composition for 9 kg textile was selected according to the IEC 61121. The fan speed was changed from 2850 to 3450 rpm and the compressor frequency was changed from 27 to 43 Hz. Results showed that with increasing the compressor frequency from 27 to 43 Hz, the power consumption increased and the drying time decreased because of increasing the air temperature at the inlet of the drum. As shown in Fig. 4, the drying time decreased with increasing the airflow rate because of increasing the moisture evaporation rate in the drum. Manufacturers of clothes dryers are seeking to reduce the power consumption and the drying time. The results showed that although energy consumption decreased with decreasing the compressor frequency, the drying time increased. The power consumption was maximum while the heat pump dryer was working with the highest compressor frequency (43 Hz) and lowest fan speed (2850 rpm). Also, the power consumption was minimum while it was working with the lowest compressor frequency (27 Hz) and the highest fan speed (3450 rpm).

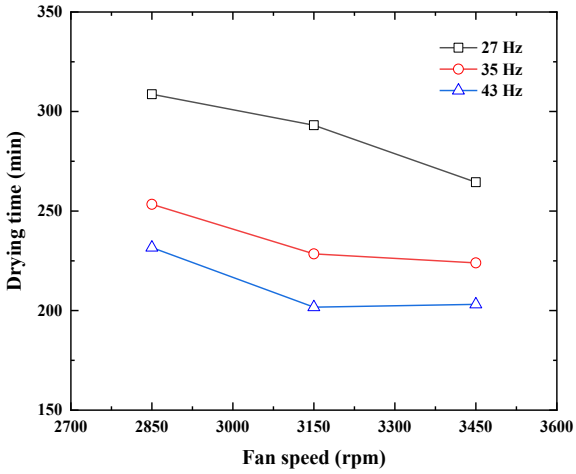

Fig. 4. Effect of fan speed and compressor frequency on drying time

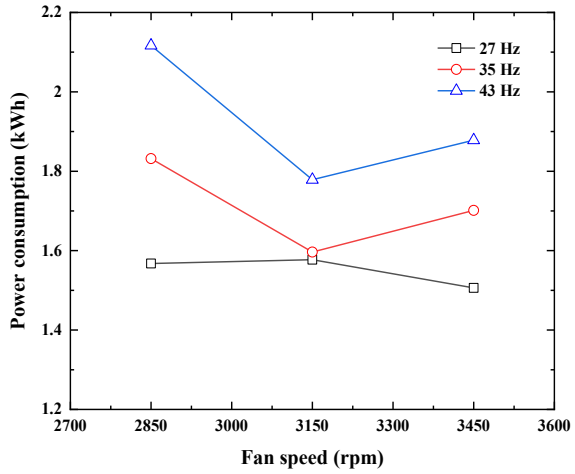

Fig. 5. Effect of fan speed and compressor frequency on total power consumption

The Energy Efficiency Index (EEI) was selected to determine the optimum condition and it was calculated according to the EU 392/2012 standard [13]. The energy efficiency of household tumble dryers is rated in terms of a set of energy labels from *A*+++ to *D*, *A*+++ being the most energy efficient, and *D* the least efficient as shown in Table 3.

Table 3. Energy efficiency classes.

Energy Efficiency Class (EEC)	Energy Efficiency Index (EEI)
A+++ (most efficient)	EEI < 24
A++	24 ≤ EEI < 32
A+	32 ≤ EEI < 42
A	42 ≤ EEI < 65
B	65 ≤ EEI < 76
C	76 ≤ EEI < 85
D (least efficient)	85 ≤ EEI

The EEI and EEC for 9 kg textiles are presented in Table 4. Results showed that case 15 (mix of textiles, fan speed: 3450 rpm, compressor frequency: 27 Hz) was the most energy efficient and case 9 (sheets, fan speed: 3150 rpm, compressor frequency: 35 Hz) was the least efficient. Moreover, the EEC was A+++ and A++ for all experiments while the heat pump dryer was working with the compressor frequency of 27 Hz and 43 Hz, respectively.

Table 4. Energy Efficiency Index of exeriments with 9 kg textile.

Case	weight of textile (kg)	Textile type	Fan speed (rpm)	Compressor frequency (Hz)	EEI	EEC
3	9	towel	3150	35	23.9	A+++
6	9	pillowcase	3150	35	26.3	A++
9	9	sheet	3150	35	35.9	A+
12	9	3 sheets/ 12 pillowcases / 36 towels	3150	35	23.5	A+++
13	9	4 sheets/ 14 pillowcases / 26 towels	2850	27	22.6	A+++
14	9	4 sheets/ 14 pillowcases / 26 towels	3150	27	22.7	A+++
15	9	4 sheets/ 14 pillowcases / 26 towels	3450	27	21.7	A+++
16	9	4 sheets/ 14 pillowcases / 26 towels	2850	35	26.4	A++
17	9	4 sheets/ 14 pillowcases / 26 towels	3150	35	23	A+++
18	9	4 sheets/ 14 pillowcases / 26 towels	3450	35	24.5	A++
19	9	4 sheets/ 14 pillowcases / 26 towels	2850	43	30.4	A++
20	9	4 sheets/ 14 pillowcases / 26 towels	3150	43	25.6	A++
21	9	4 sheets/ 14 pillowcases / 26 towels	3450	43	27	A++

4. Conclusion

This study presented effects of textile type (sheet, pillowcase, towel), conditioned weight of textiles (3, 6, 9 kg), fan speed (2850, 3150, 3450 rpm), and compressor frequency (27, 35, 43 Hz) on the drying time and power consumption of a heat pump tumble dryer. Twenty-one experiments were conducted on a heat pump tumble dryer with a 9 kg rated capacity. All experiments were conducted at the ambient temperature of 23±2 °C and initial moisture content of 60%. The results showed that the drying time and the power consumption increased by increasing the weight of textiles and the size of textiles. The drying time and power consumption of 9 kg sheets were 52.3% and 56% higher than that of a mix of textiles, respectively. Moreover, the drying time decreased and the power consumption increased by increasing the compressor frequency. The results showed that the lowest EEI was belonged to drying 9 kg of a mix of textiles while the heat pump dryer was working with the lowest compressor frequency (27 Hz) and highest fan speed (3450 RPM).

Thermodynamic analysis of refrigerant selection for high temperature heat pump cycles

Takenobu Kaida[a,*]

[a] Central Research Institute of Electric Power Industry (CRIEPI), Yokosuka 240-0196, Japan

Abstract

Industrial heat pump is recognized as one of decarbonization technologies in industry by a couple of its high efficiency and electrification with low carbon electricity. For expanding applications of heat pumps into various industrial heating processes, it is necessary to increase the supply temperature of heat pumps. Recently, some new refrigerants have been developed, which allows to increase the choice of refrigerants expected to be applied to higher temperature heat pumps. The purpose of this study is to illustrate working domain maps which can determine the promising refrigerant and the upper limit of heat pumping temperature lift for each supply temperature. First, with thermodynamic analysis for simple heat pump cycle, refrigerant selection in the wide range of the heat pump supply temperature from 60°C to 200° C is analyzed comprehensively for 17 pure refrigerants currently available on the market. Then, the effect of a high efficiency improvement by two-stage cycle with economizer are examined on the refrigerant selection.

Keywords: Industrial heat pump ; High temperature heat pump ; Refrigerant selection ; Low GWP ; Thermodynamic analysis

1. Introduction

Industrial heat pump is recognized as one of decarbonization technologies in industry by a couple of its high efficiency and electrification with low carbon electricity. Figure 1 shows the distribution of heat demand by temperature in the Japanese industrial sector [1]. The high temperature heat demand above 200°C is limited to energy-intensive industries such as steal, metals, cement and petrochemicals, and most of the heat is used as combustion by burner. On the other hand, below 200°C, various industries exist, having various types of heat demands such as drying, washing, sterilization, distillation and concentration. Another feature is that it is used mainly as a form of steam. This heat demand area below 200°C accounts for 28% of the total industrial heat demand and is expected to be applied to heat pumps.

For expanding the heat pump application range, it is necessary to prepare heat pumps with various supply temperatures up to 200°C for use in various heating processes. In general, heat pump performance largely depends on the refrigerant selection, and thus it is desirable to select the appropriate refrigerant. Recently, some new refrigerants have been developed for corresponding to lowering the global warming potential (GWP), which allows to increase the choice of refrigerants expected to be applied to higher temperature heat pumps.

The purpose of this study is to provide working domain maps which can determine the promising refrigerant and the upper limit of heat pumping temperature lift for each supply temperature. Brunin et al. investigate the working domain of many refrigerants in the heat pump supply temperature range up to 200°C [2]. However, majority of the investigated refrigerants are banned today (CFCs, HCFCs) and will be restricted in near future use (HFCs). Ommen et al. investigate the working domains focusing on 4 natural refrigerants (R290, R600a, R744 and R717) [3]. They consider not only technical and thermodynamic constraints but also economic constraints, however the investigated heat pump supply temperature is limited up to 120°C.

In this study, for 17 pure refrigerants currently available on the market including newly developed HFOs and HCFOs, refrigerant selection in the wide range of the heat pump supply temperature from 60°C to 200°C is analyzed comprehensively with thermodynamic analysis for simple heat pump cycle. In addition, the effect of a high efficiency improvement by two-stage cycle with economizer are examined on the refrigerant selection.

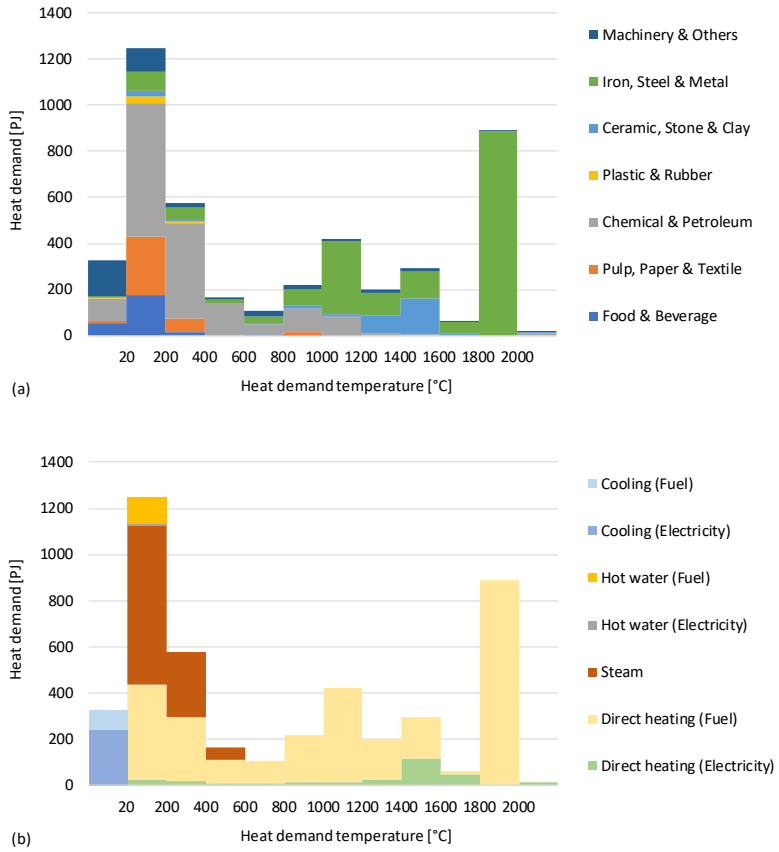

Fig. 1. Heat demand in the Japanese industry (a) by industry and (b) by heat use form

2. Refrigerants for high temperature heat pumps

Table 1 shows the basic properties of 17 refrigerants investigated in this study. Although 3 HFCs (R32, R134a and R245fa) have relatively high GWPs and will be restricted in near future use, they are included in this study for comparison. Other 14 refrigerants have very low GWPs. Among them, 2 HCFOs (R1224yd(Z) and R1233zd(E)), 1 HFO (R1336mzz(Z)) and 2 natural refrigerants (R718 and R744) are classified as A1 in ASHRAE Standard 34 safety group classification, which indicates low-toxicity and non-flammability. The ozone depletion potentials (ODPs) of the HCFOs are not zero but recognized negligible small. Thus, they are not listed as ozone depleting substances (ODSs) in the Montreal Protocol. 3 HFOs (R1234yf, R1234ze(E) and R1234ze(Z) are classified as A2L of low-toxicity and mild-flammability. 5 HCs (R290, R600, R600a, R601 and R601a) are classified as A3 of low-toxicity and high-flammability. R717 is classified as B2L of high-toxicity and mild-flammability.

Table 1. Basic properties of 17 pure refrigerants

Type	Refrigerant	Chemical formula	Molar mass [g/mol]	ODP	GWP	Safety	Critical temperature [°C]	Critical pressure [MPa]
HFC	R32	CH_2F_2	52.0	0	677	A2L	78.1	5.78

Figure 2 shows the relation between the molar mass and the critical temperature for these refrigerants. Focusing on HCs, it can be seen that the critical temperature becomes higher as the molar mass becomes larger. However, some refrigerants have the same molar mass but the different critical temperatures, which is because of the isomers. The same tendency applies to HFCs, HCFOs and HFOs, however the molar mass is larger than that of HC when viewed at the same critical temperature. Therefore, because of its large molar mass and complicated molecular structure, the development possibility of new refrigerants for high temperature heat pumps is relatively high. On the other hand, it can be seen that R717, R718 and R744 show peculiar characteristics.

The relatively large molar mass is a characteristic of the refrigerant for high temperature heat pump. This characteristic affects the shape of saturated vapor curve. It is known that the slope of the saturated vapor curve on *T-s* diagram becomes positive from negative when the value of specific heat becomes relatively large. Morrison investigates the shape of saturation curves [4]. From general thermodynamic relation, the slope of the saturation curve on *T-s* diagram can be written as follows:

$$\left.\frac{dT}{ds}\right|_{sat} = \left[\frac{c_v}{T} + \left(\frac{\partial p}{\partial T}\right)_v \left.\frac{dv}{dT}\right|_{sat}\right]^{-1} \tag{1}$$

Here the value of c_v/T is always positive and the value of $(\partial p/\partial T)_v$ is generally positive. The value of $dv/dT|_{sat}$ is generally positive for liquid and negative for vapor. Therefore, the slope of the liquid saturation curve is generally positive, but the slope of the vapor saturation curve can be positive or negative mainly depending of the value of c_v. When the molar mass becomes relatively large and the specific heat c_v becomes relatively large, the slope of saturated vapor curve changes from negative to positive.

As an example, Figure 3 shows the comparison of the saturated curves of R134a and R1336mzz(Z) on *T-s* diagram. It can be seen that the slope of the saturated vapor curve of R134a (molar mass: 102.0 g/mol) is negative, but the slope of R1336mzz(Z) (molar mass: 164.1 g/mol) is positive. Therefore, when using R134a, there is no concern that liquid compression will occur even if the compressor suction superheating is zero, but when using R1336mzz(Z), liquid compression will occur unless the sufficient superheating is secured. Hence, it is necessary to secure the suction superheating when using some refrigerants for high temperature heat pumps, for example, by installing an internal heat exchanger.

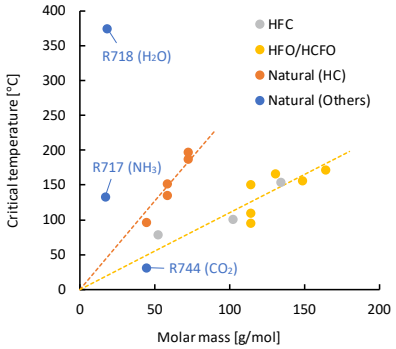

Figure 2. Relation between molar mass and critical temperature

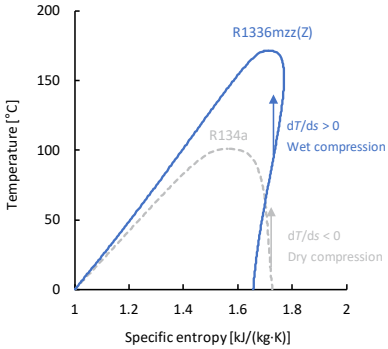

Figure 3. Slope of saturated vapor curve

3. Analysis for simple heat pump cycle

This study analyzes subcritical heat pump cycles using pure refrigerants, assuming that the temperature glides on both of heat source and heat sink are relatively small. Therefore, among the refrigerants shown in Table 1, 16 refrigerants were targeted, excluding R744, which has a lower critical temperature than 60°C.

3.1. Method

Figure 4 and Table 2 show the schematic diagram and calculation condition of the heat pump cycle, respectively. The temperature lift (ΔT_{lift}) is defined by the difference between the heat sink outlet temperature (T_{h2}, heat supply temperature) and the heat source inlet temperature (T_{c1}). The temperature glides on both of heat source (ΔT_{c}) and heat sink (ΔT_{h}) are fixed at 5 K. The pinch temperature differences on both of evaporator ($\Delta T_{\mathrm{pinch,evp}}$) and condenser ($\Delta T_{\mathrm{pinch,cnd}}$) are fixed at 2 K. Strictly speaking, the pinch point of the condenser occurs somewhere in the condenser, but in order to simplify the calculation, it is defined by the difference between the condensation temperature (T_{cnd}) and the heat sink outlet temperature (ΔT_{h2}). The evaporator superheating ($\Delta T_{\mathrm{sh,evp}}$) and the condenser subcooling (ΔT_{sc}) are fixed at 5 K. As mentioned above, depending on the type of refrigerant, the discharge superheating may be smaller than the suction superheating. Thus, the smaller superheating of them (ΔT_{sh}, minimum superheating) is fixed at 5 K. When the discharge superheating is smaller, the insufficient superheat amount covered with an internal heat exchanger. Compressor isentropic efficiency (η_{cmp}) generally depends on the pressure ratio of discharge pressure to suction pressure, but it is set to a constant value of 0.8 in this calculation. The thermophysical properties of each refrigerant are calculated using REFPROP Ver. 10.0 by NIST [5].

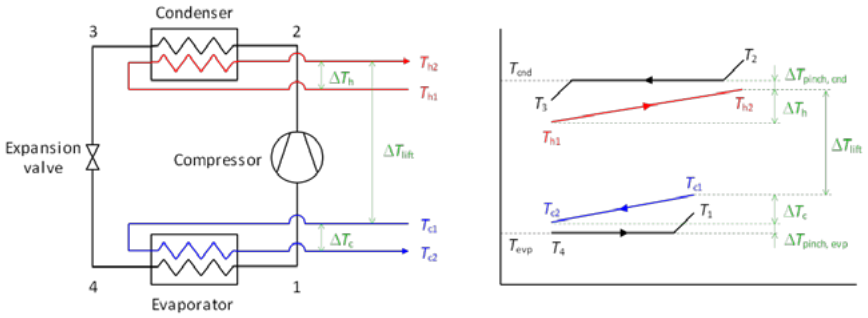

Figure 4. Schematic diagram of simple heat pump cycle and temperature profile

Table 2. Definition of temperature differences and calculation condition

Symbol	Value	Unit	Definition
ΔT_{lift}	Variable	K	$= T_{\mathrm{h2}} - T_{\mathrm{c1}}$
ΔT_{c}	5	K	$= T_{\mathrm{c1}} - T_{\mathrm{c2}}$
ΔT_{h}	5	K	$= T_{\mathrm{h2}} - T_{\mathrm{h1}}$
$\Delta T_{\mathrm{pinch,evp}}$	2	K	$= T_{\mathrm{c2}} - T_{\mathrm{evp}}$
$\Delta T_{\mathrm{pinch,cnd}}$	2	K	$= T_{\mathrm{cnd}} - T_{\mathrm{h2}}$

ΔT_{sc}	5	K	$= T_{\mathrm{cnd}} - T_{3}$
ΔT_{sh}	5	K	$= \min\{T_{1} - T_{\mathrm{evp}}, T_{2} - T_{\mathrm{cnd}}\}$
η_{cmp}	0.8	-	$= (h_{2,\mathrm{is}} - h_{1}) / (h_{2} - h_{1})$

When selecting a refrigerant, it is necessary to take into consideration all of the following 5 items:

- Thermodynamic performance
- Safety
- Stability
- Economy
- Environmental friendliness

In this study, first, thermodynamic constraints are set from the viewpoint of energy and economic performances. Specifically, the constraints are placed on the coefficient of performance (COP) and the volumetric heating capacity (VHC). Assuming the current condition of industrial heat pump installation in Japan, the lower limits of COP and VHC are roughly set to 4 and 2 MJ/m^2, respectively. Next, it is conceivable to set a restriction on the discharge temperature from the viewpoints of thermal and chemical stabilities of refrigerant and lubricant and viscosity of lubricant, however in this study the restriction is not set because the limitation is not clear at this moment. For example, the upper limit temperature could be increased by newly development of addition agent. Then, considering the safety and environmental friendliness of refrigerant, this analysis divided into the following 3 cases; (1) the case of selecting from low GWP and A1 refrigerants, (2) the case of selecting from low GWP and A1 or A2 refrigerants, and (3) the case of selecting from natural refrigerants.

3.2. Results

As an example of the calculation result, Figure 5 shows the working domain in the case of R245fa. The maximum heat pump supply temperature is determined only by the critical temperature because there is no restriction set on the discharge temperature. This heat pump can operate competitively in the range of the temperature lift of about 50 K or less due to the constraint of COP of 4 or more. Then, it can be seen that there is a region where the VHC is less than 2 MJ/m^2, even when the COP is 4 or more.

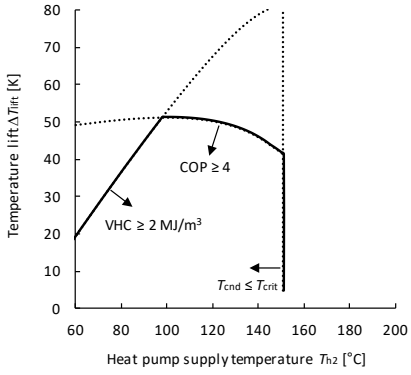

Figure 5. Constraints and working domain of simple heat pump cycle with R245fa

Figure 6 shows the working domains of each refrigerant. The left figure (a) illustrates HFC, HCFO and HFO refrigerants, and the right figure (b) illustrates natural refrigerants. It can be seen that the upper sides of the working domains of R1234yf and R1234ze(E) are close to R32 and R134a, respectively, and the right ends can be expanded. R1234ze(Z) and R1224yd(Z) have similar working domain to R245fa. R1233zd(E) and R1336mzz(Z) have the working domains on relatively higher temperature side.

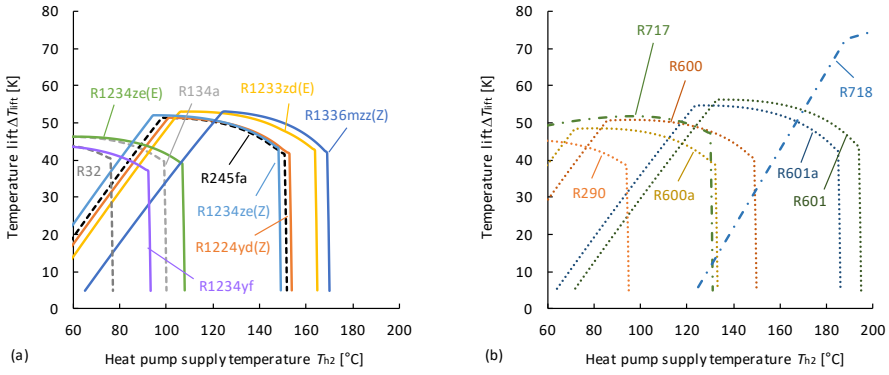

Figure 6. Working domains of simple heat pump cycles with 16 pure refrigerants

Figure 7 shows the composite diagrams so that the working domain is maximized when selecting refrigerants from each case of HFCs, HCFOs or HFOs, and natural refrigerants. It can be seen that the development of the new refrigerants (HCFOs and HFOs) has expanded the working domain and made it possible to construct competitive heat pumps under the conditions where the heat pump supply temperature is higher than before. On the other hand, natural refrigerant has the wide working domain. This indicates high temperature heat pumps can be constructed in a wide temperature range using only natural refrigerant in terms of thermodynamic performance.

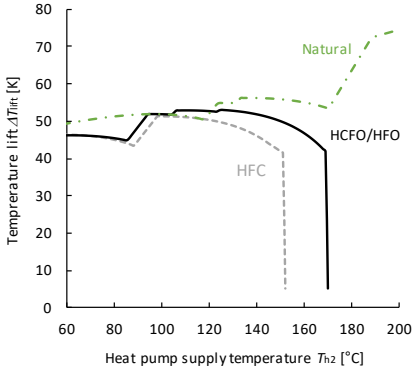

Figure 7. Maximum working domain of simple heat pump cycle

Next considers the safety and environmental friendliness of refrigerant. Figure 8 shows the maximum working domain in the following 3 cases; (1) the case of selecting from low GWP and A1 refrigerants, (2) the case of selecting from low GWP and A1 or A2L refrigerants, and (3) the case of selecting from natural refrigerants.

When selecting from low GWP and A1 refrigerants shown in the figure (a), R1224yd(Z) is promising in the heat pump supply temperature range below 105°C, R1233zd(E) from 105°C to 125°C, R1336mzz(Z) from 125°C to 165°C, and R718 over 165°C.

Then, when approving A2L refrigerants shown in the figure (b), R1234ze(E) becomes a candidate in the heat pump supply temperature range below 85°C, R1234ze(Z) from 85°C to 105°C, and then the working domain of R1224yd(Z) disappears.

On the other hand, when selecting from natural refrigerants shown in figure (c), R717 is promising below 120°C, R601a from 120°C to 130°C, R601 from 130°C to 170°C, and R718 over 170°C. However, it should be noted that the discharge temperature of R717 becomes relatively high. For example, the discharge temperature is 182°C when the heat pump supply temperature is 100°C. In the practical use, it would be necessary to cool the discharge vapor in some way.

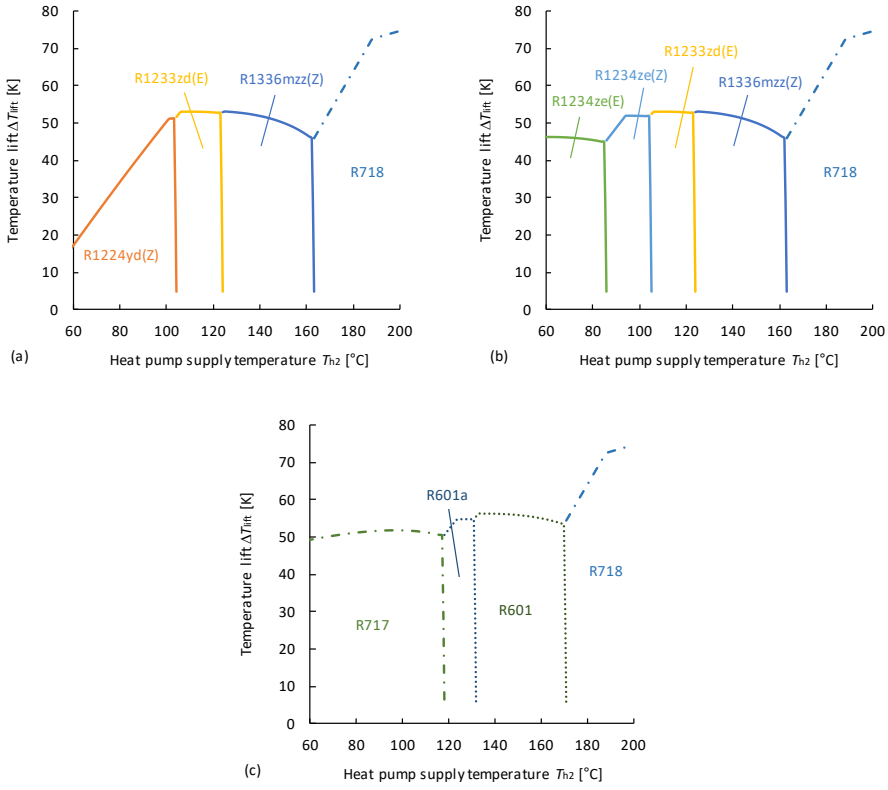

Figure 8. Maximum working domain of simple heat pump cycle (a) selecting from low GWP and A1 refrigerants (b) selecting from low GWP and A1 or A2L refrigerants (c) selecting from natural refrigerants

4. Analysis for two-stage heat pump cycle with economizer

Next, the effect of a high efficiency improvement by two-stage cycle with economizer are examined on the refrigerant selection.

4.1. Method

Each of the minimum superheating of the high-stage compressor and the low-stage compressor is fixed at 5 K. An internal heat exchanger is installed when the discharge superheating is smaller than the suction superheating. The compressor isentropic efficiency of each stage is set to a constant value of 0.8. The

intermediate pressure is defined by the square root of the product of the discharge pressure and the suction pressure. The ratio of refrigerant mass flow rate in the high-stage and low-stage is fixed at 1.5.

4.2. Results

Figure 9 shows the maximum working domain in the following 3 case; (1) the case of selecting from low GWP and A1 refrigerants, (2) the case of selecting from low GWP and A1 or A2L refrigerants, and (3) the case of selecting from natural refrigerants.

When selecting from low GWP and A1 refrigerants shown in the figure (a), R1224yd(Z), R1233zd(E), R1336mzz(Z) and R718 are promising in ascending order of heat pump supply temperature like the case of simple heat pump cycle.

On the other hand, when approving A2L refrigerants shown in the figure (b), R1234yf in the heat pump supply temperature range below 70°C and R1224yd(Z) in a narrow range around 120°C become candidates unlike the case of simple heat pump cycle. This would be because R1234yf has a larger effect of improving COP by the two-stage compression with economizer than R1234ze(E) and R1224yd(Z) has the larger effect than R1234ze(Z).

When selecting from natural refrigerants shown in figure (c), the working domain of R717, which has a relatively small performance effect by the two-stage compression with economizer, becomes narrowed, and R600 becomes a candidate.

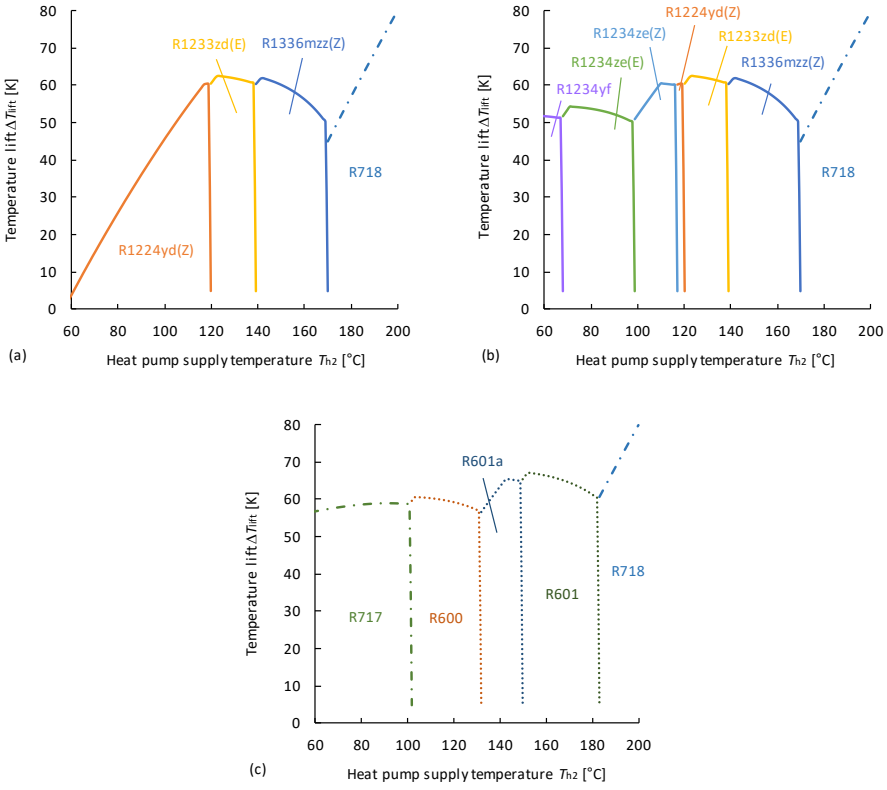

Figure 9. Maximum working domain of two-stage heat pump cycle with economizer (a) selecting from low GWP and A1 refrigerants (b) selecting from low GWP and A1 or A2L refrigerants (c) selecting from natural refrigerants

Figure 10 shows the comparison in maximum working domain between simple heat pump cycle and two-stage heat pump cycle with economizer. In any of the 3 cases, it can be seen that the temperature lifts expand by about 10 K thanks to the higher efficiency, although the improved ranges are limited; the range from 110°C to 160°C when selecting from low GWP and A1 refrigerants, the ranges below 85°C and from 110°C to 160°C when selecting from low GWP and A1 or A2L refrigerants, and the ranges below 115°C and from 140°C to 170°C when selecting from natural refrigerants. In other words, it means that the thermodynamic performance can be kept even when the heat source temperature become about 10 K lower than in the case of the simple heat pump cycle.

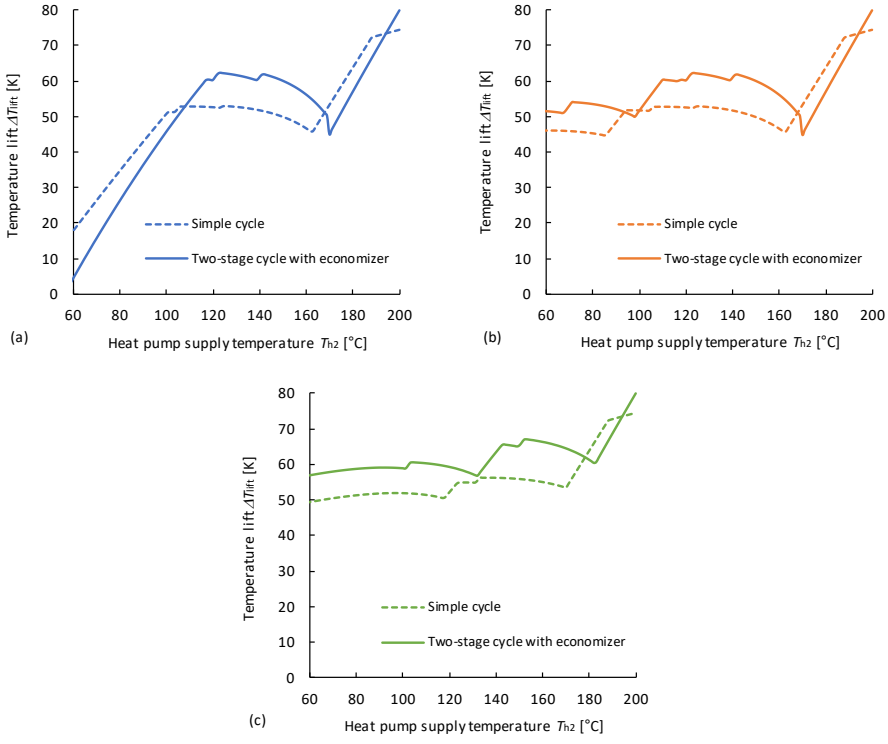

Figure 10. Comparison in maximum working domain between simple heat pump cycle and two-stage heat pump cycle with economizer (a) selecting from low GWP and A1 refrigerants (b) selecting from low GWP and A1 or A2L refrigerants (c) selecting from natural refrigerants

5. Conclusion

In this study, refrigerant selection for high temperature heat pump cycles is analyzed thermodynamically for the purpose of providing working domain maps which can determine the promising refrigerant and the upper limit of heat pumping temperature lift for each supply temperature. The following results are obtained:

- In terms of thermodynamic performance, high temperature heat pumps can be constructed in a wide temperature range from 60°C to 200°C using only natural refrigerant. R717, R601a, R601 and R718 are promising in ascending order of heat pump supply temperature. By improving the heat pump cycle with two-stage compression with economizer, R600 becomes a candidate and the working domain of R717 becomes narrowed.
- Considering the safety of the refrigerant, when selecting from low GWP and A1 refrigerants, R1224yd(Z), R1233zd(E), R1336mzz(Z) and R718 are promising. When approving A2L refrigerants, R1234ze(E) and R1234ze(Z) become candidates and the working domain of R1224yd(Z) disappears.

- By improving the heat pump cycle with two-stage compression with economizer, R600, R1234yf and R1224yd(Z), which have relatively larger effects, become candidates. And the temperature lift expands by about 10 K by the higher efficiency.

However, this study did not set the restriction on the discharge temperature. And this study focuses on the case where the temperature glides on both of heat source and heat sink are relatively small. Therefore, the following items are listed as the future issues:

- To set the restriction on the discharge temperature by considering the limitation of refrigerant stability and lubricant viscosity
- To analyze cases where the temperature glides on heat source and heat sink are relatively large by including transcritical heat pump cycle and other cycles with zeotropic mixed refrigerants

Abstract

As a method of improving the heat transfer of vapor-liquid two-phase flow in a mini-channel, there is the method of changing the shape. However, in previous researches, only the channel cross-sectional shape has been changed. In this study, the flow patterns of vapor-liquid two-phase flow in a plate heat exchanger with straight and wavy mini-channel was visualized, and the effect of changing the shape in the flow direction and the prospects for improving the heat transfer characteristics of the heat exchanger were investigated. A visualization experiment showed that imbalance in the liquid film thickness in the annular flow region of the wavy mini-channel in the flow direction. The thickness of the liquid film in the wavy mini-channel was measured and it was found that the thickness of the liquid film in the thin sections was less than half of that in the straight mini-channel and that in the thicker sections it was about 1.4 times thicker than that in the straight mini-channel. Then the heat transfer coefficient of wavy channel was almost 1.53 times better than the straight one.

Keywords:Mini-channel, Heat transfer, Vapor-liquid two phase flow, Boiling

1. INTRODUCTION

Currently, global warming is becoming a problem on a global scale. The production and consumption of CFC which causes global warming was restricted by the Montreal Protocol in 1987 and the emission factor was fixed in the Kyoto Protocol in 1997. In addition, alternative CFC was restricted by the Kigali Revision of the Montreal Protocol in 2016, too. Under the circumstances, it is considered that the refrigerant used in the refrigerator and air conditioner shifts to natural refrigerant such as ammonia. However, it is desirable to minimize the amount of refrigerant in them for safety because ammonia is toxic. In addition, we can achieve not only safety but also heat exchangers can be smaller by reducing the amount of refrigerant in heat exchangers. Therefore, enhancing the heat transfer performance in heat exchangers is need.

The heat transfer performance in heat exchangers can be improved by using microchannels with a diameter of about 1 mm. The reason of this phenomena are the evaporation heat transfer which occurs by heat conduction through the liquid film (liquid film evaporation heat transfer) in the slug flow area because the smaller the tube diameter, the thinner the liquid film present on the tube wall in addition to nucleate boiling heat transfer and forced convective heat transfer which are the mechanism of boiling heat transfer in the conventional channels and since the tube diameter is small in the micro tube, the liquid film present near the tube wall becomes thinner and the densification the heat transfer area with respect to the flow path area is increased.

K. Enoki (2013) [1] conducted experiments on boiling heat transfer coefficient and pressure drop measurement for each mini-channels, which has circular, rectangular and triangular cross sections. R 410A was used as the refrigerant, and the flow direction were vertical upward, vertical falling and horizontal. It

* Corresponding author.
E-mail address: enoki.koji@uec.ac.jp.

has been found that the boiling heat transfer coefficient was good for both circular, rectangular and triangular mini-channels. The high heat transfer coefficient was maintained up to high quality and decreased rapidly after occurred dryout. However, it was reported that the local heat transfer coefficient was different depending on the cross section.

In this study, the vapor-liquid two-phase flow in a heat exchanger was visualized by changing the mini-channel shape in the flow direction from a straight to a wavy, and the effects on the flow patterns and whether it can be expected to improve the heat transfer characteristics were confirmed. In addition, the boiling heat transfer coefficient of a single mini-channel was experimentally examined to show how much better the boiling heat transfer coefficient of a wavy mini-channel is compared with that of a straight one.

2. EXPERIMENTAL SET-UP AND PRODURES

The fluid used in this study is HFE-7000. For calculating the physical property value, we used NIST's REFPROP ver9.1 [2].

2.1. Visualization of flow patterns of a heat exchanger with wavy mini-channels

Figure 1 presents the schematic diagram of the experimental set-up for visualization of flow patterns. The fluid leaving the tank was sufficiently cooled by the double-pipe heat exchanger and pumped out at a constant flow rate by the syringe pump. The fluid was sufficiently cooled again by the double-pipe heat exchanger and flowed into the Coriolis flowmeter to measured mass flow rate. After that, the fluid was heated to a predetermined vapor quality by the preheater and flowed into the test section. The refrigerant leaving the test section was cooled by the condenser and returned to the tank.

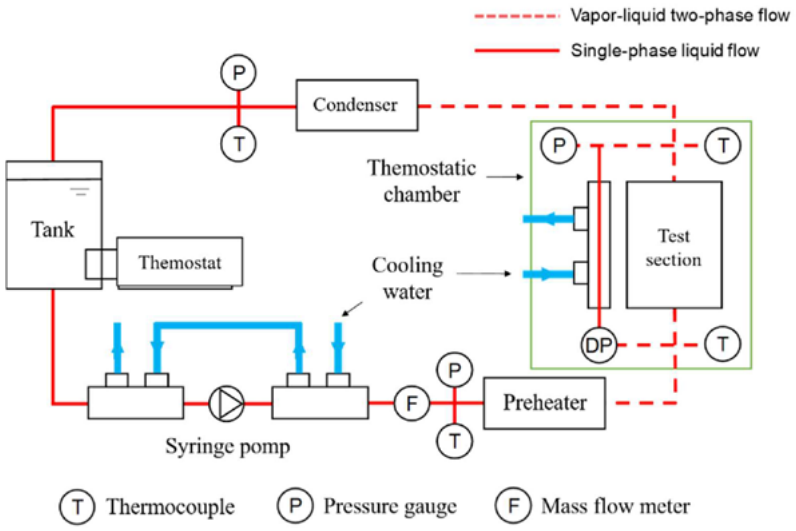

Fig. 1. Schematic diagram of experimental set-up for visualization

Two test sections were used in this study, one with a wavy and straight combined mini-channel and the other with only a straight mini-channel for comparison. The combined test section has wave-shaped in the upstream part and straight-shape in the downstream part channels, respectively. This combined test section is hereafter referred to simply as "wavy". Figure 2 shows a view of the wavy test section. The right figure of Fig. 2 shows the details of the test section when it is disassembled. As shown in these figures, the test section consisted of a glass for visualization, a metal plate made of stainless steel with a flow channel, a back plate with an inlet pipe, a back plate with an outlet pipe, and a copper plate, which were welded or bonded together. Flow channel plate is made of stainless steel in order to prevent corrosion even when ammonia is used as a refrigerant. The channels of the flow channel plate were created by etching. The visualization is achieved by mounting a glass in front of the flow channel plate and sealing it. The copper plate contains a cartridge

heater that directly heats the refrigerant flowing in the flow path uniformly by AC power. The refrigerant inlet is in the lower left corner and the outlet is in the upper center hole.

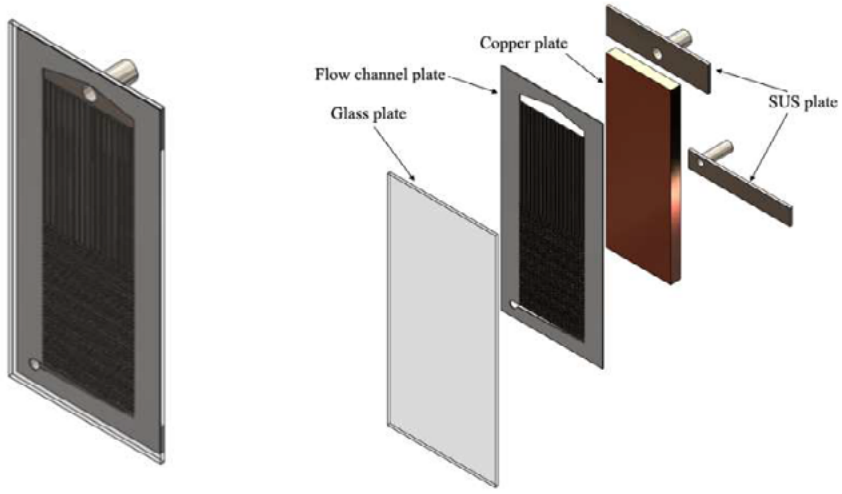

Fig. 2. Test section of wavy mini-channels

Figure 3 presents the schematic diagram of wavy mini-channels plate. Table 1 presents the specification of the wavy test section. The test unit processes 48 channels in a SUS304 plate. The flow path was structured such that the lower half was a wavy path with an amplitude of 0.4 mm and a wavelength of 4mm, and the upper half was a straight path. The right figure of Fig. 3 shows the details of the flow path of the test section. The width of the mini-channel was 1.49 mm and the width of the inlet of the mini-channel was 0.86 mm. The fluid flow was a vertical upward flow. The fluid flowed into the test section with an inlet quality of $x_{\text{in}} = 0.2$ and an outlet quality of $x_{\text{out}} = 0.9$. A high-speed camera was used to capture the flow of fluid in wavy paths. Red frames in Fig. 3 were the areas where videos were taken. The channel numbers are given from the inlet side and range from 1 to 48. The detailed locations of the red frames in Fig. 3 are, from left to right, channels 1 to 8 on the left side of the channel, 21 to 28 in the center of the channel, and 41 to 48 on the right side of the channel, and, from bottom to top, the inlet, 40 mm from the inlet, 132 mm from the inlet, and the outlet.

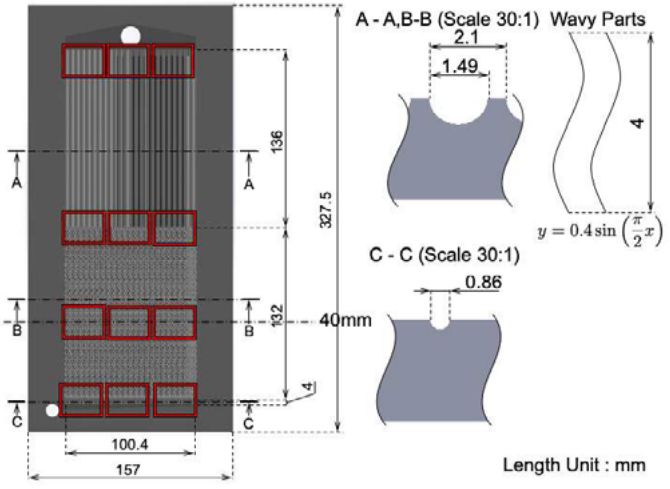

Fig. 3. Schematic diagram of wavy mini-channels plate

Table 1. Specification of wavy test section

	Flow path section	Choke section
Plate material	SUS316L	
Hydraulic diameter D[mm]	0.98	0.63
Flow area A[mm^2]	0.98	0.39
Wet perimeter l[mm]	4.02	2.46
Width d[mm]	1.49	0.86
Wavy amplitude a[mm]	0.4	
Wavelength of one wavy unit L[mm]	4	
The number of waves	33	1
Wavy line	$y = 0.4\sin(\frac{\pi x}{2})$	
The length of straight line [mm]	136	-
The length of wavy line [mm]	132	4
Number of flow paths	48	

2.2. Visualization of flow patterns of a heat exchanger with straight mini-channels

The visualization glass is installed in front of the flow channel plate, the heating method, the inlet and outlet ports, the direction of refrigerant flow, the shape of the inlet header, and shooting location are the same as for the wavy test section. The outlet header has a choke at the outlet end of the flow path to prevent backflow of the accumulated refrigerant. Figure 4 presents the schematic diagram of straight mini-channels plate. The right figure of Fig. 4 shows the details of the flow path of the test section. The width of the mini-channel was 1.59 mm and the width of the outlet of the mini-channel was 0.68 mm. Table 2 presents the specification of the straight test section

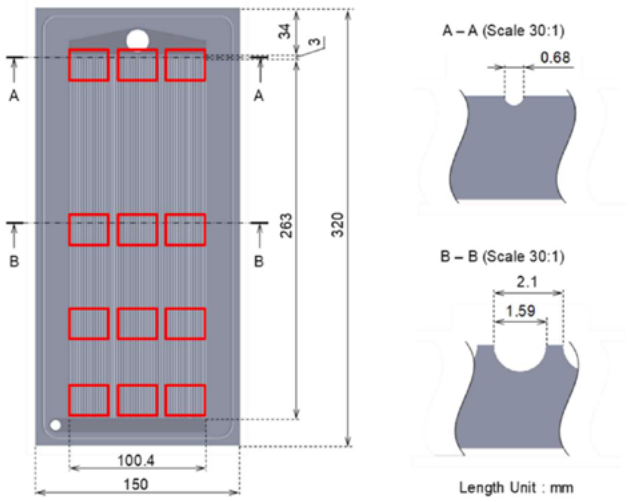

Fig. 4. Schematic diagram of straight mini-channels plate

Table 2. Specification of straight test section

	Flow path section	Choke section
Plate material	SUS316L	
Hydraulic diameter D[mm]	0.935	0.617
Flow area A[mm^2]	0.97	0.34
Wet perimeter l[mm]	4.14	2.22
Width d[mm]	1.61	0.69
Number of flow paths	48	

Table 3 presents the experimental conditions for the straight test section and the wavy test section.

Table 3. Experimental condition of test section

Refrigerant	HFE-7000
Saturation temperature [°C]	30
Absolute saturation pressure [MPa]	0.087
Mass flow rate M[kg/s]	0.002
Mass flux G [kg/(m^2 · s)]	40
Heat flux q [kW/m^2]	7.5
Latent heat Δh_v [kJ/kg]	135.5
Test section inlet quality x_{in}	0.2
Test section outlet quality x_{out}	0.9

The specific enthalpy of fluid mixing at the inlet and outlet of the test section was calculated based on the specific enthalpy at the inlet of the preheater, $h_{\text{PH in}}$. $h_{\text{PH in}}$ was determined from the pressure and temperature of the refrigerant in liquid single phase state measured at the inlet of the preheater. The specific enthalpy at the inlet of the test section, $h_{\text{TS in}}$, was calculated from the mass flow rate M, the electrical input at the preheater, Q_{PH}, and the heat gain from the inlet of the preheater to the inlet of the test section, Q_1, as shown in Equation (1). Furthermore, the specific enthalpy at the outlet of the test section, $h_{\text{TS out}}$, was calculated from the mass flow rate, M, the electrical input at the test section, Q_{TS}, and the heat gain from the inlet to the outlet of the test section, Q_2, as shown in Equation (2).

$$h_{\text{TS in}} = h_{\text{PH in}} + \frac{(Q_1 + Q_{\text{PH}}) \times 10^{-3}}{M} \tag{1}$$

$$h_{\text{TS out}} = h_{\text{TS in}} + \frac{(Q_2 + Q_{\text{TS}}) \times 10^{-3}}{M} \tag{2}$$

Using the values of Equations (1) and (2), the vapor quality x_{in} at the inlet of the test chamber and the vapor quality x_{out} at the outlet of the test chamber were calculated as shown in Equations (3) and (4) below. $h_{x=0}$ is the specific enthalpy of saturated liquid and Δh_v is the latent heat of evaporation of the refrigerant.

$$x_{\text{in}} = \frac{h_{\text{TSin}} - h_{x=0}}{\Delta h_v} \tag{3}$$

$$x_{\text{out}} = \frac{h_{\text{TSout}} - h_{x=0}}{\Delta h_v} \tag{4}$$

The quality errors at the inlet and outlet were calculated using the following equations (5) and (6).

$$\Delta x_{\text{in}} = \frac{(\Delta Q_1 + \Delta Q_{\text{PH}}) \times 10^{-3}}{M \times \Delta h_v} \tag{5}$$

$$\Delta x_{\text{out}} = \frac{(\Delta Q_2 + \Delta Q_{\text{TS}}) \times 10^{-3}}{M \times \Delta h_v} \tag{6}$$

The estimation errors for heat gain are $\Delta Q_1 = 0.00016\text{W}$ and $\Delta Q_2 = 0.00027\text{W}$, respectively. On the other hand, when we find the estimation error of each heater, we find that $\Delta Q_{\text{PH}} = 0.66\text{W}$ and $\Delta Q_{\text{TS}} = 1.5\text{W}$, which is large enough for the estimation error of heat gain. Therefore, the estimation error of each heater is dominant to the estimation error of quality. From the above, the quality errors at the inlet and outlet are calculated to be $\Delta x_{\text{in}} = 0.002$ and $\Delta x_{\text{out}} = 0.005$, respectively.

2.3. Measurements of boiling heat transfer coefficient

Figure 5 presents the schematic diagram of the experimental set-up for experimental investigation of boiling heat transfer coefficient in mini-channels. The fluid was pumped into the flow meter 1 and the flow rate was measured. Then, it branched in two directions, one goes to the test section and the other passes through the flow meter 2 and returned to the pump again. It was possible to adjust the flow rate of the fluid flowing to the test section accurately by adjusting the degree of opening of the valve before the preheater. The flow rate of fluid flowing to the test section was obtained by subtracting the value indicated by flow meter 2 from the value

indicated by flow meter 1. After that, the fluid heading for the test section was heated by the preheater. Afterward, the heat transfer coefficient was measured.

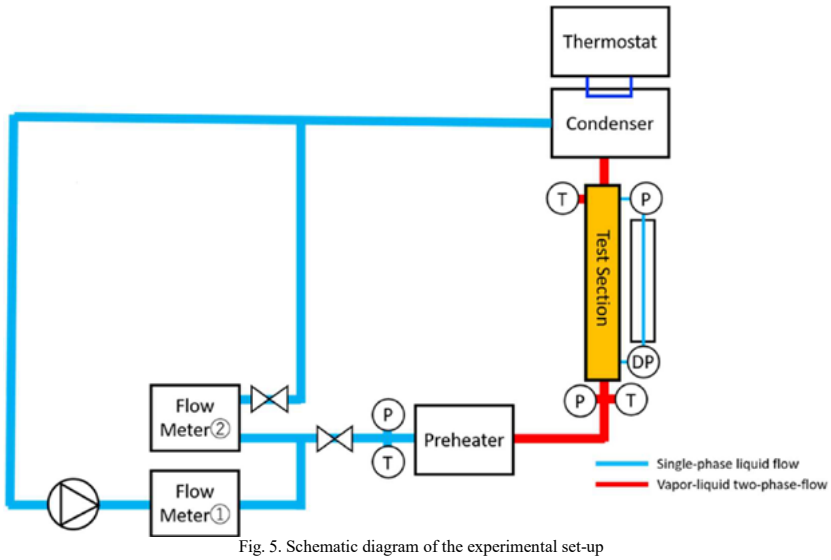

Fig. 5. Schematic diagram of the experimental set-up

Table 4 presents the specification of the mini-channels. The fluid was heated to a predetermined quality by the preheater and flowing into the test section. The temperature was measured at the test section inlet and outlet.

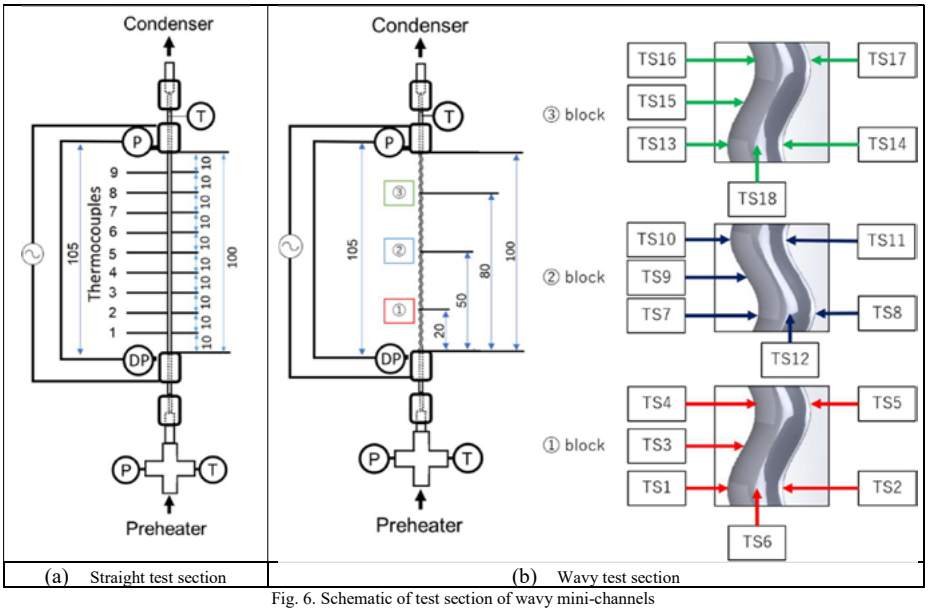

Table 4. Specification of the mini-channels

	Straight	Wavy
Material	SUS304	
Hydraulic diameter D[mm]	1.07	0.93

Amplitude a[mm]	-	0.4

Figure 6 presents a schematic view of the test section of straight mini-channels and wavy mini-channels. The fluid was heated to a predetermined quality by the preheater and flowed into the test section. The test section was directly heated by AC power. Thermocouples were attached as shown in Fig. 6 in three areas of 20 mm, 50mm and 80 mm from below the wavy mini-channels and at nine locations 10 mm apart from the entrance to the exit of the straight mini-channels. Also, the test section was covered with a cylindrical heat insulating material and glass wool was packed inside to reduce the heat loss to the surroundings as much as possible. In the test section, experiments were conducted with constant heat flux, and the inlet quality of the test section was changed. Table5 presents the experimental conditions. Local heat transfer coefficient was calculated from

$$\alpha = \frac{q}{T_\mathrm{i} - T_\mathrm{b}} \tag{7}$$

T_i was the temperature of the inner wall of the mini-channel. Since the mini-channel was heated from an AC power, T_i was calculated from the heat conduction equation by using measured temperature of the outer wall, the thickness of the mini-channel used, heat flux and the thermal conductivity of SUS304 taking into account internal heat generation. T_b was the average temperature of fluid. It was calculated from the specific enthalpy and local pressure of the fluid at the location where the thermocouple was attached by using REFPROP.

3. RESULTS AND DISCUSSION

3.1. Visualization of flow patterns in wavy mini-channels

Figure 7 shows the results of imaging of flow patterns at each location shown in Fig. 3 with a high-speed camera. In the inlet of the test section, slug flow was observed at channels of No.21 to No.28 and No.41 to No.48 and annular flow was observed at No.1 to No.8. In the area 40mm above the inlet of the test section, annular flow was observed at channels of No.1 to No.8 and No.41 to No.48 and slug flow was observed at No.21 to No.28. In other areas, annular flow was observed. It can be seen that the wavy area is filled with slug flow and annular flow. The annular flow has a high heat transfer rate in the tube forced convection boiling heat transfer. In the slug flow, liquid film evaporation heat transfer is generated by heat transfer through a thin liquid film in the mini-channels in addition to nucleate boiling heat transfer and forced convective heat transfer which are the mechanism of boiling heat transfer in the conventional channels. From this fact, it is considered the heat transfer performance of the wavy mini-channels is enhanced. Furthermore, flow disturbances were observed everywhere. Therefore, it is considered that the stretching and folding of the fluid elements by turbulence promotes fluid mixing and enhance heat transfer.

3.2. Visualization of flow patterns in straight mini-channels

Figure 8 shows the results of imaging the flow pattern of the straight test section at each of the locations shown in Fig. 4 with a high-speed camera. Annular flows were observed at the whole area of channels No.1 to No.8, slug flows in the inlet of the test section at channels No.21 to No.28 and No.41 to No.48, and annular flows in other areas. Back-flow was observed in channels No.45 to No.48, but it was only temporary.

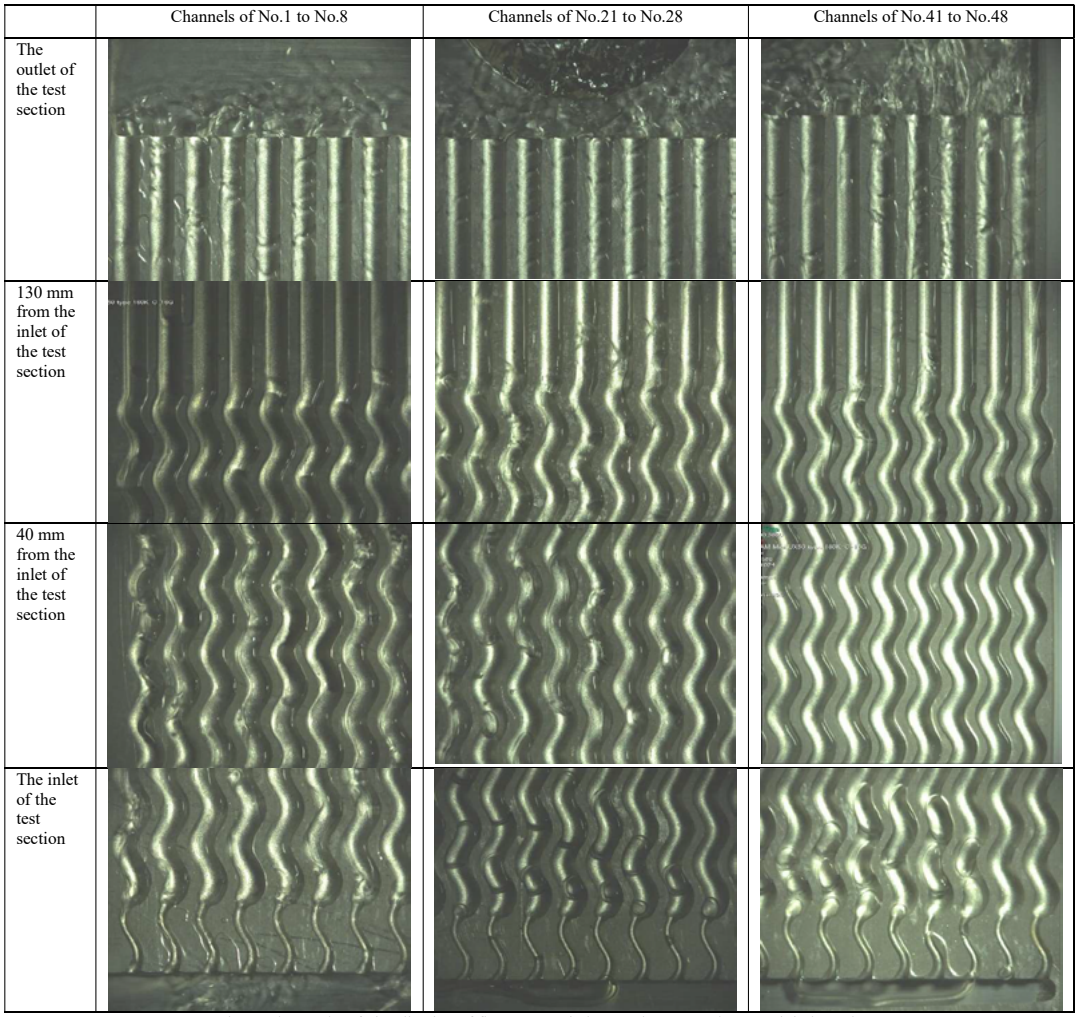

Fig. 7. The results of visualization of flow patterns in heat exchanger used wavy mini-channels

3.3. Effects of mini-channels shape change on the flow pattern and heat transfer coefficient

Enlarged images of the vapor-liquid two-phase flow in the straight test section and the wavy test section taken with a macro lens are shown in Figs. 9 and 10, respectively. The video images were taken at 132 mm from the channel entrance of channels No.21 to No.28 in the center of the test section. Figure 11 is the enlarged view of the red frame in Fig. 10. Figures 9 and 11 show that there is a clear bias in the thickness of the liquid film flowing through the channel wall in the annular channel region in the wavy channel compared to the straight channel, and that the liquid film is divided into thicker and thinner sections in the trough of the wavy mini-channel. In addition, it was found that the fluid is easily held in the trough of the wavy mini-channel and the liquid film is thick. Moreover, it turned out that thickness of liquid film is changing periodically as it became thicker and thinner in the points where it is thick. This phenomenon is considered to be due to the following mechanism. First, the liquid film grows and becomes thicker. After that, it breaks the surface tension of the channel wall and peels off as a droplet. Finally, the liquid film repeats the growth again. It can be seen that peeled droplets are believed to promote fluid mixing. On the other hand, the liquid film was very thin in other areas. Although liquid film evaporation heat transfer is originally observed in the

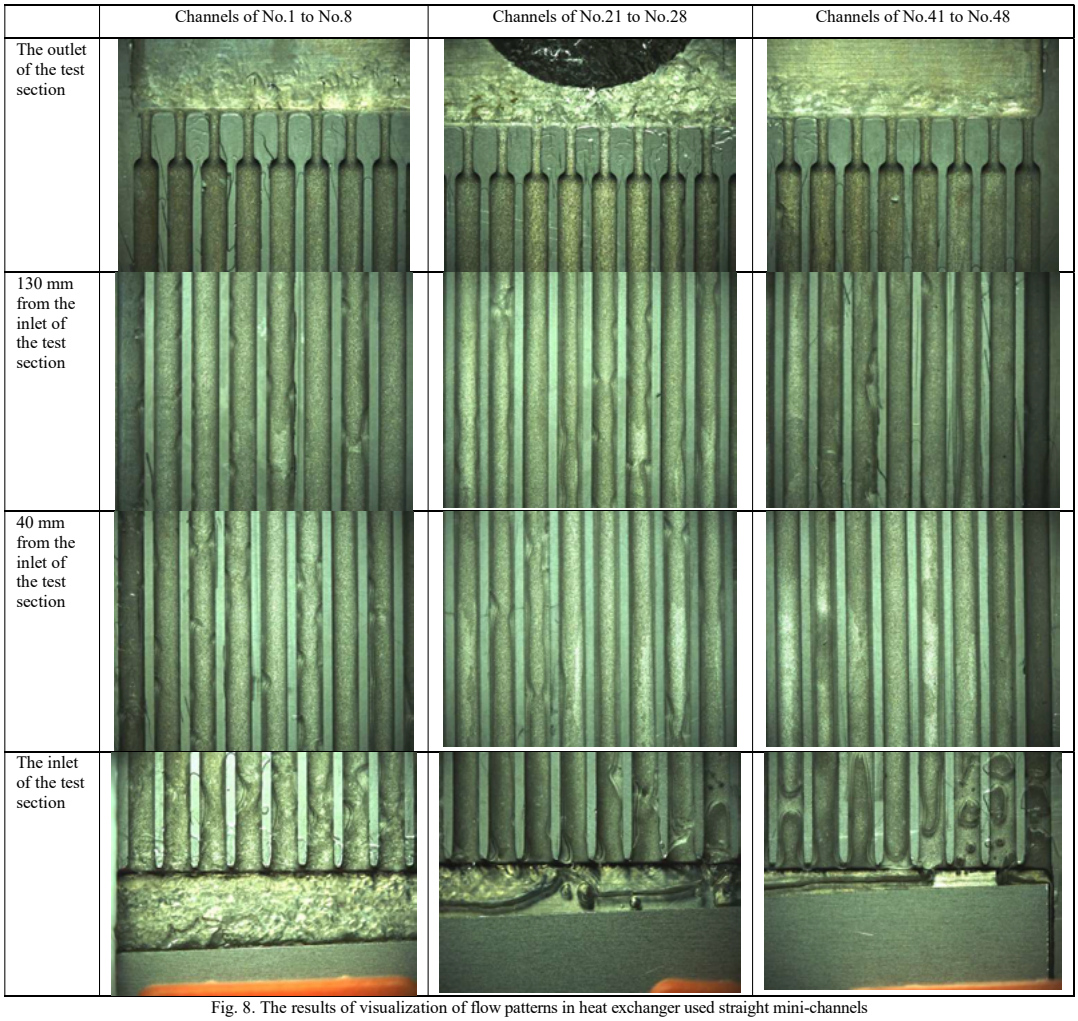

Fig. 8. The results of visualization of flow patterns in heat exchanger used straight mini-channels

slug flow area, since a very thin portion of the liquid film appears due to the thickness deviation of the liquid film, liquid film evaporation heat transfer is performed even in the annular flow area in wavy mini-channels. As a result, heat transfer performance is considered to be enhanced.

In order to estimate the thickness of the liquid film, measurements of the wall thickness of each channel were made using the video images. However, the thickness of the liquid film on the channel walls changed periodically in both straight and wavy channels. we measured the period of variation of the liquid film thickness at thicker points in the wave-shaped channel, and averaged the results of the measurement of the liquid film thickness within the period to obtain the average liquid film thickness as a parameter. In order to measure the period of the film thickness variation, images were taken at 132 mm from the channel entrance of the channel No.21 to No.28 (Fig. 8), where the film thickness variation was most clearly captured, by using a Photron FASTCAM Viewer 3. Table 6 shows the results of the measurement of the thickness variation period of the liquid film. The channel numbers are numbered 1 to 7, from left to right, for channels No.21 to No.28 in the center of the channel, as seen in the video taken at 132 mm from the channel entrance.

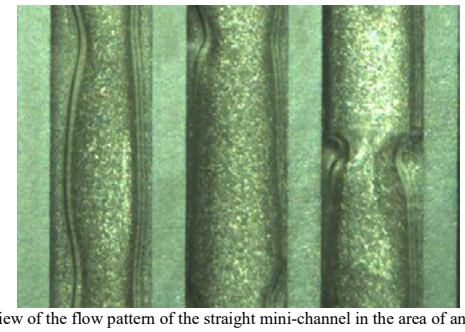

Fig. 9. View of the flow pattern of the straight mini-channel in the area of annular flow

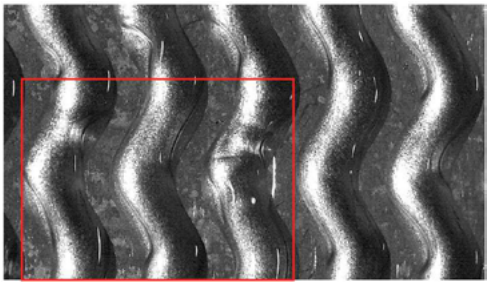

Fig. 10. View of the flow pattern of the wavy mini-channel in the area of annular flow

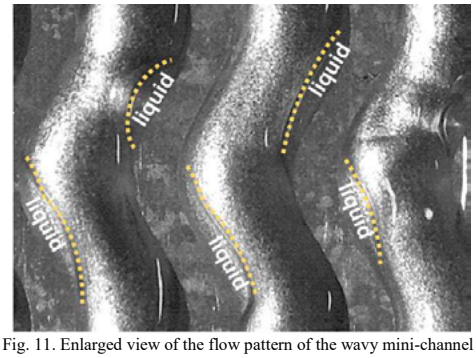

Fig. 11. Enlarged view of the flow pattern of the wavy mini-channel

Table 6. Fluctuation period of thickness of liquid film

Number of flow path	1	2	3	4	5	6	7
Fluctuation period of thickness of liquid film (frame, 1frame = 0.0005 s)	75.5 (0.038 s)	45.4 (0.023 s)	80.2 (0.040 s)	43.5 (0.022 s)	55.4 (0.028 s)	69.1 (0.035 s)	59.2 (0.030 s)

The average period of variation in the thickness of the liquid film was calculated by averaging the values in Table 6 to obtain 61.2. Therefore, the shooting speed used 60 frames out of 2000 fps as the approximate period of liquid film thickness variation, and measurements of 60 frames of liquid film thickness were made for both straight and wavy channels. Here, the period of liquid film thickness variation is 0.03 seconds. The wavy channel was divided into two sections, one where the film thickness was thicker and one where it was thinner, and the other where the film thickness was too thin to be measured, and the thickness of the wavy channel was measured for 60 frames. The area of the thickest liquid film in each frame was measured. The liquid film thicknesses were measured for 60 frames in the straight channel, the wavy channel where the film is thin, and the wavy channel where the film is thick, and averaged. The average liquid film thicknesses of the straight and wavy mini-channels are shown in Table 7. Table 7 shows that the liquid film thickness in

the wavy channel is about 1.4 times thicker than that in the straight mini-channel and less than half in the thin section.

Table 7. Average of thickness of liquid film

Straight	Wavy(thick parts)	Wavy(thin parts)
0.278mm	0.388mm	0.129mm

3.4. Boiling heat transfer coefficient in wavy mini-channels

Figure 12 shows that heat transfer coefficients at each position where thermocouples were attached. In addition, it is shown with heat transfer coefficients in straight mini-channels for comparison. As you can see from Fig. 12, the heat transfer coefficient at the mounting position of each thermocouple increases with increasing quality and it becomes maximum around the quality 0.45 and then drops. Therefore, it is considered that the dryout occurs at around the quality 0.45. In Fig. 12, the heat transfer coefficient is higher in the crest of the wavy mini-channels compared to the trough. From visualization experiments, it can be observed that the liquid film is thinner in the crest of the wavy mini-channels. These results suggest that the liquid film is thinner in the crest of the wavy mini-channels, which leads to liquid film evaporation heat transfer and thus improved heat transfer performance. The average heat transfer coefficients of the straight and wavy mini-channels before dryout are calculated as $\alpha = 1.73\mathrm{kW/(m^2 \cdot K)}$ for straight one and $\alpha = 2.65\mathrm{kW/(m^2 \cdot K)}$ for wavy one. Therefore, it can be seen that heat transfer coefficient of the wavy mini-chnnels was about 1.53 times better than that of straight one with the same cross section area of flow path.

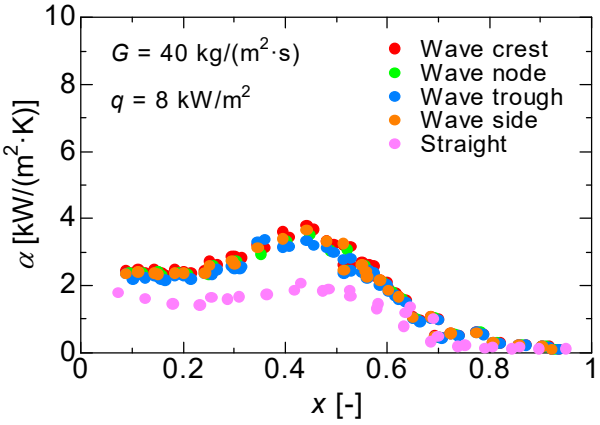

Fig. 12. Heat transfer coefficient at each thermocouple mounting position of the wavy mini-channel in $G = 40\ \mathrm{kg/(m^2 \cdot s)}$

4. CONCLUSIONS

In this study, the visualization of the flow pattern of vapor-liquid two phase flow in the wavy mini-channels and straight mini-channels were performed. In addition, in order to consider these, boiling heat transfer coefficient of wavy mini-channels and straight mini-channels were investigated experimentally. From the results of the experiment, we got the knowledge shown below.

(1) Compared to straight channels, there is a clear bias in the thickness of the liquid film flowing on the wall of the annular flow region in wavy channels. In addition, thickness of liquid film is changing periodically in the points where it is thick. As a result, heat transfer performance is enhanced by liquid film evaporation heat transfer not only in the slug flow region but also in the annular flow region. Furthermore, the disturbances observed may promote fluid mixing and contribute to improved heat transfer. The bias of the liquid film thickness in the wavy mini-channels is less than half of that in the straight mini-channels and about 1.4 times thicker in the thicker areas.

(2) Heat transfer coefficients in wavy mini-channels increase with increasing quality and it drop after becoming maximum. The heat transfer coefficient is improved in the crest where the liquid film in the wavy mini-channels is considered to be thin. In addition, heat transfer coefficients in wavy mini-channels before dryout show about 1.53 times better than that of straight mini-channels.

Abstract

In this study, the heat transfer coefficients of R 32 and R 1234ze(E) were measured, respectively. In order to mixing affect, the heat transfer coefficient and mass ratio were measured and analyzed by changing the mixture mass ratio of the R 32 / R 1234ze(E) from 3 to 100 kW/m^2 heat flux. By attaching a thermocouple directly to the copper boiling surface, raw data were successfully measured without obtaining the surface temperature by a calculation formula. The mass fraction on the heating surface were also analyzed by gas chromatography. The above methods have made it possible to acquire data with high accuracy. The heat transfer coefficient was decreased for the zeotropic refrigerant mixtures compared to the pure refrigerants, specifically, the data of refrigerant mixture R 32 / R 1234ze(E) with a mass ratio of 0.2/0.8 showed the minimum value. The variation of the mass ratio near the heating surface that was not observed for the near-azeotropic refrigerant mixture occurred for the zeotropic refrigerant. In zeotropic mixtures, it was clear that the change in properties occurred in the boiling region.

Introduction

1. Introduction

Currently, one of the measures to cope with global warming is the development of a refrigerant with a low GWP for use in refrigeration air conditioner. In addition, the Kigali amendment to the Montreal Protocol, agreed upon in 2016 and issued in 2019, restricted the production and consumption of HFC-based refrigerants. Therefore, development and use of natural refrigerants such as olefin-based low-GWP refrigerants and natural refrigerants using CO_2 and NH_3 as new alternative refrigerants have been promoted. However, due to flammability, toxicity, and reduced efficiency, some proposed new alternative refrigerants for use in refrigeration air conditioner units have not been determined at this stage[1]. New refrigerant mixtures of HFCs and olefin-based refrigerants are expected to be developed to solve this problem.

On the other hand, the phase change heat transfer equation is necessary for the optimal design of the heat exchanger of a refrigeration and air-conditioning equipment. There are various correlations, but they are limited due to their dependence on the diameter, the shape of the pipe and the type of refrigerant used. In actual phase change flow studies of existing refrigerant mixtures, boiling and condensation heat transfer and pressure drop in the tubes are obtained by changing the mixing ratio[2-9]. Pool boiling of refrigerant mixture has also

* Corresponding author.
E-mail address: enoki.koji@uec.ac.jp.

been studied from various viewpoints[10-13]. However, even if the mixing ratio of the system is known, the local properties where pressure drop and heat transfer occur remain unknown.

The purpose of this study is to measure the local physical properties by using an experimental apparatus of nucleate pool boiling heat transfer and to enable the calculation of local physical properties from the mixing ratios of the location where thermal physical phenomena occur. Ultimately, this method will enable us to treat complex refrigerant mixtures, which are not dependent on tube size or refrigerant, as a single refrigerant by simply using a conversion formula from system properties to local physical properties. In this study, as an initial step, the nucleate pool boiling heat transfer and phase of zeotropic mixture R 32 / R 1234ze(E) on a circular copper block were investigated and observed. Moreover, Gas chromatography was used to analyze the mass ratios of the boiling area of the refrigerant.

2. Experiment

2.1. Experimental apparatus and methods

A schematic diagram of the experimental apparatus used in this experiment is shown in Fig. 1. Refrigerants flowed through the port valves of System 2, passing through a solenoid valve, a check valve, a Coriolis flowmeter, and a needle valve, in that order, to the tank beyond valve 4. The Coriolis mass flowmeter, control system, and solenoid valve were synchronized, and the Coriolis mass flowmeter measured the mass flow rate, and when the mass flow rate reached the mass flow rate set by the control system, the solenoid valve automatically stopped the flow. Two thermostatic baths, one in the tank and the other in the test section, were used to transport the refrigerant using pressure fluctuations caused by temperature differences. The tanks were removable and weighed using digital measurements as the refrigerant was transported or recovered. Pressure sensors are installed in two locations to measure both in vapor and liquid. The mass flow rate of the lost refrigerant could be measured and confirmed by assembling a circuit to allow the refrigerant that was spilled when using gas chromatography to flow to the port valve in System 1. A vacuum pump was used to draw a vacuum throughout the entire apparatus before and after the experiment, and when the mixing mass ratio was changed, it was done outside the test section. After the experiment, refrigerants were disposed of in the refrigerant collection unit beyond valve 5.

Figures 2 and 3 show the test section of copper surface (diameter of 30 mm) and Copper block. Thermocouples were placed at seven locations: three on the copper surface, three in the copper block, and one in the liquid. Thermocouples in the copper block with metal grease were installed to measure the heat flux, and thermocouples on the copper surface were installed to measure the raw data directly, so it was expected to be measured with greater accuracy. Incidentally, all of the thermocouples used in this study were tested and were able to be measured with an accuracy of ±0.05°C.

Figure 4 shows a visualization of the nucleate pool boiling. The long bar in the center is a probe, which sucks up refrigerant and makes it possible to analyze the local mass ratio where boiling occurs. The distance between the probe tip and the copper surface is 6 mm. The wall superheat can be calculated from the saturation temperature measured by thermocouples in the liquid refrigerant and the wall temperature measured by thermocouples attached to the copper surface.

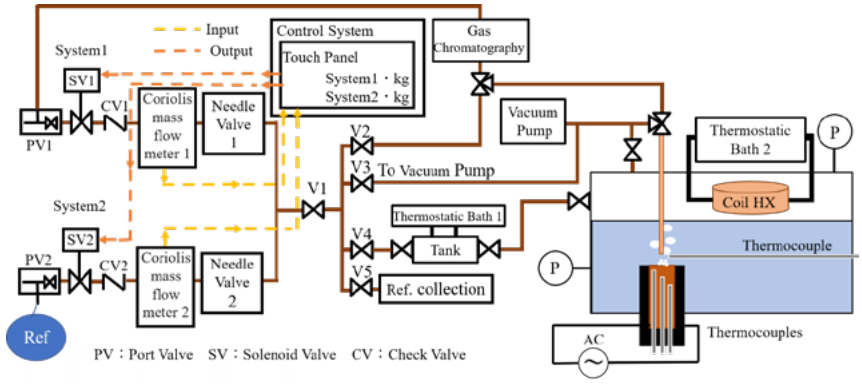

Fig. 1. Schematic diagram of experimental apparatus

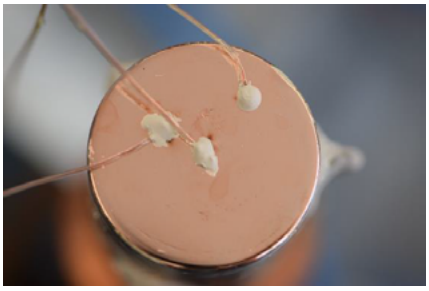

Fig. 2. Test section of copper surface

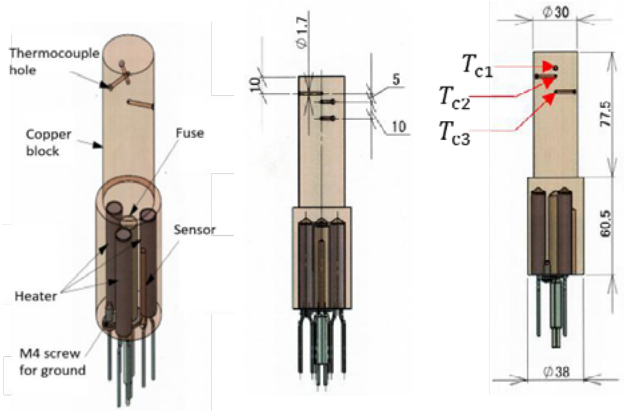

Fig. 3. Test section of copper block

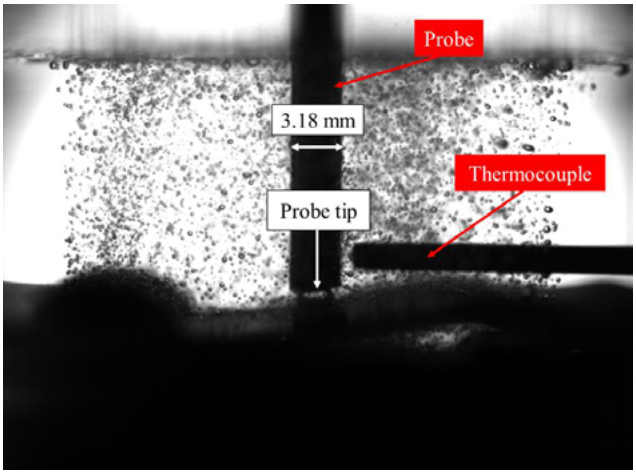

Fig. 4. Visualization of nucleate pool boiling (R 32 / R1234ze(E) (0.7/0.3), $q = 7$ kW/m^2)

2.2. Data reduction methods

The heat flux was calculated by Eq. (1).

$$q = \lambda \frac{dT}{dx} \tag{1}$$

where q and λ are the heat flux of the copper block [W/m^2] and the thermal conductivity of copper [W/mK], respectively. As for dT/dx, it is determined by the temperature gradient [K/m] calculated from the temperature T_{c1}, T_{c2} and T_{c3} measured by the first, second, and third thermocouples from the top inserted in the copper block and the displacement between each thermocouple, as shown in Fig. 5.

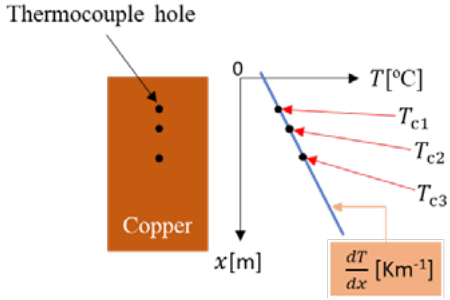

Fig. 5. How to determine heat flux

Using Equation (1), the local heat transfer coefficient is defined as follows:

$$\alpha = \frac{q}{(T_w - T_l)} \tag{2}$$

where α, T_w and T_l are local heat transfer coefficient of the copper surface [W/m^{2}K], the measured temperature of the thermocouple directly mounted on the copper surface [°C], and the temperature measured by the thermocouple in the liquid [°C], respectively. As described in section 2.1, raw data could be obtained by attaching the thermocouple directly to the copper surface, and therefore, more accurate measurements were expected.

When analyzing the local properties of a boiling region using gas chromatography, the mass ratio is calculated as follows:

$$W_{R\,32} = \frac{\frac{w_{R\,32}}{S_{R\,32}} S'_{R\,32}}{\frac{w_{R\,32}}{S_{R\,32}} S'_{R\,32} + \frac{w_{R\,1234ze(E)}}{S_{R\,1234ze(E)}} S'_{R\,1234ze(E)}} \tag{3}$$

$$W_{R\,1234ze(E)} = \frac{\frac{w_{R\,1234ze(E)}}{S_{R\,1234ze(E)}} S'_{R\,1234ze(E)}}{\frac{w_{R\,32}}{S_{R\,32}} S'_{R\,32} + \frac{w_{R\,1234ze(E)}}{S_{R\,1234ze(E)}} S'_{R\,1234ze(E)}} \tag{4}$$

where w and S are mass ratio and peak area determined by gas chromatography before boiling. W and S' are mass ratio and peak area determined by gas chromatography while boiling in optional heat flux. The peak area is automatically analyzed and shown by gas chromatography.

2.3. Investigation of soundness of the experimental equipment

In order to confirm the soundness of the experimental equipment used in this study, a comparison of the experimental data for refrigerant R 32 and R410A with the equation of Jung et al.[14] is shown in Fig. 6. The results were able to predict the experimental data within 8.2% mean deviation and 9.2% standard deviation. These results provide relatively accurate data that will enable reliable measurements of the heat transfer

coefficients for any unknown refrigerant from now on. All properties were obtained from REFPROP 10.0 when using the Jung et al.'s correlation.

Figure 7 shows the results of measuring the mass ratio of the R 32 component of R 410A for each heat flux. Since R 410A is a near-azeotropic refrigerant mixture, it was confirmed that the physical properties near the heat transfer surface didn't change during boiling. On the contrary, different mass ratios were revealed to cause changes in local physical properties.

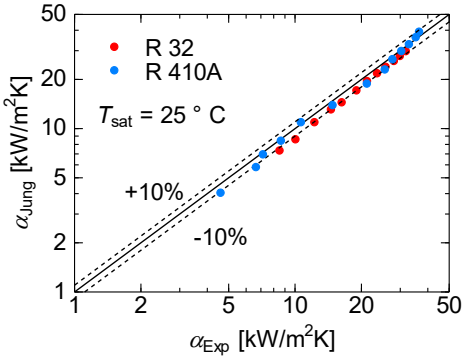

Fig. 6. Comparison of experimental values of R 32 and R 410A with Jung et al.'s correlation

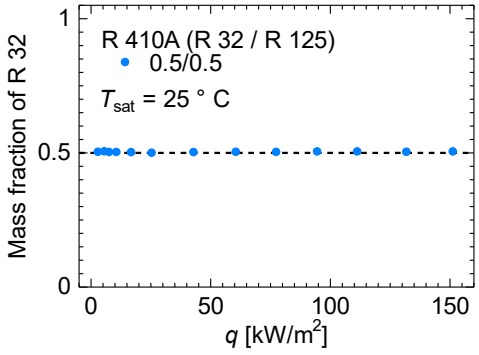

Fig. 7. Mass fraction of R 32 of R 410A

3. Results

In this study, local heat transfer coefficient measurements of pure refrigerants R 32 and R 1234ze(E) and local heat transfer coefficients and mass ratios of the refrigerant mixture R 32 / R 1234ze(E), varying the mixture mass ratio, were measured under the experimental conditions of saturation temperature of 25°C and heat flux of 3 to 100 kW/m^2.

3.1. Local heat transfer coefficients of each refrigerant

Figure 8 shows R 32, R 1234ze(E) and the refrigerant mixture R 32 / R1234ze(E) as heat flux on the horizontal axis and heat transfer coefficient on the vertical axis. As reported by other researchers, a feature of the zeotropic mixtures was found to be a decrease in the amount of increase in heat transfer coefficient decreased with increasing heat flux[10,11]. The reduction in heat transfer coefficient in this zeotropic mixture has been attributed to mass transfer resistance caused by interdiffusion due to the concentration gradient of the mixed refrigerant[2,3,6,7,8,12]. Moreover, the heat transfer coefficient of the nucleate pool boiling of R 32 /

R1234ze(E) was found to be the lowest at a mixing mass ratio of 0.2/0.8. The results are similar to the report that the evaporative heat transfer coefficient was at a minimum value for the mass ratios of refrigerant mixture R 32 / R 1234ze(E) of 0.15/0.85, 0.20/0.80, and 0.25/0.75 for quality 0.2, 0.5, and 0.8, respectively, as shown in the Kondo et al.'s flow experiments[3] and the evaporative heat transfer coefficient was at a minimum value for the mass ratios of refrigerant mixture R 32 / R 1234ze(E) of 0.25/0.75 as shown in the Lee et al.'s flow experiments[4]. The reason why the refrigerant mixture R 32 / R 1234ze(E) of 0.2/0.8 was the lowest heat transfer coefficient will be the subject of future research.

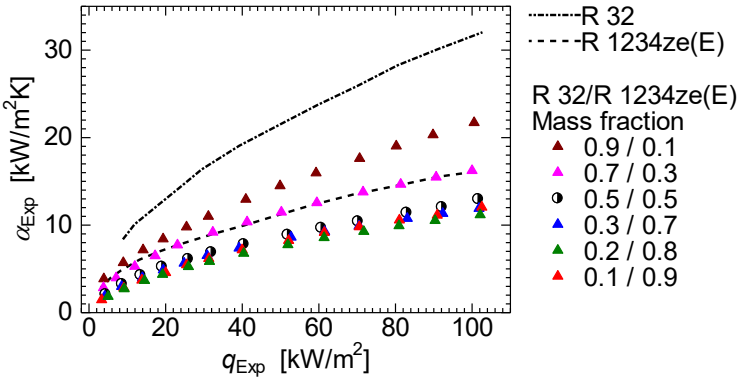

Fig. 8. Local heat transfer coefficients of R 32, R 1234ze(E) and R 32 / R 1234ze(E)

3.2. Mass fraction change of refrigerant mixture R 32 / R 1234ze(E)

Figure 9 shows the local mass fractions of nucleate pool boiling for R 32 and R 1234ze(E) during heat flux measurements for each mixture of R 32 / R 1234ze(E) with different mass ratios. The plot points represent the mean value of the mass ratio and the error bars indicate the range of concentrations that can be taken, i.e. the maximum and minimum values. When the mass ratio of the mixture was biased in favor of one of the refrigerants, there was relatively little variation, but when the mass ratio was close, significant variation was observed. In particular, for the refrigerant mixture R 32 / R1234ze(E) mass ratios of 0.5/0.5, there was an overall decrease in the mass ratio of R 32 and an increase in the mass ratio of R 1234ze(E). In addition, on the whole, in the case of a mass ratio of R 32 below 0.5, the local mass ratio of the boiling region tended to become decrease, and the mass ratio tended to become increase when the mass ratio was greater than 0.5. Comparing the results of Figs. 6 and 8, it was confirmed that the zeotropic refrigerant mixture caused a remarkable change in properties near the heat transfer surface. In addition to the mass transfer resistance, this change in physical properties may have a marked effect on the heat transfer coefficients of an azeotropic mixture.

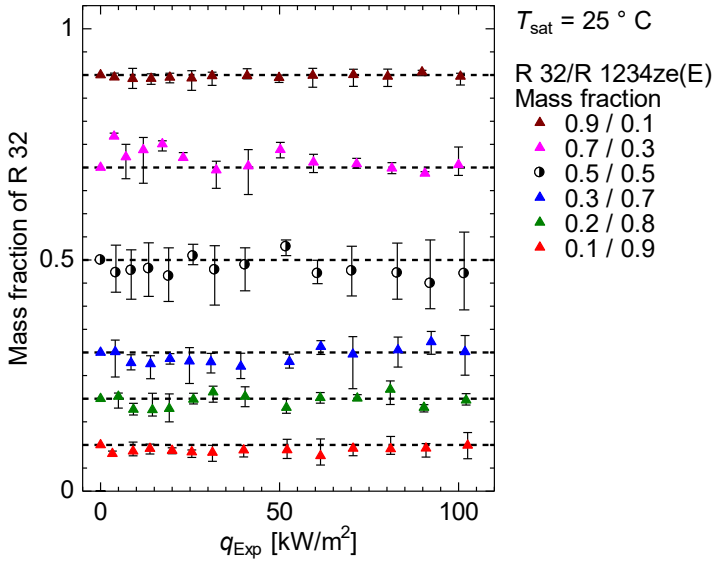

Fig. 9. Mass fraction of R 32 of R 32 / R 1234ze(E)

4. Conclusions

This study measured the pool boiling heat transfer coefficient for R 32, R 1234ze(E) and refrigerant mixture R 32 / R 1234ze(E) and the mass ratio near the heating copper surface for R 32 / R 1234ze(E) under experimental conditions of 25 °C saturation temperature and heat flux from 3 to 100 kW/m^2. Based on the results of this experiment, the following conclusions can be drawn.

1. For all refrigerants, the increase in heat transfer coefficient decreased as the heat flux increased, but for the zeotropic mixtures, the increase was significantly less. Especially, the heat transfer coefficient of the refrigerant mixture R 32 / R 1234ze(E) with a mass ratio of 0.2/0.8 was minimal.
2. In case of a mass ratio of 0.5/0.5 for the refrigerant mixture R 32 / R 1234ze(E), there was a large variation in the mass ratio near the heating surface and a noticeable decrease in the mass ratio of R 32.
3. The variation of the mass ratio near the heating surface that was not observed for the near-azeotropic refrigerant mixture occurred for the zeotropic refrigerant. In zeotropic mixtures, it was clear that the change in properties occurred in the boiling region.

Since there is little information on the local boiling properties of azeotropic refrigerant mixtures, more detailed investigation and further research are needed. We will develop our discussion and research based on these results and conclusions in the future.

Load-Based Testing Methodology for Evaluating Advanced Heat Pump Control Design

Parveen Dhillon[a*], W. Travis Horton[a], James E. Braun[a]

[a]*Ray W. Herrick Laboratories, School of Mechanical Engineering, Purdue University, West Lafayette, 47907-2099, USA*

Abstract

Optimum control design has been an important aspect of improving the performance, efficiency and thermal comfort delivery of heat pump systems. Despite extensive research work on the development of advanced controls for heat pumps, most heat pump systems in the field still utilize simple controls such as PI (Proportional-Integral), cascaded PI, etc. One of the main reasons for this is the difficulty in assessing the actual improvement in energy performance and thermal comfort delivery of heat pumps with advanced controls. The current practice of performing extensive season-long field studies is time-consuming and requires significant resources to carry out. Also, the performance results of these field studies are limited to the test building type and local climate conditions. To overcome this problem, a load-based testing methodology has been developed to evaluate the performance of advanced heat pump control design for different building types and climate zones in a psychrometric test facility. This methodology provides a way for product developers to significantly accelerate the development of advanced control design and to obtain realistic performance assessments in a timely manner. In this paper, the load-based testing approach is demonstrated for performance assessment of two different control algorithms for a residential heat pump. In addition, the effect of equipment oversizing and undersizing on heat-pump performance is studied utilizing the test approach.

Keywords: Load-based Testing; Performance Evaluation; Control Design; Heat Pump

1. Introduction

In recent years, the increase in microprocessor computing power and decrease in hardware cost have facilitated an opportunity for implementing more advanced controls in heat pump and air-conditioning systems. Even though these improvements lead to more efficient system operation, only a very small fraction of residential air conditioners and heat pumps currently sold in the U.S. market utilize advanced high-efficiency controls [1]. One of the primary reasons for this is the difficulty in evaluating short-term and seasonal performance improvements with advanced controls in a timely and cost-effective manner. To address this issue, a load-based testing methodology has been developed, which allows qualitative and quantitative evaluations of equipment performance with different embedded control designs for representative buildings and climate conditions using tests performed in a laboratory facility. With this methodology, it is also possible to study how equipment performance varies with oversizing or undersizing for a building. The developed methodology can further be used as a basis for seasonal performance ratings of air-conditioning and heat-pumping equipment as presented in [2], [3] and [4].

The load-based testing methodology emulates the response of building sensible and latent loads to the equipment controls in a psychrometric test chamber by continuously updating the room temperature and humidity based on a virtual building model. The test unit thermostat naturally responds to this dynamic temperature variation and controls the equipment in response to a deviation from its setpoint. This method can

capture realistic performance of a heat pump in a psychrometric test chamber, similar to a field application. In this way, load-based testing can be implemented to quantify performance differences among different equipment control architectures in a lab-setup and also qualitatively study the dynamic performance and comfort delivery of the equipment. This testing methodology can be applied to both variable-speed as well as staged equipment.

The method is based on an approach presented by Hjortland & Braun [5] for performance characterization of fixed-speed and variable-speed unitary air-conditioning equipment. Patil *et. al.* [2] and Cheng *et. al.* [6] applied the load-based testing methodology to generate data for estimating seasonal performance of variable-speed residential heat pumping and air conditioning equipment. In the current paper, the load-based testing methodology is implemented to perform a qualitative and quantitative comparison of the dynamic performance of a variable-speed heat pump in cooling mode in terms of energy efficiency and comfort delivery. The impact of two different control modes is considered along with equipment undersizing and oversizing.

To capture the dynamic performance of equipment that is representative of field applications with this methodology, it is important to have a representative virtual building model and representative outdoor ambient conditions. Also, to allow for testing different size heat pumps, the virtual building model needs to be scalable with equipment rated capacity. In this study, the load-based testing methodology was implemented on a 5-ton residential heat pump with an appropriately scaled virtual building model. The study considered only cooling mode performance for typical mid-summer and peak-summer season days with representative daily outdoor temperature profiles.

2. Load-Based Testing Overview

The load-based testing methodology captures the holistic performance of an equipment including its thermostat and integrated controls in a test facility setup. Fig. 1 outlines the layout of the load-based test approach of a split-type heat pump system installed in two side-by-side psychrometric chambers.

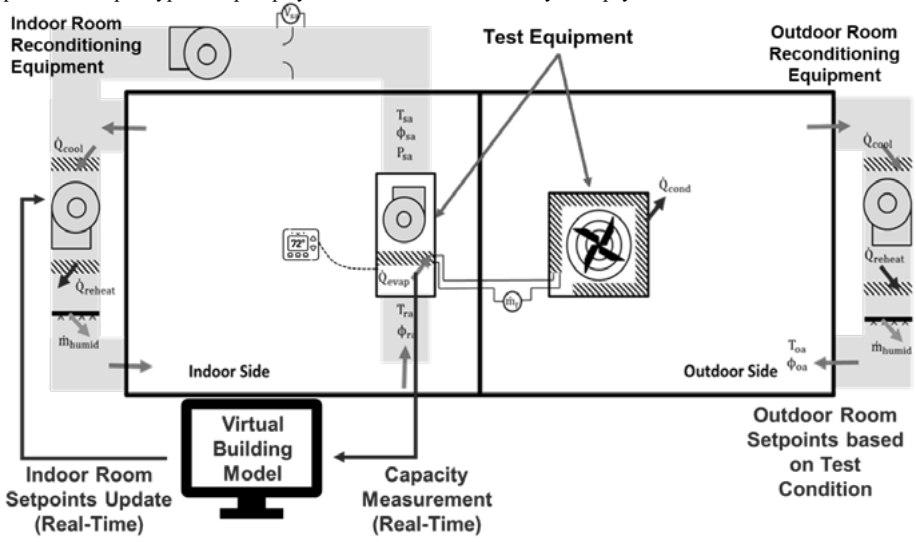

Fig. 1. Load-Based Testing Schematic of a Split-type Heat Pump System

As shown in Fig. 1, in this methodology, the equipment capacity is measured in real-time and fed into a virtual building model. The virtual building model estimates the building load based on the current indoor and outdoor conditions. Then, based on the difference in the equipment capacity and building load, the virtual building temperature and humidity are updated according to the virtual building thermal and moisture dynamics. The updated virtual building conditions are then provided as setpoints to the indoor psychrometric room reconditioning system. In this way, the response of a virtual building is emulated in the indoor-side test room. The outdoor test room conditions are varied according to a representative temperature profile according to climate and season.

In cooling mode tests, when the equipment sensible capacity is more than the sensible building load, the indoor room temperature decreases; whereas, the indoor room temperature increases when the capacity is lower than the load. Similarly, the indoor room humidity varies based on the virtual building latent load and the equipment latent capacity. The test unit thermostat senses this dynamic variation of indoor space temperature and humidity, and to maintain the indoor conditions to the thermostat setpoint, the equipment responds to this variation based on its integrated controls. This enables the load-based testing methodology to capture an overall dynamic performance of equipment that is representative of a field application.

The virtual building model can be defined based on the desired complexity of the representative building for the underlining experimental study. Hjortland & Braun [5] and Patil *et. al.* [2] described a virtual building model for a representative residential building that was employed for the experimental study presented here.

The virtual building model calculates the building sensible heat gain to the air or load scaled according to the equipment rated sensible capacity ($\dot{Q}_{cool,s,D}$) at design conditions as per the equation (1).

$$\dot{Q}_{load,s} = \frac{1}{F} \cdot \frac{\dot{Q}_{cool,s,D}}{\left(T_{OD,D} - T_{Bal,D}\right)} \cdot \left(T_{OD} - T_{Bal}\right) \tag{1}$$

where the building-load sizing factor (F) is used to scale the building load, based on the equipment sizing for a building. For example, for the case of F equal to 1.25 which makes $1/F$ 0.8 i.e. building load which the equipment meets is 80% of the load for which equipment is designed, so in this case, the equipment is 20% oversized. The effective balance point temperature (T_{Bal}) is updated according to equation (2) based on the current indoor temperature (T_{ID}) and the indoor target temperature ($T_{ID,SP}$) which is also the equipment thermostat temperature setpoint. This formulation accounts for the change in building load due to variations in the indoor temperature from its design conditions.

$$T_{Bal} = T_{Bal,D} + \left(T_{ID} - T_{ID,SP}\right) \tag{2}$$

The virtual building latent energy gain or load is calculated using a constant sensible heat ratio model for the representative building as per equation (3).

$$\dot{Q}_{load,l} = \dot{Q}_{load,s} \cdot \left(\frac{1}{SHR_{building}} - 1\right) \tag{3}$$

Then based on the virtual building loads and equipment measured capacities, the virtual building temperature and humidity ratio are updated for the next time step as per equation (4) and (5), which are supplied as the indoor test room setpoints that are controlled by the reconditioning system.

$$T_{ID}(t + \Delta t) = T_{ID}(t) + \Delta t \cdot \left(\frac{\dot{Q}_{load,s} - \dot{Q}_{cool,s}}{C_s}\right) \tag{4}$$

$$\omega_{ID}(t + \Delta t) = \omega_{ID}(t) + \Delta t \cdot \left(\frac{\dot{Q}_{load,l} - \dot{Q}_{cool,l}}{h_{fg} \cdot C_w}\right) \tag{5}$$

where the sensible (C_s) and moisture (C_w) capacitances for a representative residential building are scaled with the equipment capacities at design conditions using equation (6) and (7) respectively.

$$C_s[J/°\mathrm{F}] = \frac{\dot{Q}_{cool,s,D}[W] \cdot 150[s]}{\Delta T_{tstat,db}[°\mathrm{F}]} \tag{6}$$

$$C_w[kg] = \frac{\dot{Q}_{cool,D}[W]}{12.9[W/kg]} \tag{7}$$

Based on the equations (1)-(7), the virtual building model continuously controls the indoor test room conditions to emulate the response of a representative building to the equipment performance. The first step in

load-based testing is to measure the equipment rated sensible and latent capacity at design conditions and use them to scale the virtual building parameters. This measurement is done using a steady-state test with constant indoor and outdoor test room conditions and the equipment running at maximum capacity.

3. Experimental Method

For each test, the outdoor temperature is varied according to a typical daily temperature profile for the season considered. For a representative mid-summer day, the outdoor temperature is varied between 65°F (18.33°C) and 85°F (29.45°C). For a peak-summer day, the outdoor temperature is varied between 85°F (29.45°C) and 105°F (40.56°C). The representative hourly outdoor temperature profiles were generated based on Erbs *et. al.* [7] and Mitchell & Braun [8] as per equation (8).

$$T_{OD} = \left(T_{OD,max} - \frac{(T_{OD,max} - T_{OD,min})}{2}\right) + (T_{OD,max} - T_{OD,min}) \cdot [0.4632\, cos(\tau - 3.8051) + 0.0984\, cos(2\tau - 0.360) + 0.0168\, cos(3\tau - 0.822) + 0.0138 cos\,(4\tau - 3.513)] \quad (8)$$

where,

$$\tau = \frac{2\pi(2.4 \cdot t - 1)}{24}; t: time\ of\ day\ in\ hours \quad (9)$$

Equation (9) was modified to compress the complete daily temperature change from 24 hours to 10 hours to accelerate the testing. This is reasonable because the dynamic response of the equipment with its integrated controls is still orders of magnitude faster than the dynamic variation of the outdoor temperature. Fig. 2 shows the derived typical outdoor temperature profile for the emulated mid-summer and peak-summer days.

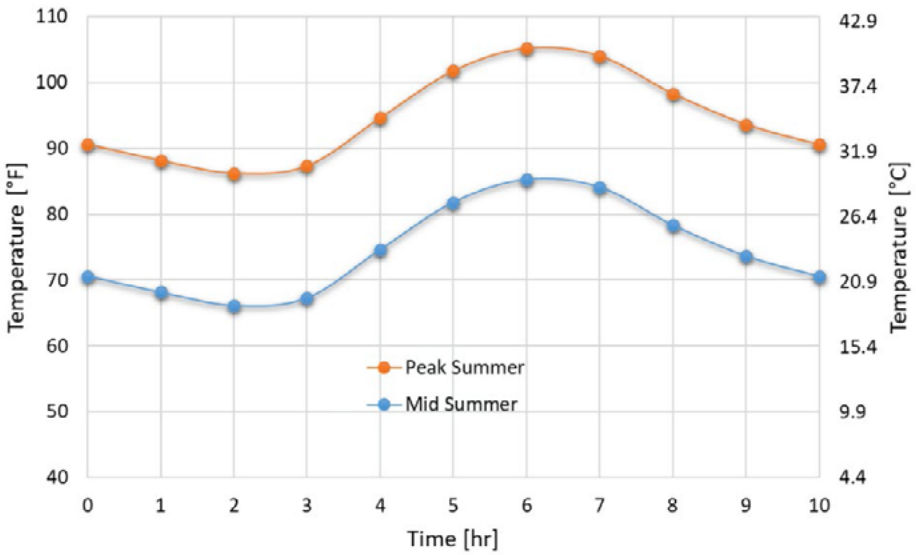

Fig. 2. Representative Outdoor Temperature Profile for Mid-Summer and Peak-Summer Day

The equipment was tested with two different control modes: A and B; three different equipment sizing scenarios: nominal, undersizing and oversizing; and for the two representative cooling season days: mid-summer and peak-summer. Table 1 outlines the test matrix for the experimental study conducted in this paper.

Table 1. Test Matrix for the Experimental Study of the Heat-Pump

Test	Cooling Season Day	Equipment Sizing	Control Mode
0	Baseline Steady-State Test at Design Conditions		
1	Peak-Summer	Nominal	A
3	Peak-Summer	Nominal	B
2	Mid-Summer	Nominal	A
4	Mid-Summer	Nominal	B
5	Mid-Summer	Oversize (20%)	A
6	Mid-Summer	Oversize (20%)	B
7	Peak-Summer	Oversize (20%)	B
8	Mid-Summer	Undersize (20%)	A
9	Mid-Summer	Undersize (20%)	B
10	Peak-Summer	Undersize (20%)	B

To scale the virtual building parameters for the heat-pump under investigation, first, rated capacity is measured through a baseline steady-state test conducted at the cooling design conditions (Table 2) using a thermostat setpoint such that the equipment providTable 7. Average of thickness of liquid film es maximum cooling capacity.

Table 2. Cooling Design Conditions

Indoor Conditions		Outdoor Conditions
Temperature	Relative Humidity	Temperature
75°F (23.8°C)	50%	95°F (35°C)

Based on the equipment performance at design conditions, the virtual building parameters were derived for the heat pump being studied as shown in Table 3.

Table 3. Virtual Building Parameters

Parameter	F			$\dot{Q}_{cool,s,D}$	$\dot{Q}_{cool,D}$	$T_{OD,D}$	$T_{Bal,D}$
	Nominal	Oversize (20%)	Undersize (20%)	W	W	°F (°C)	°F (°C)
Value	1	1.25	0.83	12850.6	15192.6	95 (35)	62 (16.6)
Parameter	$T_{ID,SP}$	$RH_{ID,SP}$	C_s	C_w	$\Delta T_{tstat,db}$	$SHR_{building}$	Δt
	°F (°C)	%	$J/°F\,(J/°C)$	kg	°F (°C)	-	second
Value	75(23.8)	50	1927596 (1070887)	1177.7	1 (0.56)	0.8	1

For each test, the first two hours were used as a warm-up period for the equipment. In these two hours, the outdoor temperature was kept constant to the 2nd hour temperature (Fig. 2); and indoor conditions were kept constant at target comfort conditions of $75°F\,(23.8°C)$ and 50% RH. Following this, the outdoor room temperature varied according to the defined temperature profile from the 2nd to 10th hour (Fig. 2). During these tests, the indoor temperature and humidity setpoints for the reconditioning system were updated continuously according to the virtual building model response, as outlined in section 2, utilizing the parameters from Table 3. In this way, the equipment dynamic performance was captured for an 8-hour test duration. The test unit performance results were analyzed only for this 8-hour duration when the outdoor temperature was varying. The results are presented in section 5.

In order to compare comfort delivery for the different strategies during cooling load-based tests, comfort violation limits were defined. Based on [9], a temperature limit of 2°F higher than the target indoor temperature setpoint, i.e. 77°F, was established. In addition, relative humidity of 10% higher than a target indoor relative humidity setpoint, i.e. 60%, was selected. The total time-duration that the heat-pump failed to maintain these limits was determined for temperature and humidity comfort individually and used as a measure of discomfort.

4. Test Setup Layout

The load-based testing was implemented at Purdue University on a split-type heat-pump system using two side-by-side psychrometric test chambers at the Ray W. Herrick Laboratories. Fig. 1 shows the layout of the system installation in the test facility, along with an outline for controlling the indoor and outdoor test room conditions during dynamic testing. Fig. 3 illustrates the schematic of the heat pump system along with the air, refrigerant, and power side measurements. The heat-pump was installed in the test rooms based on ASHRAE guidelines for performance measurement as outlined in [10], [11], [12], [13], [14], [15] and [16]. The indoor unit return and supply air temperatures were measured using a thermocouple grid, and humidities were measured using a chilled mirror dew point hygrometer. The indoor unit supply air volumetric airflow was measured using a nozzle box code-tester that was used to calculate the air-side sensible and latent capacity with the air-enthalpy method. To verify the air-side measurements, refrigerant side capacity was also measured. For this, refrigerant mass flow rate was measured using a Coriolis-effect based mass flow meter installed in the liquid line. In addition, pressure and temperature sensors were installed to measure the refrigerant side properties at different state points of the cycle as shown in Fig. 3. Furthermore, two power-meters were installed to measure the indoor and outdoor unit power consumption.

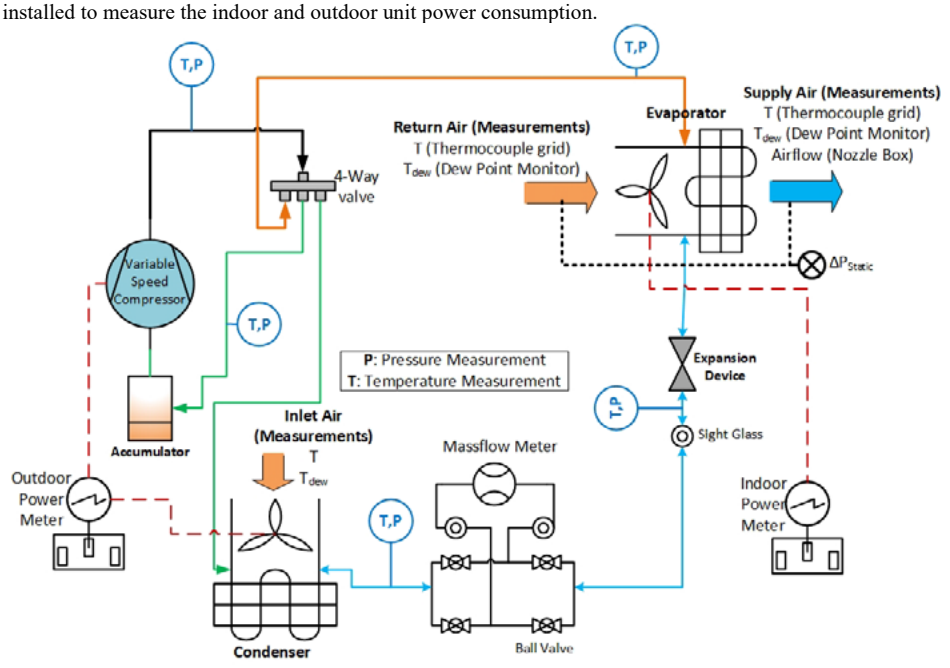

Fig. 3. Test Heat-Pump Schematic with the Air, Refrigerant, and Power Side Measurements

5. Results

Fig. 4 presents the performance of the heat pump for 8-hour dynamic test duration on a typical mid-summer day with nominal equipment sizing for control mode A. The upper subplot shows the equipment performance variation with time, including the virtual building load (sensible and latent), the heat-pump capacity (sensible and latent), and the equipment total power consumption. The lower subplot illustrates the virtual building and test rooms temperature and relative humidity variation for the test duration. In the lower subplot, the left vertical axis corresponds to the indoor virtual building (dotted line) and indoor test room (solid line) temperature and relative humidity; whereas, the right vertical axis corresponds to outdoor temperature variation.

As can be seen from Fig. 4, the virtual building outdoor temperature changed between 65°F and 85°F for this representative mid-summer day. When the heat-pump cycled on/off, the outdoor temperature fluctuated around the setpoint (Virtual Building ODT) which is due to the sudden changes in capacity requirement from

the test room reconditioning system. This could be overcome by fine-tuning the test room controller gains and updating architecture, but for this study, these modifications were not implemented due to time constraints.

The test unit thermostat was set at the target comfort conditions of 75°F (black dotted line); however, for this equipment, there is no provision to set a target humidity setpoint. Subsequently, the indoor temperature and humidity varied based on the interaction of the equipment thermostat controls with the virtual building load. When the building sensible load (red dotted line) is higher than the equipment sensible capacity (green solid line), the indoor temperature (blue solid line) increases; whereas, when the heat-pump sensible capacity is higher than the building sensible load, the indoor temperature decreases. Similarly, the indoor humidity varies based on the difference in the latent load (orange dotted line) and the latent capacity (sky-blue solid line).

In this test, the virtual building indoor temperature varied between 71°F and 76.4°F, and relative humidity varied between 49.7% to 64%. For moderate day, this variable-speed equipment cycled on and off throughout the day based on the thermostat interaction with the changing indoor temperature and demonstrated a behavior effectively similar to a single-stage system. As the outdoor temperature increased, correspondingly, the building load increased and to compensate for this higher load, the heat-pump run-time fraction for a cycle increased. The equipment was able to maintain the indoor temperature within comfort levels (<77°F) for the complete duration of the test; however, it failed to maintain the humidity within the comfort limit (<60%) for some duration around the 2nd hour and towards the end from the 7th hour onwards. Also, Fig. 4 reveals that the system maintained the indoor temperature below the thermostat setpoint for most of the time and the indoor temperature variation band was larger than ±1°F around the thermostat setpoint, which might be due to its inbuilt offset and dynamics. These results illustrate the ability of the test methodology to capture the dynamic interaction of the equipment, its controls, and the building load. On a side note, the building load does not follow the exact profile as of the outdoor temperature variation, because of the dependence of building load on indoor temperature deviations from its target design conditions.

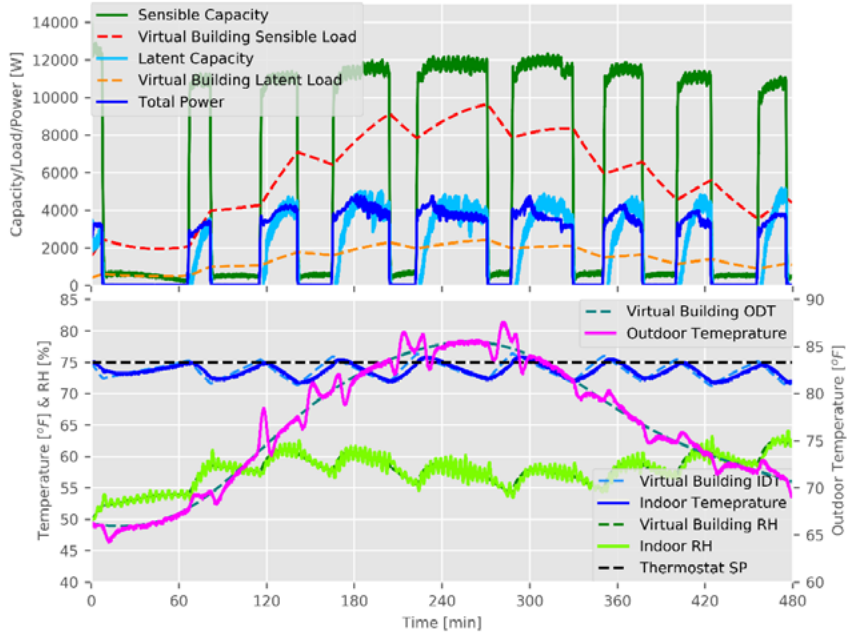

Fig. 4. Equipment Dynamic Performance on a Mid-summer Day with Nominal Equipment Sizing and Control Mode A

Fig. 5 presents the equipment performance for a peak-summer day with control mode A and nominal equipment sizing. Initially, when the ambient temperature was relatively low, the heat-pump cycled on/off and was able to maintain the indoor temperature around its setpoint; however, as the outdoor temperature increased, the equipment ran at full capacity and failed to compensate for the larger building load leading to indoor temperatures that rose above the comfort limits. However, the equipment was able to maintain the relative

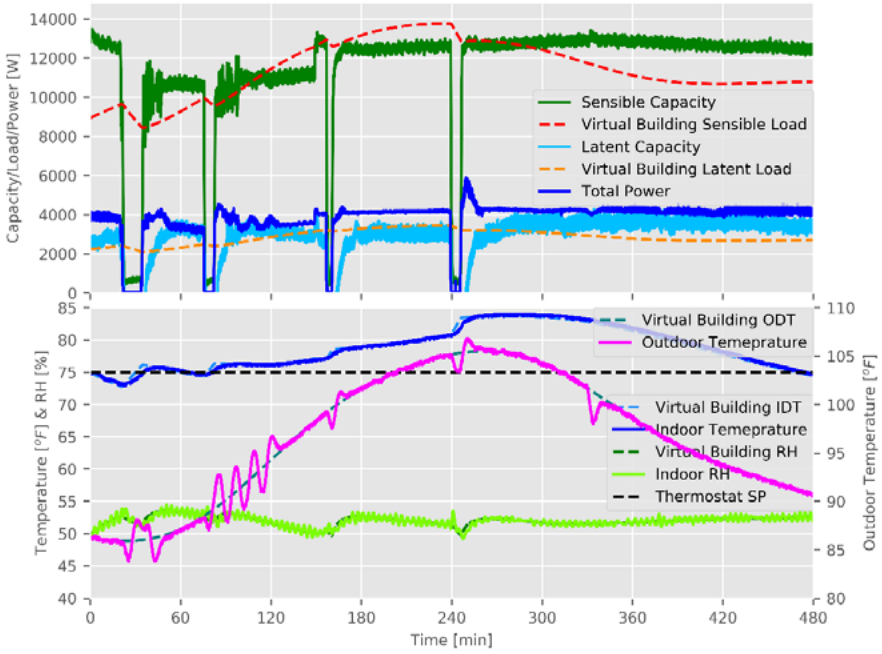

Fig. 5. Equipment Dynamic Performance on a Peak-summer Day with Nominal Equipment Sizing and Control Mode A

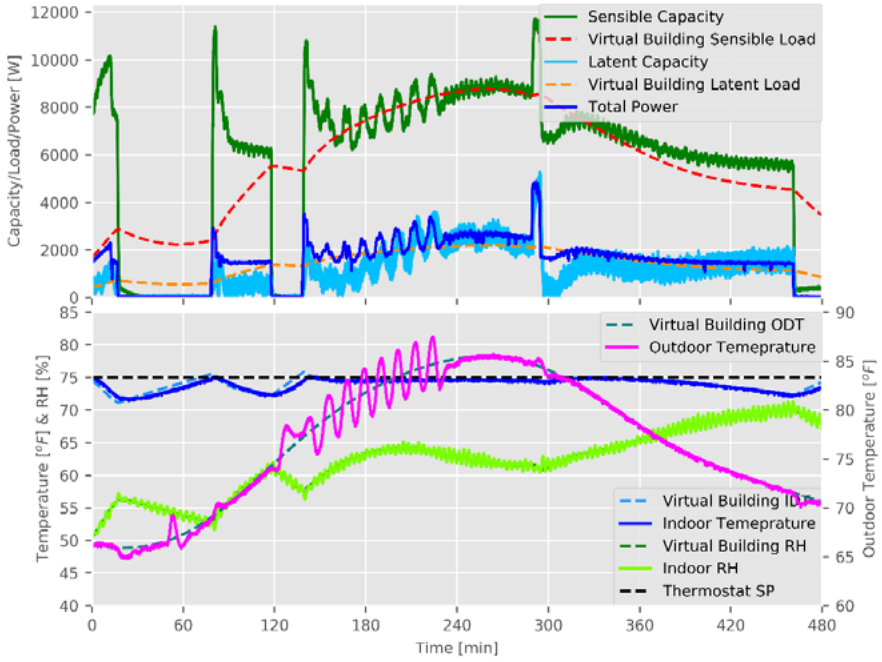

Fig. 6. Equipment Dynamic Performance on a Mid-summer Day with Nominal Equipment Sizing and Control Mode B

humidity within comfort limits, which can be attributed to a smaller sensible heat ratio of the evaporator coil at full compressor speed. These results illustrate the consequences of not properly sizing the equipment for the design conditions. The other interesting observation is that the equipment cycled off at some conditions even when the indoor temperature was well above the thermostat setpoint, which might be due to some inbuilt features in the equipment controls. These types of control issues and their impact on performance can be identified in the laboratory through load-based testing prior to deployment in the field.

The heat-pump performance was also evaluated with a 2nd controller design (control mode B). Fig. 6 shows the results of a test with control mode B for a mid-summer day and nominal equipment sizing. At the start, when the outdoor temperature was low i.e. the building load was low, the equipment cycled on/off similar to the case of control mode A (Fig. 4), although with lower power consumption and longer cycle duration compared to control mode A. Next, as the outdoor temperature increased the system ran continuously in variable speed mode rather than cycling on/off as with control mode A. Then the system cycled off again at low ambient temperature towards the end. The equipment was able to maintain the indoor temperature steadily around the thermostat setpoint instead of oscillating around the setpoint as occurred with control mode A (Fig. 4). However, in this control mode B, the heat-pump failed considerably to keep the indoor humidity within comfort levels compared to control mode A. These results illustrate the usefulness of the load-based test approach in comparing the dynamic performance and comfort delivery of a system with different controller designs.

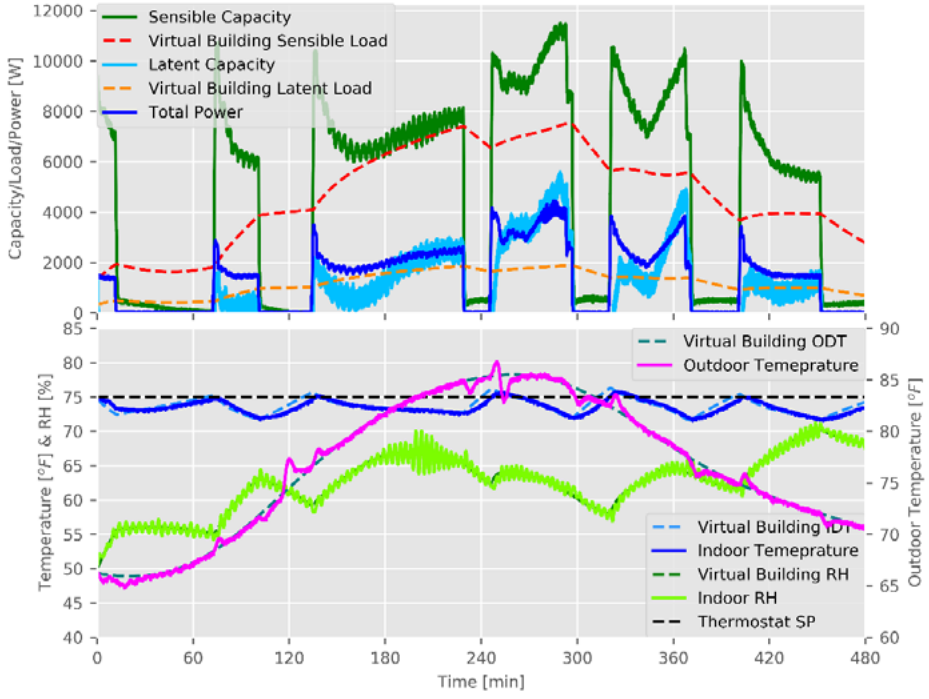

Fig. 7. Equipment Dynamic Performance on a Mid-summer Day with Equipment Oversizing and Control Mode B

Heat-pump performance was also evaluated for the case of equipment oversizing and undersizing. Fig. 7 and Fig. 8 illustrate the test results for the equipment oversizing and undersizing cases respectively, for a mid-summer day with control mode B. In the case of equipment oversizing (Fig. 7), where the building load was smaller compared to nominal sizing for the same ambient conditions, the equipment cycled on/off during the entire time, in contrast to the continuous operation in case of nominal sizing (Fig. 6). For equipment undersizing (Fig. 8), where building load was higher compared to nominal sizing, the heat-pump ran continuously for most of the time, similar to nominal sizing case (Fig. 6), but with higher power consumption to compensate for the larger building load. As observed earlier, when equipment is cycling on/off, as in case

of oversizing, the indoor temperature oscillations are relatively large around the thermostat setpoint, which can be uncomfortable for occupants; whereas, in the undersizing case with continuous equipment operation, the system was able to maintain indoor temperature more steadily around the setpoint. Nonetheless, with control mode B, the equipment was not able to provide humidity comfort for both the undersizing and oversizing cases.

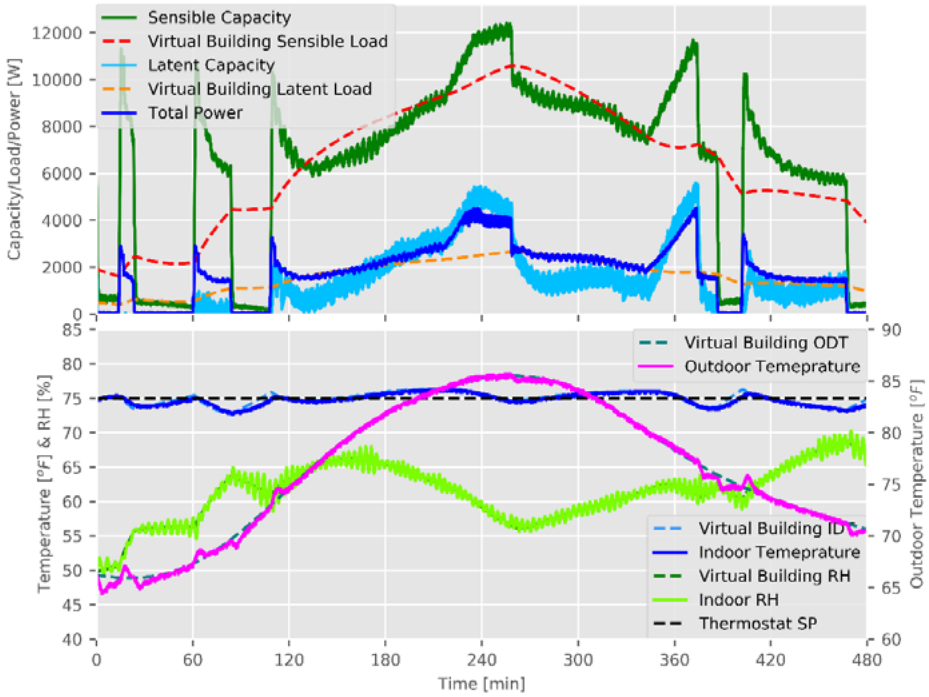

Fig. 8. Equipment Dynamic Performance on a Mid-summer Day with Equipment Undersizing and Control Mode B

Table 4 and Table 5 show overall performance results for the 10 different combination cases of the season (mid-summer & peak-summer), equipment sizing (nominal, oversize, & undersize) and control mode (A & B). Table 4 presents the integrated equipment capacity, building load, power consumption, and COP for the 8-hour dynamic load-based tests. For the same season and equipment sizing scenario, the integrated virtual building sensible and latent loads are comparable for both control modes. There is a slight difference, because with different control modes, the indoor temperature varies differently, which then propagates to the building load. The results show that as the ambient temperature increases in peak-summer season, the system average COP decreases. Furthermore, with the same ambient conditions and equipment sizing, the system performs more efficiently with control mode B. In addition, for mid-summer season, with control mode A, the equipment efficiency improves with oversizing and worsens with undersizing; whereas, the contrary happens with control mode B.

Table 5 summarizes the comfort delivery performance of the equipment for the different tests. It indicates the total number of hours, out of the 8-hour test duration, that the system is not able to maintain the indoor temperature and humidity within comforts limits for cooling, which were 77°F for temperature and 60% for relative humidity. Table 5 also shows the minimum and maximum virtual building temperature and relative humidity for each test. The system failed to maintain the temperature comfort for most of the peak-summer season tests. This was particularly extreme at high load periods with equipment undersizing. In the mid-summer season, even though the temperature comfort levels were mostly maintained, the humidity comfort was violated in both control mode A and B for all three equipment sizing scenarios. In addition, the humidity comfort violation duration with control mode B was more than twice the period in case of control mode A. So, although the control mode B is better from an energy consumption perspective, humidity comfort is sacrificed.

Table 4. Building Load, Cooling Rate, and Power Consumption Performance Results

Test	Season	Equipment Sizing	Control Mode	Virtual Building Sensible Load	Sensible Capacity	Virtual Building Latent Load	Latent Capacity	Power Consumption	System COP

6. Summary and Conclusions

This paper presents the application of a new load-based testing methodology for evaluating the dynamic performance of a residential heat-pump system under conditions that are similar to a field application. First, an overview of the approach was provided along with a representative residential virtual building mathematical model, followed by the experimental study method and the representative outdoor ambient conditions for this investigation. Testing of the heat-pump was limited to cooling mode and equipment dynamic performance was measured for various scenarios based on a combination of two different representative summer days, two different control modes, and three distinct equipment sizing situations. The results illustrate the benefits of load-based testing in assessing the qualitative and quantitative effect of different ambient conditions, control design, and equipment sizing on the equipment performance from efficiency as well as comfort perspective. For example, one of the control modes was observed to be more energy efficient but failed to maintain indoor humidity comfort levels. In this way, the methodology provides a way to evaluate realistic equipment dynamic performance in a test-facility environment much more quickly and at a much lower cost than would be possible

for field testing. The methodology can be readily used for different building types and climate locations of interest by updating the virtual building model and ambient conditions accordingly. This can be advantageous in accelerating the development and assessment of advanced controls, diagnostics, and other features.

7. Nomenclature

Variable	Description	Variable	Description
$\dot{Q}_{load,s}$	ng sensible load [W]	F	building load sizing factor [-]
$\dot{Q}_{cool,s,D}$	equipment design sensible capacity [W]	$T_{OD,D}$	the outdoor dry-bulb temperature at design condition [°C]
$T_{Bal,D}$	n balance point temperature [°C]	T_{OD}	outdoor dry-bulb temperature [°C]
T_{Bal}	effective balance point temperature [°C]	T_{ID}	virtual building indoor dry-bulb temperature [°C]
$T_{ID,SP}$	indoor temperature comfort condition (test unit thermostat setpoint) [°C]	$RH_{ID,SP}$	target indoor humidity comfort condition (test unit thermostat setpoint) [%]
$\dot{Q}_{load,l}$	ng latent load [W]	Δt	update time-step [s]
ω_{ID}	l building indoor humidity ratio $[kg_{water}/kg_{dryair}]$	h_{fg}	the heat of vaporization of water [J/kg]
$\dot{Q}_{cool,s}$	ment sensible cooling capacity [W]	$\dot{Q}_{cool,l}$	equipment latent cooling capacity [W]
C_s	l building sensible capacitance [J/°C]	C_w	virtual building moisture capacitance [kg]
$\Delta T_{tstat,db}$	ostat deadband [°C]	$\dot{Q}_{cool,D}$	equipment design total capacity [W]
RH	relative humidity [%]	$SHR_{building}$	building sensible heat ratio [-]
COP	coefficient of performance [-]	IDT	indoor temperature [°C or °F]

Novel Cascade Solution of Ultra-temperature Industrial Heat Pump System With Multiple Functions

Xiaoning Chen*, Niansheng Han

Emerson Research and Solutions Center, No.35 Su Hong West Road, Suzhou, 215021, China

Abstract

Industrial Heat Pump (IHP) is widely leveraged to gain more economic benefits instead of boilers and electric heating. The process demands of high temperature above 80°C, such as chemical separation-rectification and lithium battery coating, are significantly increasing. Under such conditions, operating stability, system capability and efficiency are all technical difficulties. Therefore, to satisfy the industrial requirement and overcome the difficulties, this paper will provide an integrated cascade solution, including system design, component selection and control strategy, to obtain about 30kW heating capacity with 100°C ~ 120°C air stably. By method of simulation and prototyping test, enhanced vapor injection (EVI), heat recovery and valve cooling technology are well applied to guarantee high efficiency and system reliability, achieving an excellent applicability based on current component condition. In the meantime, not only ultra-temperature air function, space cooling function or medium cold source can be also acquired by evaporating side of MT circuit.

Keywords: Cascade; IHP; EVI; Ultra-temperature ;

1. Introduction

As is shown in Table 1, the heat source above 100 ℃ is in great demand in industry application, such as the coating process of Lithium battery, PCB board drying, rubber fluid making, etc. The medium is mainly hot wind and steam. Currently the heat source above 100℃ is usually achieved by electric heating, coal & gas burning. On the one hand, these methods consume a lot of energy and the waste heat is difficult to be recovered. On the other hand, the pollution is quite serious. Therefore, Heat pump system attracts a lot of attention due to its high efficiency and environmental friendliness and is now widely applied in many occasions.

However, there are still many challenges in IHP, such as high inlet temperature of expansion valve and low system efficiency. The required condensing temperature is higher than 100 ℃ in IHP. If the hot air temperature needs to be 125 ℃, the condensing temperature will reach up to 130~135 ℃. So the cascade system is a common system type for such high pressure ratio applications, which is shown in Fig. 1(a). Assume the system subcooling degree is 5℃, so the temperature before the throttle valve will be about 130 ℃. There are very few high temperature resistant EXVs in the market. One implementation is as shown in Fig. 1(b). The high-temperature (HT) cycle is enhanced vapor injection cycle which induces a higher efficiency and a lower liquid refrigerant temperature before EXV compared with non-injection cycle. The HT and LT pressure-enthalpy diagrams are shown in Fig. 1(c) and Fig. 1(d), respectively. Taking the condition of HT stage into calculation, the result of the saturation temperature of injection (SIT) is about 103 ℃. Assume that the heat exchange temperature difference between SIT and point b is 5 K, the liquid temperature before EXV is 108 ℃, which is still beyond most EXV product available range. This is a big challenge to the reliability of the EXV. Long-term operation at high temperatures may lead to demagnetization failure and bidirectional performance attenuation caused by non-metallic seal failure, so more solutions are necessary for ultra-temperature application.

Accordingly, in order to achieve air supply at 120°C stably and reliably, this paper presents an integrated solution of ultra-temperature IHP system with novel cascade structure. This solution can also recovery some special air condition function to take full advantage of heat source and to improve the system efficiency.

2. Solution and Prototyping

2.1. System Design

This novel cascade system is designed for two functions. One is to obtain stable hot air supply at 120°C, which applies EVI technology and valve inlet temperature cooling technology. The other function is designed to expand multiple capability of air conditioning, providing cold water at 7°C for space cooling.

Fig. 2 shows the layout of ultra-temperature industrial heat pump system. The system can be divided into three parts, LT cycle, HT cycle and hot air chamber. The LT cycle is a simple loop with R410A refrigerant. The compressor is variable speed model of Emerson ZWW050. The evaporator is plate heat exchanger (HX) and the design inlet water is air conditioning return water at 12°C. The HT cycle refrigerant is R245fa. Two EVI fix-speed compressors of high temperature heating compressor model are designed in parallel. This compressor model is developed by Emerson and specialized for high-temperature IHP application. With the enhanced design of motor cooling, lubrication system, and new high-temperature resistant materials, a special operation envelope of IHP compressor in Fig. 3 is achievable. Compared with conventional compressors, the evaporating and condensing temperature is significantly higher.

The designed condensing temperature of HT cycle is 125 °C. Hence, two-stage cooling structure of valve inlet temperature is designed. After the HT condenser, the refrigerant flows into two economizers, and then into the valve cooling plate heat exchanger, which path is shown by points (1 – 2 – 3). At this time, the fluid is divided into three branches. The main one (3 – 7 – 8 – 9) flows into HT EXV and condensing-evaporator with majority of refrigerant to guarantee enough heat exchange with LT cycle. The second one (3 – 5 – 6 – 9) is that the refrigerant passed through the evaporation side of the valve cooling plate heat exchanger after being throttled by EXV1, and then goes back to the accumulator. The third one (3 – 4 – 10/10') flows into two EVI EXVs (EXV2 and EXV3). Then after the evaporation side of two economizers, the refrigerant is injected into

two EVI compressors. With this two-stage valve inlet cooling and EVI structure, all the valve inlet temperature can be successfully controlled below 85 °C.

It is necessary that two parallel economizers connect two compressors, respectively. The main reason is EVI control logic related. When the compressor discharge temperature is below 140 °C, EVI EXV controls the injection superheat. If the compressor discharge temperature exceeds 140 °C, the EVI EXV will turn to expand opening to decrease the discharge temperature in higher priority although some liquid will be injected into compressor. In order to deal with this situation, two economizers can control two compressors, respectively. Once stepping into this logic only with one economizer, liquid has to be injected although one compressor's discharge temperature doesn't exceed limitation value. What's more, using one economizer may be not able to distribute liquid refrigerant evenly into two compressors, resulting that one compressor cannot obtain enough effects, while the other gets too much liquid.

Another water loop for heat recovery in hot air chamber is mainly designed for the pre-heating and pre-cooling function of inlet air (designed temperature at 27 °C) to improve the capability and efficiency. The re-cooling heat exchanger is just equipped for prototyping in Fig. 4 to ensure that the outlet air temperature is in safe operation. Fig. 4 also shows the internal structure of the prototyping and the designed temperatures in hot air chamber. The internal heat recovery loop can heat the inlet air up to 65 °C and cool the outlet air down to 83 °C. In the real field applications, this function can also be transferred into waste heat recovery of other heat source.

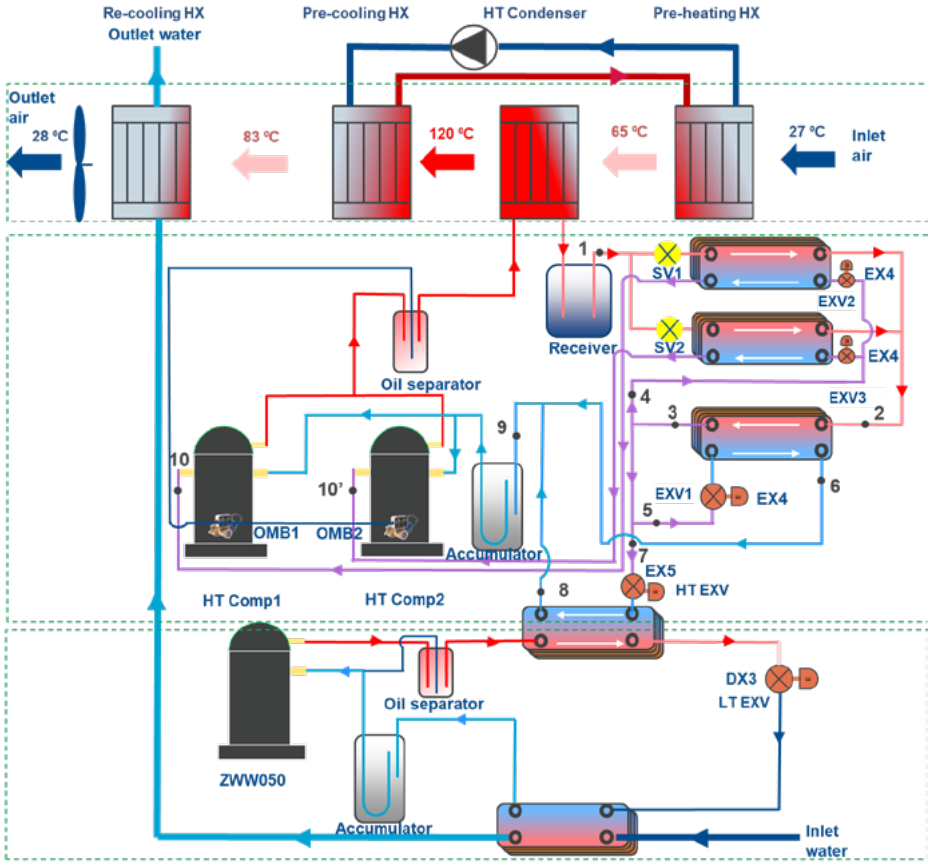

Fig. 2 Ultra-temperature Industrial Heat Pump System Layout

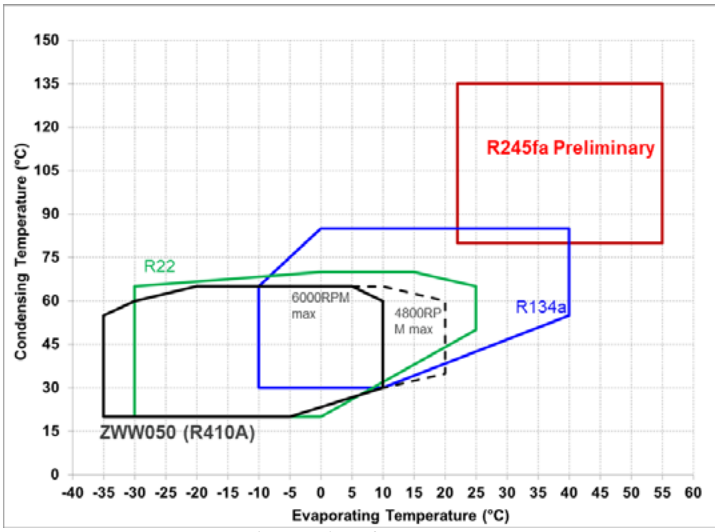

Fig. 3 Envelope of Compressors

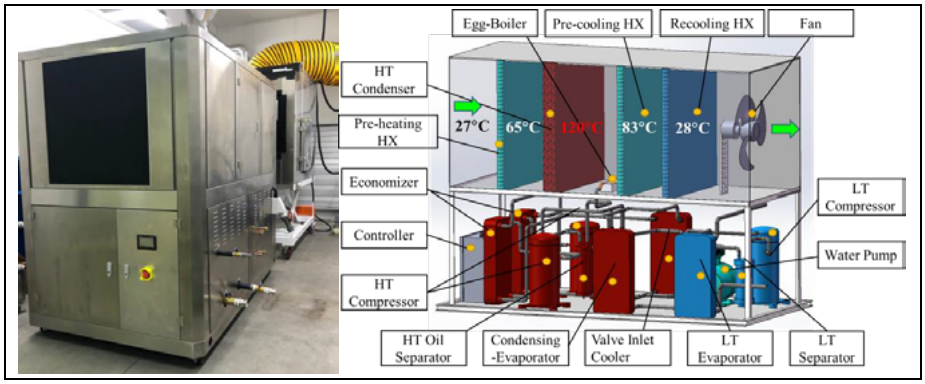

Fig. 4 Prototype and Internal Design

2.2. Control Method

It is a challenge for the reliability of control logic in such a system with multiple EXVs and variable speed compressor. There are five EXVs in this layout, LT EXV, HT EXV, EXV1, EXV2, EXV3. LT EXV is the throttling component of LT cycle, and the PID control target is the LT suction superheat at 6°C. HT EXV is the throttling valve of HT cycle with the PID control target of HT suction superheat at 8°C. EXV2 and EXV3 are the injection throttling valves with PID control target of the injection superheat at 10°C.Owing that there are four EXVs in parallel connection in HT stage, mutual interference will exist. To ensure stable system operation, EXV1 is selected to accommodate the disturbance caused by the other expansion valves because it mainly ensures cooling in front of the valve and has low control accuracy and speed requirements. Considering the cooling effect and the impact on the stability of the system operation, the opening of the cooler valve is limited, and the control method will adopt range control. The LT compressor speed is controlled by cascade adjustment. In order to avoid the delayed effect of the heat capacity of the heat recovery loop on the supply air temperature change, the outer loop PID controller with cascade control targets the HT condensing temperature, and outputs the set value of the low temperature condensing temperature. And the inner loop PID controller outputs the speed of LT compressor. Thus, the most difficult control problem is solved.

In addition, many system protection strategies are adopted, such as discharge temperature, pressure limitation, oil return, etc., are also taken into consideration.

A positive oil return loop with OMB is set to ensure the system oil balance. OMB is an oil management device to be equipped in the position of compressor oil sump. When the oil level is lower than standard level, the solenoid valve will be open to return the oil from oil separator under the action of pressure difference, until the oil level returns to normal. If the oil level lasts decreasing and exceed the upper limitation, alarm occurs, and the system will be shut down for protection. The control logic is achieved through programmable controller. And the electric control cabinet of prototyping is shown in Fig. 5.

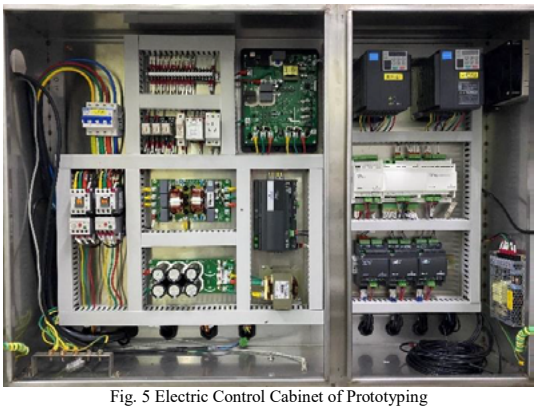

Fig. 5 Electric Control Cabinet of Prototyping

3. Test and Results Analysis

3.1. Test Conditions

Fig. 6 displays the system running envelop of the novel cascade IHP. Considering application environment and system reliability, the ambient temperature and water inlet temperature range are 15 ~ 30°C and 10 ~ 30 °C, respectively. If the water temperature is below 10°C, the risk of freezing will significantly increase. And if the water temperature is above 30 °C, LT evaporating temperature will exceed the upper limitation.

Accordingly, steady and transient performance tests were carried out with the prototyping mentioned above. And the test conditions are shown in Table 2. The rated condition is aiming to validate the IHP performance. The extreme conditions are mainly designed for system stability and reliability validation. All the steady state needs to be maintained over four hours.

3.2. Performance

Table 3 shows the comparison result of prototyping test validation and simulation in the rated condition. The feasibility of the concept can be seen that the test data and the simulation results match very well both in system performance and the operation parameters of LT stage and HT stage, respectively.

Focusing on the performance results, the hot air temperature perfectly exceeds 120°C in this rated condition, leading to enough capability of satisfying the demands of ultra-temperature application. The HT EXV inlet temperature is also successfully controlled below 85°C, which helps to guarantee the reliability of EXV under high temperature working environments. The multiple function of this IHP system is presented by the leaving water temperature. Although there exists a small difference between the simulation results, the leaving water temperature is still enough to carry part of cooling load. It means no energy will be wasted. Finally, the heating COP can reach up to 1.74, which will cause much benefit to replace boilers and electric heaters. Furthermore, taking cooling capacity of LT cycle for space cooling, the system total COP can even reach 2.83.

Table 2. Test Conditions

No.	Condition	Ambient Temperature	Water Inlet Temperature	Water Flow Rate	Target Air Temperature
		°C	°C	m3/h	°C
1	Rated Point	27	12	2	120
2		15	10	2	Above 100
3	Extreme Point	30	10	2	120
4		30	30	2	120

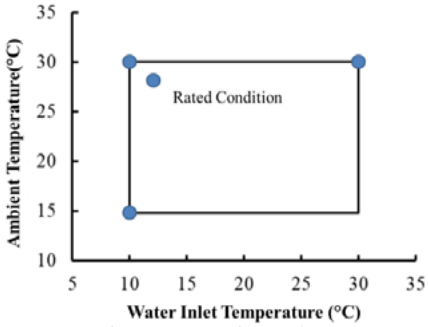

Fig. 6 System Running Envelop

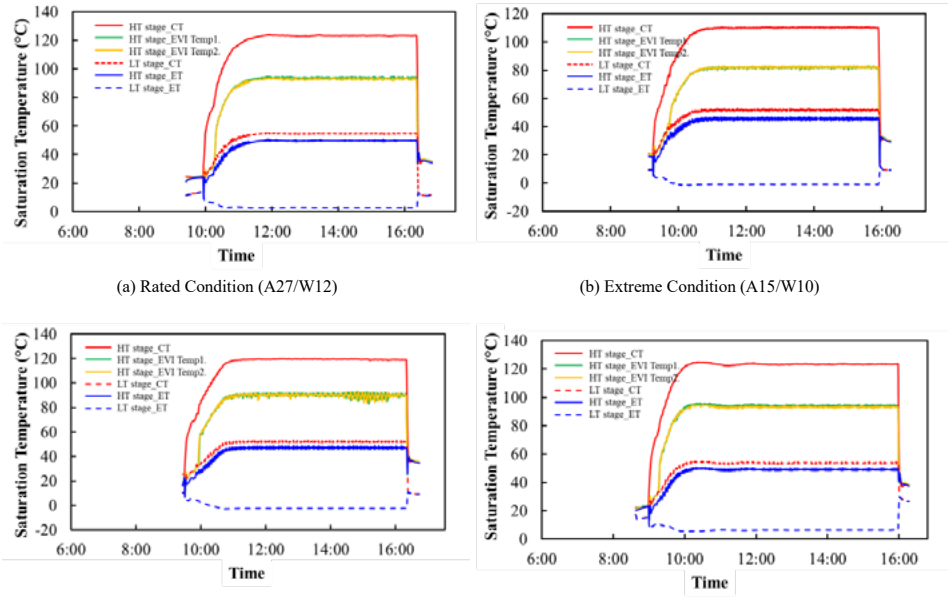
Table 3. Comparisons between test validation and simulation design

Items		Test Validation Results	Design and Simulation Results
System Performance	Inlet Air Temperature	27 °C	27 °C
	Inlet Water Temperature	12 °C	12 °C
	Hot Air Temperature	121.6 °C	120 °C
	HT EXV Inlet Temperature	80.8 °C	70~85 °C
	Leaving Water Temperature	7.8 °C	7 °C
	Heating Capacity	29.7 kW	31.2 kW
	Total Compressor Power	17.1 kW	18.0 kW
	Heating COP	1.74	1.73
LT stage	Suction Saturation Temp.	2.6 °C	1.3 °C
	Discharge Saturation Temp.	54.7 °C	52.7 °C
	Suction Superheat	4.0 K	4.0 K
HT stage	Suction Saturation Temp.	49.7 °C	47.7 °C
	Injection Saturation Temp.	93.3 °C	86.2 °C
	Discharge Saturation Temp.	123.2 °C	124.8 °C
	Suction Superheat	11.0 K	11.0 K
	Injection Superheat	10.3 K	10.3 K



3.3. Transitional Behavior and Discussion

Fig. 7 displays an excellent result of the system dynamic characteristics. All the four conditions perform a stable running process from startup to steady operation. The hot air temperatures are 121.6°C, 103.2°C, 119.4°C and 120.2°C, respectively. In fact, No.3 condition is the worst condition for IHP and will rarely occur. Although the heating capacity has attenuation, the target air temperature is still higher than 100°C.

Compared with Fig. 7(c) and 7(d), when the water temperature decreases, it will take longer time to get to the steady state. When the water temperature is 10°C, the LT evaporating temperature is nearly below 0°C, increasing the freezing risk. And also, the capacity of LT stage is too small to induce a lower HT evaporating temperature.

The whole system is in interior relation and needs a balance adjustment control. For instance, if there are problems in the HT EXVs control method, the refrigerant distribution will cause big trouble. Once too little refrigerant flows into the condensing-evaporator, the LT condensing temperature will be too high duo to the lack of heat exchange. Or too much refrigerant flows into the condensing-evaporator, it means that too little fluid can be used to cool the valve inlet temperature.

Hence, the control logic is very crucial to obtain a good performance and reliability and has been solved in this study.

(c) Extreme Condition (A30/W10)

(d) Extreme Condition (A30/W30)

Fig. 7 Test results of transient system performances

4. Conclusion

This study focuses on the performance and reliability of the novel cascade solution of ultra-temperature industrial heat pump. The EXV temperature resistance problem is solved by the design of economizer and valve inlet cooler, and the inlet temperature is controlled below 85°C. In this system, other technologies, such as OMB oil return, heat recovery loop and EVI technology, are also optimized to improve the efficiency and stability. In addition, the advanced control method is discussed and succeed to achieve the hot air temperature up to 120°C in an internal balanced state. In the future, the study on new refrigerant substitution can be developed.

Electrochemical reaction and fluid flow analysis in PEMWE

Kyu Heon Rho[a], Dong Kyu Kim[a*]

[a]School of Mechanical Engineering, Chung-Ang Universaity, Seoul 06974, Korea

Abstract

In this study, a numerical model is developed to analyze the electrochemical reaction and fluid flow in a polymer electrolyte membrane water electrolyzer using OpenFOAM®. The activation overpotential distributions of hydrogen reduction reaction, and oxygen oxidation reaction and the current density distribution by electrochemical reaction are analyzed; Then, the volume fraction of oxygen in anode and hydrogen velocity in cathode are studied to verify their influences on the current density distribution and activation overpotentials. Where oxygen gas accumulates in the porous transport layer of anode, the local current density decreases sharply; The maximum and minimum local current density are 10,263 A/m^2 and 6,921 A/m^2 at operating current density of 10,000 A/m^2, respectively. Maldistribution of the overpotentials by electrochemical reaction are also observed by oxygen gas. This study contributes to the development of numerical analysis of polymer electrolyte membrane water electrolyte.

Keywords: Polymer electrolyte membrane water electrolyte; numerical analysis; electrochemical reaction analysis; two-phase flow analysis; interner behavior analysis

1. Introduction

With the rise of interest of green energy society, the interest of hydrogen was also rising. Currently, hydrogen is produced through by product hydrogen, so the price of hydrogen is 8,000 KRW/kg in Korea; and many researchers predict that the amount of by product hydrogen will be scarce when hydrogen energy becomes popular. Therefore, many researchers have interest on new technologies to produce hydrogen continuously, which is polymer electrolyte membrane water electrolyzer (PEMWE). PEMWE can produce the hydrogen at high current density, so it can produce the large amount of hydrogen, and produced hydrogen has a high purity of 99%. Therefore PEMWE is suitable to produce hydrogen to use in green energy society. However, PEMWE has disadvantage. The oxygen generated by the oxygen oxidation reaction (OOR) at the anode can decrease performance of PEMWE. When generated oxygen gas is accumulated in porous transport layer (PTL) in anode, oxygen gas disturbs the contact between catalyst and water, so active area for reaction also decrease. This phenomenon often occurs when PEMWE is operated at high current density. Therefore, it is necessary to smoothly remove the generated oxygen when PEMWE is operated at high current density.

In this study we developed the numerical model to analyze the two-phase flow and electrochemical reaction in PEMWE. The current density distribution and activation overpotentials in anode and cathode are analyzed. This study contributes to the development of numerical analysis of PEMWE.

2. Methodology

A PEMWE comprises end plate, current density, bipolar plate, gasket, and membrane electrode assembly (MEA); and MEA comprises the membrane, catalyst, and PTL. Water decomposition reaction occurs in PEMWE and this reaction is given by Eq. (1), which the standard voltage is 1.23V

* Corresponding author. Tel.: +82-02-820-5192 ;.
E-mail address: dkyukim@cau.ac.kr .

$$H_2O \quad \rightarrow \quad H_2 \quad + \quad \frac{1}{2}O_2 \tag{1}$$

The five serpentine flow field was analyzed to confirm the internal behavior in PEMWE, which shape is in Fig. 1, and geometric parameters are listed in Table 1.

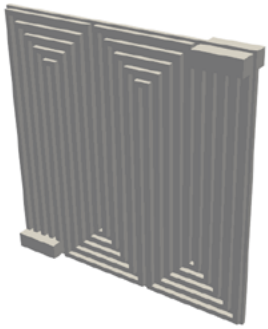

Fig. 1. Shape of the five serpentine flow field of PEMWE.

Table 1. Geometric parameters of PEMWE.

Parameter	Symbol	Value
Area of electrolyte	A_{cell}	25 cm^2
Area of inlet and outlet	$A_{in,out}$	27 mm^2
Membrane thickness	L_m	0.13 mm
PTL thickness at anode	L_A	0.36 mm
PTL thickness at cathode	L_C	0.20 mm
Chanel height	H_C	1 mm
Channel width	W_C	1 mm
Lib width	W_L	1 mm

2.1. Electrochemical model

The Nernst voltage(E^0) calculated by activities of reactant/product and the standard voltage of reaction (E_0), which can be expressed as [1]:

$$E^0 = E_0 - \frac{RT}{F} ln\left(\frac{\prod a_{product}}{\prod a_{reactant}}\right) \tag{2}$$

where F is Faraday's constant, T is temperature, and R is the gas constant. Activity of liquid is 1 and activity of gas is pressure of gas. The relation between activation overpotential (η) and current density (i) is expressed by Butler-Volmer equation, which equation is [2]:

$$i = i_0\left(e^{\frac{2\alpha F\eta}{RT}} - e^{\frac{2(1-\alpha)F\eta}{RT}}\right) \tag{3}$$

Where i_0 is the exchange current density, α is the transfer coefficients for the reaction.

2.2. Conservation equation

The mixture of liquid water and oxygen gas flow in anode, so two-phase flow model is applied in the anode. The continuity equation and momentum equation are expressed as [3,4]:

$$\begin{cases} \frac{\partial}{\partial t}\alpha_i\rho_i + \nabla\cdot(\alpha_i\rho_i U_i) = 0 \\ \nabla\cdot(\alpha_i\rho_i U_i U_i) = -\alpha_i\nabla P + \nabla\cdot\left(\alpha_i\mu_{eff}(\nabla\mu + (\nabla\mu)^T)\right) + \alpha_i\rho_i g + M_k \end{cases} \quad (4)$$

where α_i is volume fraction, ρ_i is density and U_i is velocity of species i. P is pressure of fluid, and μ_{eff} is the effective viscosity of fluid.

Only hydrogen gas is flow in cathode, so single-phase flow model is applied in the cathode. The continuity equation and momentum equation are express as [5]:

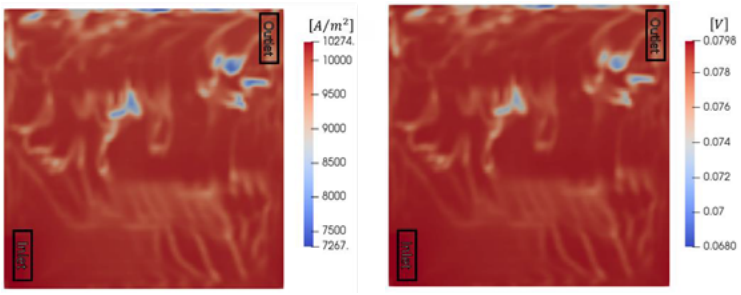
$$\begin{cases} \nabla\cdot(\rho U) = 0 \\ \nabla\cdot(\rho U U) = -\nabla P + \nabla\cdot(\mu\nabla U) \end{cases} \quad (5)$$

where ρ is density and U is velocity, and μ is viscosity of hydrogen, respectively. P is pressure of fluid.

2.3. Boundary and initial conditions

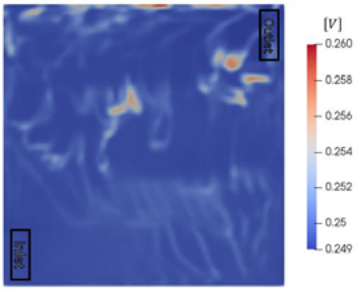
Boundary condition and initial condition is expressed as:

$$\begin{cases} U = \frac{Q}{A_{in}} \\ P_{out} = P_0 \\ T_{in} = T_0 \end{cases} \quad (6)$$



Where Q is the flow rate, P_0 is the outlet pressure, and T_0 is the inlet temperature (listed in Table 2). Simulation were conducted using OpenFOAM® (Open Field Operation and Manipulation).

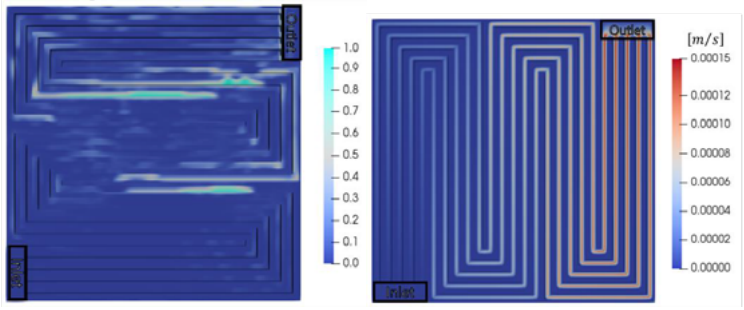
Table 2. Boundary and initial condition of simulation.



Parameter	Symbol	Value
Flow rate of water	Q	20 cm^3/min
Inlet temperature	T_0	80 ^{0}C
Outlet pressure	P_0	101,325 Pa

3. Result and discussion

Figure 2 presents the result of the electrochemical reaction in PEMWE. The current density was 10,000 A/m^2 and the flow rate was 20 cm^3/min. The maximum current density was 10,263 A/m^2 and the minimum current density was 6,921 A/m^2. The difference between maximum and minimum current density was 3,342 A/m^2. As a result, we conclude that maldistribution of current density distribution was observed. The maximum and minimum overpotential of anode reaction were 0.26 V and 0.24 V, respectively, and the maximum and minimum overpotential of cathode reaction were 0.068 V and 0.080 V, respectively. By these results we conclude that maldistribution of overpotential also occurred.



(a) (b)

(c)

Fig. 2. Electrochemical behaviors. The flow rate as 20 cm^3/min. (a) is current density distribution, (b) is overpotential of cathode reaction, and (c) is overpotential of anode reaction.

The volume fraction in anode and velocity of hydrogen are in Fig.3. The maximum volume fraction of oxygen was 0.99 in channel. When oxygen gas was accumulated in PTL, it disturbed the contact between catalyst and liquid water, so performance of PEMWE decreases. In anode, only hydrogen gas flow, so velocity of hydrogen increased continuously in channel. As a result, we conclude that oxygen gas was eliminated smoothly to increase performance of PEMWE.

(a) (b)

Fig. 3. Fluid flow distribution in PEMWE. (a) is volume fraction of oxygen in anode, and (b) is velocity of hydrogen in cathode.

4. Conclusion

In this study, we developed the numerical model for PEMWE; in this model, electrochemical reaction and fluid flows of mixture and single-phase gas in PEMWE. In cell, maldistributions of current density distribution and activation overpotential was observed; this maldistribution occurred by accumulated oxygen gas which was generated by water decomposition reaction. Therefore, to increase the performance of PEMWE, it is necessary to eliminate the oxygen gas in channel. We think that this study contributes to develop the numerical model of PEMWE.

Abstract

As the supply of hydrogen energy increases, the need for development of hydrogen storage technology is emerging. In the case of the existing mechanical hydrogen compressor, there are many problems such as low compression efficiency and high power consumption, huge volume and noise due to parts of the driving part, and high maintenance cost due to corrosion. As an alternative to this, an electrochemical hydrogen compressor that compresses hydrogen using an electrochemical reaction has been proposed. In this study, an analysis of the operating characteristics of an electrochemical hydrogen compressor was performed through a parametric study in consideration of the factors affecting the compression of the electrochemical hydrogen compressor. First, the performance change of the compressor due to the change of activation loss and resistance loss according to the change of current density was measured. Second, the performance change of the compressor due to the difference in potential energy according to the temperature change was measured. Finally, the performance change of the compressor due to the difference of inlet pressure was measured. Through this study, it is possible to understand the optimum driving conditions and efficiency of the electrochemical compressor. This study will serve as a guideline for introducing electrochemical compressors into the industry.

Keywords: Electrochemical compressor; Hydrogen; Polymer electrolyte membrane; Parametric study.

1. Introduction

Currently, the world is striving to realize an eco-friendly future globally [1]. They are striving to change the existing fossil fuel society to a hydrogen society and to use hydrogen as an energy source. In order to realize such a hydrogen society, a hydrogen compressor technology that compresses produced hydrogen and compresses transported hydrogen, stores it in a charging station is very important.

Existing hydrogen compressors are mostly mechanical, such as reciprocating piston and diaphragm. For example, the hydrogen compressor currently used in the Korean hydrogen charging station uses a diaphragm type compressor. In the case of a mechanical compressor, a large number of drives (cylinders) are required, and for this reason, the need for maintenance is large and noise and vibration are severe, so the life of the entire system is low. In addition, there is a risk of hydrogen contamination in the case of compressors using lubricating oil. An electrochemical compressor can be proposed as a way to overcome this [2].

In the case of an electrochemical compressor, the hydrogen purification and compression mechanism are unified, so the loss is small [3]. In addition, since there are no continuously moving parts such as pistons, energy consumption and maintenance costs are low, and there is no noise [4]. The study of the principle of electrochemical compressors was experimentally studied by S.A Grigoriev [5]. It is shown that a cell voltage of only 350 mV is required to obtain a current density of 1 A/cm^2. The polarization curve through modeling of the electrochemical compressor is shown in N.V Dale [6]. To account for real time losses the efficiency of electrochemical compressor is assumed to be 70% for current density of 0.7 A/cm^2. Studies on the performance of electrochemical compressors have been carried out, but mechanism analysis for the influencing factors has not been performed. It is necessary to grasp the mechanism of electrochemical compressors through parametric

E-mail address: dkyukim@cau.ac.kr.

studies of electrochemical compressors. In this research, a parameter study on an electrochemical compressor was carried out. An analysis of the performance of an electrochemical compressor according to current density, temperature and inlet pressure was performed.

2. Methodology

2.1. Principle of electrochemical compressor

Figure 1 shows the principle of electrochemical compressor. Hydrogen is oxidized to H^+ ions at the anode due to the potential difference. And it is reduced to hydrogen at the cathode after passing through the polymer electrolyte membrane. Hydrogen produced by proton reduction in an enclosed cathode space is compressed and discharged at high pressure. Table 1 describes the reactions that take place inside the electrochemical compressor.

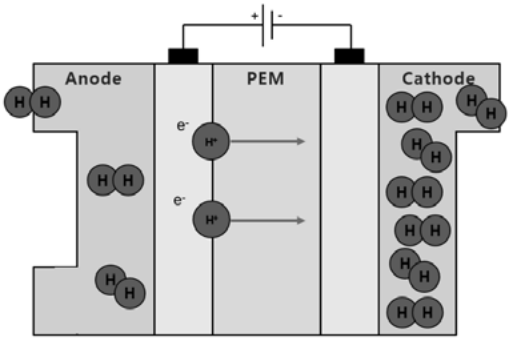

Fig. 1. Principle of electrochemical compressor

Table 1. Reactions in electrochemical compressor

Location	Expression
Anode	$H_2 \rightarrow 2H^+ + 2e^-$
Cathode	$2H^+ + 2e^- \rightarrow H_2$

The theoretical cell voltage of an electrochemical compressor is determined by the Nernst equation (1) [7].

$$E = \frac{RT}{2F} ln(\frac{P_c}{P_a}) \quad (1)$$

Here, R is the gas constant, T is the temperature of the cell, F is the Faraday constant, and P_a and P_c are the hydrogen partial pressures at the anode and cathode, respectively. For the total cell voltage, the resistance loss η_{ohm} and the activation loss η_{act} are included and are described as follows (2) [7].

$$V_{cell} = E + \eta_{ohm} + \eta_{act} \quad (2)$$

2.2. Experimental setup

The experiment was conducted with a single cell, and it was evaluated by mounting it on a test station. Hydrogen was controlled at a constant flow rate through mass flow constoller (MFC, Bronkhornst), humidified through bubbler (CNL), and supplied to the electrochemical compressor. The gas temperature was controlled using a line heater and a temperature controller (HX9, Hanyoungnux), and the gas temperature and pressure of the electrochemical compressor inlet and outlet were measured. The performance of the fuel cell was measured through power supply (EX20-240, ODA). The schematic of the electrochemical compressor experiment was shown in Figure 2.

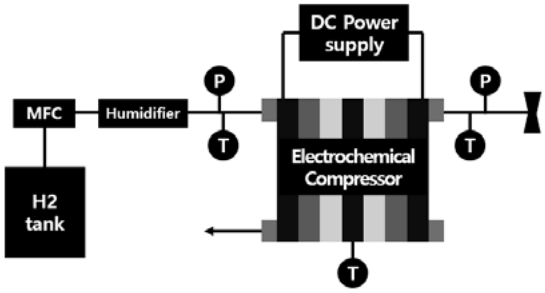

Fig. 2. Schematic of electrochemical compressor system

3. Result

3.1. Effect on current density on electrochemical compressor

Figure 3 shows the voltage change according to the pressure ratio on different current density. In order to reach the target pressure within a short time, it must be driven with a high current density. However, the voltage is lower at the same pressure when driven at a low current density. This means that the Nernst efficiency is high when driving with a low current density. This is because the ohmic loss and activation loss increase in proportion to the current. The total power consumption from 1 bar to 5.4 bar is 0.00632 Wh on 1 A/cm^2, 0.005 Wh on 0.7 A/cm^2, and 0.00359 Wh on 0.3 A/cm^2. When driving with a low current density, the total power consumption up to the target pressure can be reduced.

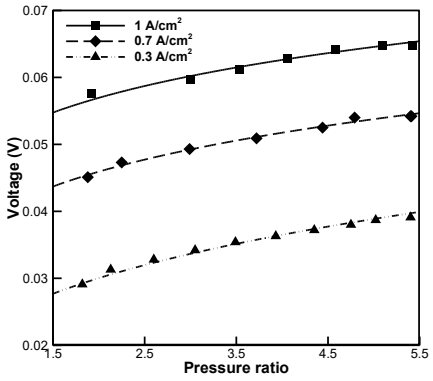

Fig. 3. Voltage change according to the pressure ratio on different current density

3.2. Performance analysis according to operating temperature

Figure 4 shows the voltage change according to the pressure ratio at different operating temperature. There is little difference in compression depending on temperature. However, when driven at a low temperature, the electrode potential of the battery is low, so the Nernst efficiency is high. The total power consumption from compression ratio 1.5 to compression ratio 5 is 0.00339 Wh at 70 ºC, 0.00330 Wh at 60 ºC, and 0.00318 Wh at 50 ºC. When operating at low temperatures, the total power consumption up to the target pressure can be reduced.

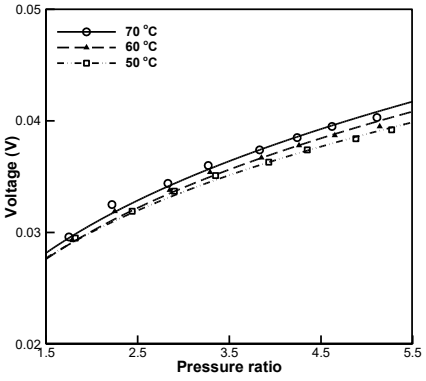

Fig. 4. Voltage change according to the pressure ratio at different operating temperature

3.3. Effect of inlet pressure on electrochemical compressor

Figure 5 shows the voltage change according to the pressure ratio on different inlet pressure. The higher the inlet pressure of the electrochemical compressor, the lower the compression ratio increase rate. This is because the number of H_2 passing from the anode to the cathode is determined according to the current density. Since the same amount of H_2 goes over, the lower the inlet pressure, the higher the increase rate of the compression ratio. The lower the inlet pressure, the lower the voltage at the same pressure ratio, so the Nernst efficiency is better.

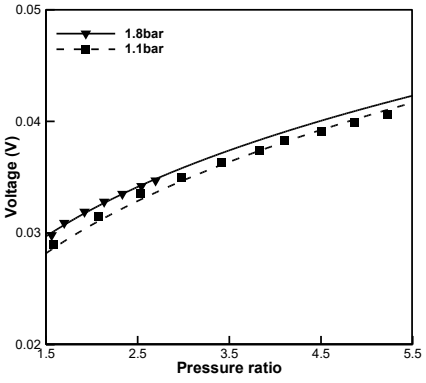

Fig. 5. Voltage change according to the pressure ratio on different inlet pressure

4. Conclusion

In this study, the performance of the electrochemical hydrogen compressor was analyzed through parametric studies that affect the compression of the electrochemical hydrogen compressor. For electrochemical compressors, the Nernst efficiency is good when operating at low current density, low temperature and low inlet pressure. This study will serve as a guideline for applying to industry by replacing the existing mechanical compressor with an electrochemical compressor.

"Experimental study of PEMFC conditioning methods"

Joohee Song[a], Minsoo Kim [a], Dongkyu Kim[a*]

School of Mechanical Engineering, Chung-Ang University, Seoul 06974, Korea

Abstract

The conditioning procedure of polymer electrolyte membrane fuel cell (PEMFC) requires to acquire its maximum performance and promote commercialization of fuel cell society. Depending on the conditioning method, this procedure terminates in various time. To analyze the effect and time required for conditioning, commonly used procedures involving constant current (0.25A/cm^2) and constant voltage (0.6V) and new method which suggested in this study were adopted to experiments and optimize most effective conditioning methods. The best performance was reached by new conditioning method called Cathode Oxygen Depletion (COD) during 2hours, but 4hours and 21hours for CC and CV, respectively. As that results, COD conditioning method proceeded remarkably fast, and most of the conditioning process was finished within just few hours. It could be concluded that the MEA activation procedure had a significant effect on the MEA durability and reduction hydrogen gas required for conditioning.

Keywords: Polymer electrolyte membrane fuel cell; Cathode oxygen depletion; conditioning

1. Introduction

The worldwide effort for the reduction of greenhouse gas emissions by fossil fuels has generated Eco-friendly devices which capable of replacing internal combustion engines. Among the commonly used Eco-friendly devices, the Polymer electrolyte membrane fuel cell (PEMFC) is highly demanded as zero-emission energy conversion devices. Typically, the PEMFC is used for portable power and transportation due to their compactness, simple-structure and sustainability. For an active electrochemical reaction of PEMFC, a part in which reaction gas, hydrogen ions and electrolyte can coexist is required. This part is called as triple-phase boundary (TPB), and it is important to secure TPB as much as possible during operating the fuel cell. The procedure so-called break-in/conditioning /activation is essential to acquire TPB expansion which described in Figure 1, leading to maximize PEMFC performance. However, using inappropriate conditioning methods can result in unnecessary hydrogen consumption and conditioning time. It is the main assignment to optimize effective conditioning method.

There are hypothetical theories usually mentioned during conditioning procedure are i) Conditioning expands passage of the reactants to reach the catalyst[1]. ii) Membrane of PEMFC is initially dry, hindering the cell performance until the membranes are hydrated during the conditioning[2]. iii) The continuous activity of hydrogen ions and electrons is secured by improving the ion conductivity. Most theories are lack of direct experimental support or concrete experimental validation A systematic investigation of conditioning and its theories about mechanism is still required[3].

The conditioning procedures are classified to two strategies: on-line and off-line conditioning methods. The traditional conditioning methods are as follows. On-line techniques explored include current control[4,5], potential control[7,8,], temperature control[9-11], hydrogen pumping[12], CO stripping[13], and air braking[14]. Off-line methods include electrochemical conditioning of the MEA and steaming or boiling the electrode[15]. In this study, we suggested state-of-the-art conditioning method called Cathode oxygen

* Corresponding author. Tel.: 82-02-820-519
E-mail address: dkyukim@cau.ac.kr

depletion (COD) that is controlled the air-supplying and shortened time to reach maximum MEA performance remarkably. To verify the effect of COD, the commonly used conditioning methods were chosen and compared each performance.

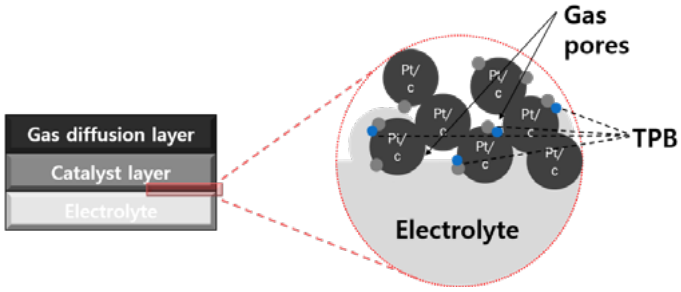

Fig. 1. Schematic of Triple-Phase Boundary (TPB)

2. Experimental

2.1 Description of Experiment equipment set-up

The PEMFC had an active area of 25cm^2. The entire conditioning methods were carried out using Vinatech Co. membrane-electrode-assembly. The Pt loading on the anode and cathode electrodes was 0.4mg/cm^2. The cell was assembled between two graphite plates with serpentine flow channel, current collectors coated with copper and fastened under constant pressure. After assembly, cell was connected to electrode load (PLZ664WA, Kikusui). The heating rods were used to maintain experiment operating temperature. Air and hydrogen gas were humidified and then controlled using mass flow controller (SEHWA Hightech). The flow rate of hydrogen and air were 100 and 200 mL/min, respectively. Experiment equipment diagram was described in Figure 2.

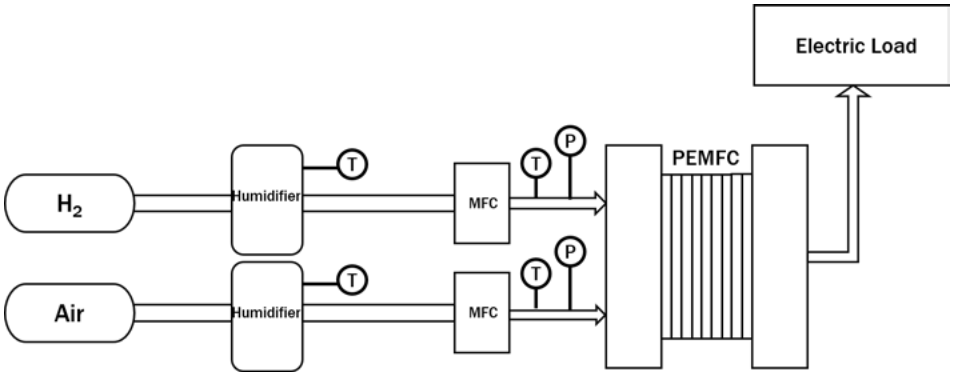

Fig. 2. Schematic of Experiment equipment

2.2 Performance measurement

The conditioned MEA performance was measured in galvanostatic mode and characterized by polarization curve. The applied conditions were maintained at 65℃ under relative humidity (RH) of 100%. For the polarization curve, the electric load was connected to PEMFC. The voltage from 0.9V to 0.1V was hold for 5 minutes at each voltage step. Power density was calculated from the current and applied voltage.

2.3 Conditioning procedures

The three kinds of conditioning methods were conducted in this study: Constant voltage, Constant current and Cathode Oxygen Depletion. Each method is explained below.

(a) Constant voltage. The cell is operated under constant voltage at 0.6V for 4h.
(b) Constant current. The cell is operated under constant current at 0.25A/cm^2 for 21h
(c) Cathode Oxygen Depletion. (i) Constant voltage Open circuit voltage (OCV) operation for 15~20s. (ii) Air supplied off and wait until voltage drops. (iii) Air supplied on and voltage maintains at 0.2V for 30s.

3. Results and discussion

3.1. Polarization curves of MEAs on conditioning methods

The comparison of Polarization curves after conditioning for 2h is shown in Figure 3(a). As can be seen, the OCV of COD, CV and CC has similar value due to experiment condition of temperature and gas partial pressure is equivalent. The current densities at 0.6V of COD, CV and CC are 1.0588 A/cm^2, 0.914A/cm^2 and 0.7632A/cm^2, respectively. We aimed that when the current density reaches above 1.0A/cm^2 at 0.6V, conditioning procedure terminates. According to the performance of COD achieves target value after 2h conditioning, activation using COD is sufficient only 2 hours. However, the performances of CV and CC do not reach aimed current density at 0.6V, it is difficult to finish conditioning within 2 hours.

Figure 3(b) describes the comparison of current density at 0.6V depending on conditioning time. It shows that a rapid performance increase within a short time using COD method. Also, the COD conditioning has its peak performance after 2 hours and maintains steady state as time passes. In case of CV, the performance achieves above 1.0A/cm^2 within 4hours and has steady state after 4hours. On the other hand, performance using CC increases slowly and the target performance does not reach over time.

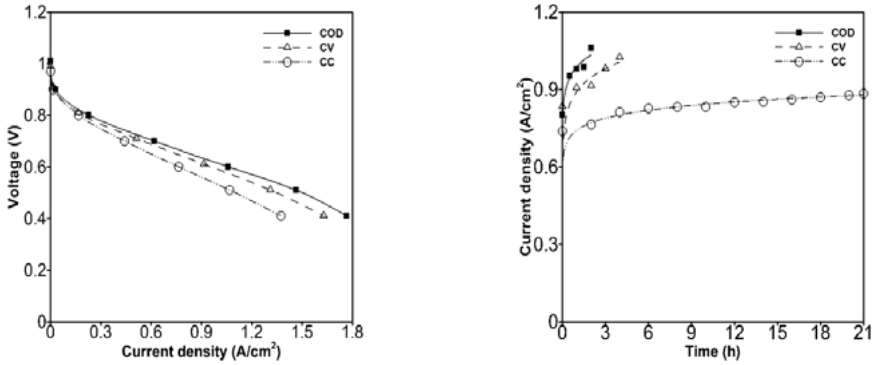

Fig. 3 (a) Polarization curve after 2h of conditioning procedures (b) Current density at 0.6V depending on conditioning time.

3.2. Final performance of conditioning by different procedures

Figure 4 presents the performance of all MEAs after finishing the conditioning procedures. The results show that current densities using COD, CV and CC are 2.062A/cm^2, 2.0308 A/cm^2 and 1.9256 A/cm^2, respectively. Using COD method can acquire highest performance of MEA within only 2hours. Because cod accelerates the catalyst penetration into membrane which is the component of TPB. Then, the MEA performance by CV method obtain second highest performance within 4hours. However, the performance CC has lowest performance and does not reach peak performance of MEA. This result indicates by the fact that amount of produced water in the MEA is insufficient, because it is operated at low current density; therefor the MEA can not be hydrated enough, leading to be unable to achieve aimed performance. Comparatively, investigation

of the conditioning cells shows that COD conditioning procedure is an effective method for conditioning and shorten conditioning time significantly.

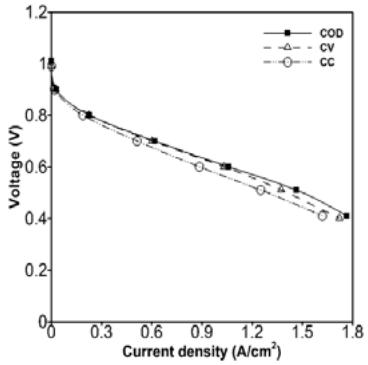

Fig. 4. Polarization curve after end of conditioning procedures

4. Conclusion

The performance of MEA subjected to a new conditioning method: Cathode Oxygen Depletion. Also, the effect of MEA using COD method by comparing commonly used conditioning methods, involving Constant current and Constant voltage. The time required to condition MEA using the COD procedure to reach maximum performance is 2 hours, comparing to 4 hours for CV and 21hours for CC. The results demonstrated that activating by COD conditioning is the most time-effective and secures economics of Fuel cell society.

Initial stage of Thermal Response Tests combined with transient numerical model – a foundation of short-term ground storage of cold for effective cooling of office buildings.

Kamil Kwiatkowski[a,*], Jakub Garbacik[a], Tomasz Walczak[a]

[a]Euros Energy, Macieja Rataja 4F, 05-850 Koprki, Poland

Abstract

The short-term storage of cold in borehole heat exchangers (BHE) is analysed to minimise the electricity consumption for air-conditioning in large commercial or office buildings in major cities. The cold is effectively produced during the night and stored in the ground. Next, during the day, the storage cold will be discharged with very low use of electricity by so-called free-cooling. Proper design of such short-term ground storage requires full knowledge of geological conditions provided locally by Thermal Response Test (TRT). The properties of rapid loading/unloading of BHE may come from the initial stage of TRT, when heat (cold) is locally transferred in transient, unsteady, non-equilibrium way. To handle such detail heat transfer phenomena a quick numerical model is designed and adjusted to interpret the TRT data. The solver, much quicker than detail Computational Fluid Dynamics (CFD) models, is validated with several TRT data. Finally, simulations of short-term cold storage in BHE is provided.

Keywords: BHE, Short-term storage, free-cooling, TRT, cold storage;

Introduction

According to the electricity demand forecast, in Poland limitations of energy supply in the coming years are to be expected. The problem of imbalance between supply and demand is even more visible when analysing the progress of daily electricity consumption where peaks in the day and valleys in the night can clearly be seen. The worst situation occurs in the summer when the capabilities of the transmission grid are limited by high temperatures, with simultaneous high demand for energy consumed by more and more popular cooling systems. This issue is critical for large commercial and office building in big cities, when the possibility of local electricity production with photovoltaic or wind-turbines is limited due to lack of space. Moreover, typical cooling demand of office or commercial buildings is high, exceeding the heat demand even by several times.

It is known that the efficiency of standard air-conditioning systems based on dry-coolers depend on the outside temperature. The higher the temperature outside, the worse the efficiency of the cooling system, and the increased consumption of electricity. Production of cold at night when the outside temperature is lower than in the daily demand peak, ensures that the system will still be working with higher efficiency than in the daily peak and relieving the network during the daylight peak. Moreover, usually cheaper tariffs of electricity are available at night, which amplify a measurable economic effect for the customer.

Favourable option is to produce cold during night and store it for day, mainly to discharge heat to borehole heat exchangers (BHE) in the form of e.g. vertical exchangers, normally used as a lower heat source of the heat pumps. Such a solution potentially gives excellent results (e.g. lowering condensing temperatures by more than 15 °C). The use of ground heat exchangers to power the ground with cold of plus temperature, can greatly improve the efficiency of cooling with the use of a heat pump (i.e. free cooling).

* Corresponding author. Tel.: +48 22 250 16 09;
E-mail address: kkwiatkowski@eurosenergy.com

The behaviour of BHE as a short-term storage for cold must therefore be known in order to make optimal decisions about the operation of the system and to estimate usable heat capacity of such a system in the short term. Unproper construction and size of the ground heat exchanger, or too much heat discharged into the ground can cause its heating increase of condensing temperature to an unprofitable value.

To address the challenge of designing the optimal ground heat exchangers for short-term storage of cold applicable for commercial or office buildings we improve and link well-established procedure of Thermal Response Test (TRT) with transient, non-equilibrium numerical modelling of heat transfer.

The TRT is valid and well-proved to correctly estimate the long-term thermal performance of the BHE, but it fails for short-term applications when dynamics loading/reloading are included. In standard approaches, the initial phase the TRT cannot be taken into account because non-equilibrium phenomena happened. Although the very first ten hours of the thermal response test provide the most valuable insight into the BHE loading in day-night time-scale, they are often neglected and removed from the analysis. Using these initial results of standard TRT to predict the efficiency of short-term energy storage requires a new, more complex approach when local phenomena inside the borehole itself have to be considered. In fact, solving transient, local and non-equilibrium heat transfer is essential for applications when a borehole heat exchanger is loaded and reloaded rapidly.

In the present work, we propose an extended procedure of analysing TRT data, based on transient numerical modelling focused on the short time phenomena. We describe the in-house model, validate it with the results of benchmark thermal response tests, and compare with detail Computational Fluid Dynamics solution from the OpenFOAM code. Sensitivity analysis proved that the model is capable of predicting the results of the thermal response tests, both in short-term and in long-term. Finally, we present the monthly simulations of thermal energy storage in a day-night cycle with various demands from the commercial or office buildings.

2. Thermal Response Tests

Results from three standard thermal response tests are used in this work. The benchmark TRT test comes from Vienna as a joint effort of Central European project called Geoplasma-CE. In this well-documented borehole three group of researchers conducted TRT and interpreted their results. The other thermal response tests have been performed in Warsaw, in Vistula River Valley and in Koprki, outside Warsaw where Euros Energy headquarter is. The TRT test were conducted with commercially available specialised devices GERT designed to conduct TRT by UBeG company.

The following table summarized the parameters of TRT tests that were used in this work.

Table 1. Parameters of the thermal response tests.

Location	Heat load [W]	Length [m]	Mass flow rate [kg/s]	Initial borehole temperature [°C]	BHE type	Fluid
Koprki	8590	100	0.44	10.9	1U 40x3	Water
Warsaw	8730	100	0.47	9.3	1U 40x3.7	Glycol
Vienna	5130	150	0.36	12.4	1U 40x3.7	Water

3. Numerical solver and modelling

Early mathematical and numerical approaches treat BHE as two separate regions, the inside of the borehole (fluid, pipe and grout) and the outside of the borehole (ground). One-dimensional (1D) models [1] and [2] describe temperature in the ground using an analytical function, where [3] a simplified finite difference model of heat conduction is presented. The thermal capacities of the fluid, pipe and grout are neglected to simplify the model. This operation is commonly known as the quasi-steady state. It means that heat transfer inside borehole is always considered as time-independent, or that the thermal equilibrium is reached. As a result, those models are appropriate for long-term simulations only. The doctoral thesis [1] states that for times lesser than $5{r_b}^2/\alpha_s$ models are inaccurate, where r_b means radius of borehole and α_s denotes thermal diffusivity of soil (ground).

In order to simulate the short-term heat pump workloads, a more complex model of the transient heat conduction in the inside of BHE must have been implemented during work on Heat Exchanger Numeric Solver (HENS). This model, based on the [4], is composed of two parts: the outside and the inside linked via borehole heat loading.

3.1. The outside part of the model HENS

The outside part of the BHE model is a 2D axisymmetric heat conduction with Neumann boundary condition at borehole wall and Dirichlet boundary condition at far-field boundary. The ground temperature is obtained by solving the energy equation in the cylindrical coordinate system:

$$\frac{1}{a_s}\frac{\partial T}{\partial t} = \frac{1}{r}\frac{\partial}{\partial r}\left(r\frac{\partial T}{\partial r}\right) + \frac{\partial^2 T}{\partial z^2} \tag{1}$$

Partial differential equation is transformed to algebraic linear system of equation using finite volume method discretization. Due to stability, time derivative is transformed using fully implicit method. As mentioned before, boundary condition at borehole wall and far-field radius are established upfront – Neumann type $\dot{T}\,[K/m]$ (where $\dot{T} = \dot{q}/(2\pi k_s)\,[K/m]$) and Dirichlet type $T_{ff}\,[K]$ respectively. Rest of boundary conditions are arbitrary. The far-field boundary radius can be estimated by Eskilson [1] assumption $r_f = 3\sqrt{a_s t_{max}}$.

The mesh cells size in vertical direction should be refined at top and bottom boundaries. Such operation improves stability and reduces computational error. In case of mesh in radial direction the smallest cell should be at borehole and its size may vary from $r_b/6$ to $r_b/3$. Mesh size may increase along radius.

3.2. The inside part of the model HENS

Inside part of the BHE model works as a modified MTRCM [5] model considering thermal resistances and capacities of all components/regions. There are 3 regions – fluid, pipe and grout. Moreover, the grout region is split into three sections. One corresponding to the section of grout between the pipes and two sections between each pipe and borehole. To be able to simulate transiency of heat conduction each grout sections can be divided by a specific number of segments.

The vertical heat conduction and fluid mass transfer were calculated using a finite difference method. Boundary conditions are as follows: BHE heat load [W] and borehole wall temperature [K].

The idea of modelling inside part of the BHE comes from Hellström [6], who presented a 2D quasi-steady-state model. He introduced dependencies of fluid, grout and borehole temperature as thermal resistances ("delta circuit").

The number of temperature data points in one layer of the model may vary depending on the grout segments division. The number of cells in the vertical direction is related to the outside part of the model.

3.3. Solving procedure

The simulation procedure include the following steps:

1) Preprocessing data:
   a) Input thermophysical, geometrical and simulation parameters.
   b) Create a mesh.
   c) Calculate the resistances and capacities of the inside part of the model.
   d) Create initial temperature fields.
   e) Create matrices for inside and outside part of the model.
   f) Create RHS vectors for inside and outside part of the model, based on initial conditions.
2) Solving loop:
   a) Solve an algebraic system of equations of the inside part of the model.
   b) Solve an algebraic system of equations of the outside part of the model.
   c) Retrieve borehole heat load $\dot{q}\,[W/m]$
   d) Retrieve borehole temperature $T_b\,[K]$.
   e) Update RHS vectors for both part using new temperature fields and heat load and borehole temperature.
   f) Save temperature fields.
   g) Update timestep.

3.4. Initial validation with the result of CFD

To validate the solver a series of analyses has been performed. The first one is a comparison with detail computational fluid dynamics (CFD) numerical model optimized to simulate BHE. The CFD model allows simulating 3D transient heat conduction. The main tool used to perform analyses is OpenFOAM's chtMutliRegionFoam solver. The momentum equation for the fluid is solved before heat transfer simulation using simpleFoam solver. The obtained fluid velocity field is transferred to the heat conduction model to reduce calculation time. The chtMultiRegionFoam solves energy equations for all regions simultaneously. Such CFD model gives results comparable to real-life TRT's. The main disadvantage is high demand for computational power which leads to long time simulation duration. The CFD mesh has over 2.4 million cells, HENS has around 2000 cells only. The calculation speedup is expected while using a simplified model.

To determine speedup, the same case has been performed using both models. It took over 4708 seconds on average to evaluate 3D simulation results and 29 seconds on average using HENS. So the speedup reaches around 162 times, as shown in Fig. 1. Moreover, the error between obtained results is lesser than ±0.3 [K].

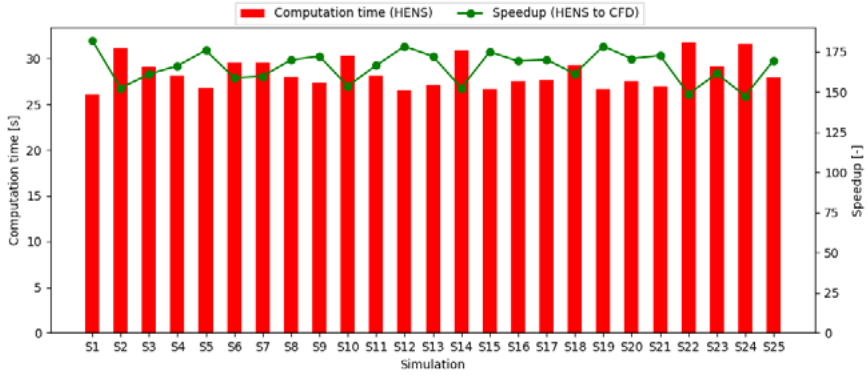

Fig. 1. Speedup of HENS solver, compare to the CDF solver in OpenFOAM.

4. Results - sensitivity analysis

4.1. Results from the TRT in Vienna, Austria

The reference thermal response test was carried on borehole heat exchanger located nearby Vienna City Centre area. This is a benchmark location to conduct TRT by various group, with well-determined geological parameters and properties od the borehole itself. The data from the TRT test is described in [7].
In Fig. 2 we summarised the results of the sensitivity analysis performed with different values of the thermal diffusivities of the ground (soil) and inject (cement). In this figure, and similar figures of the other TRT, the values of the temperature errors are presented. The errors are calculated as at each time step as a difference between the temperature directly measured during TRT and temperature computed with corresponding numerical simulation performed with HENS. We separately calculated errors based on temperature probed from the inlet and the outlet of the BHE.
The results with the minimum errors are presented in the centre sub-figure in Fig. 2. In the surrounding sub-figures errors are plotted for different values of thermal diffusivities of ground and cement, as specified in Table 2.

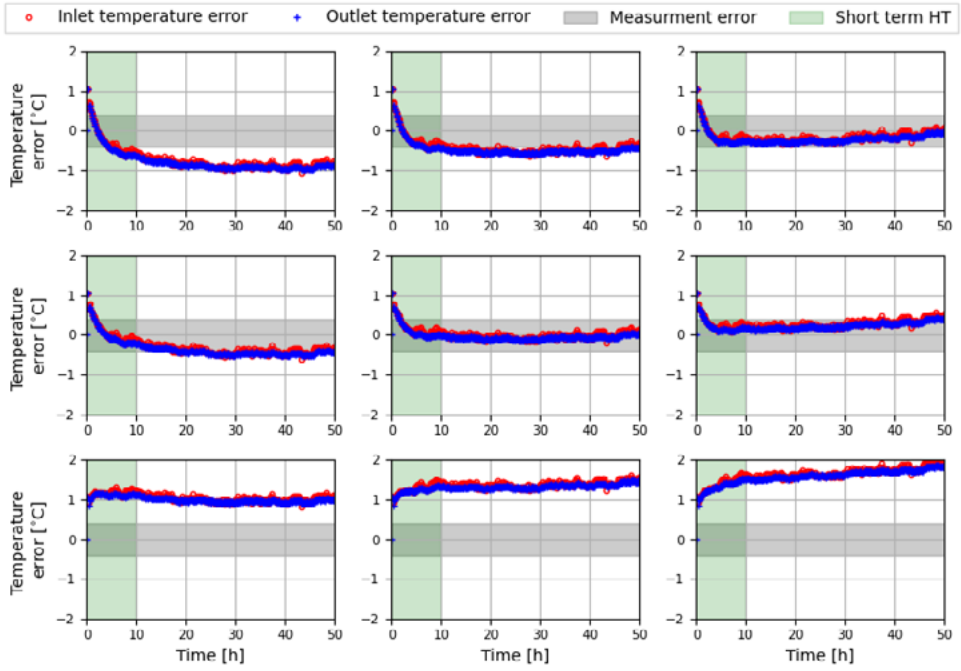

Fig. 2. Sensitivity analysis for the Vienna TRT. Each plot presents a temperature error plotted for the first 50 hours of TRT test, for the values of thermal diffusivity that corresponds to the layout in Table 2.

Table 2. The values of the thermal diffusivities of each subplots.

			Left column	Central Column	Right column
Upper row	α_s	$\left[\frac{m^2}{s}\right]$	$0.98 * 10^{-6}$	$1.09 * 10^{-6}$	$1.20 * 10^{-6}$
	α_c		$5.66 * 10^{-7}$	$5.66 * 10^{-7}$	$5.66 * 10^{-7}$
Middle row	α_s		$0.98 * 10^{-6}$	$1.09 * 10^{-6}$	$1.20 * 10^{-6}$
	α_c		$6.29 * 10^{-7}$	$6.29 * 10^{-7}$	$6.29 * 10^{-7}$
Lower row	α_s		$0.98 * 10^{-6}$	$1.09 * 10^{-6}$	$1.20 * 10^{-6}$
	α_c		$6.92 * 10^{-7}$	$6.92 * 10^{-7}$	$6.92 * 10^{-7}$

The initial temperature error converges to 0 in about 5 hours. It is worth to mention, that for this TRT the data was written every 10 minutes, so the exact time of the beginning of the test remains uncertain to this limit. That time shift may influence the temperature error values, especially when the temperature rises quickly. Such a situation occurs at the beginning of the TRT test. The overall behaviour of temperature error plots remains as stated before.

4.2. Results from the TRT in Warsaw, Poland

TRT test in Warsaw was carried on the Vistula River Shore area.

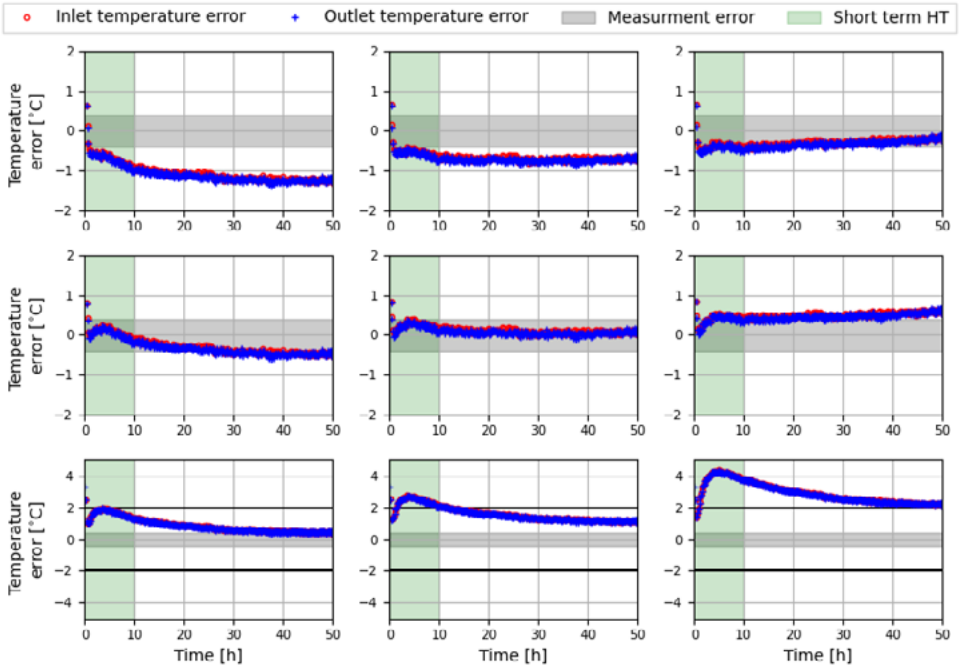

Fig. 3. Sensitivity analysis for the Warsaw TRT. Each plot presents a temperature error plotted for the first 50 hours of TRT test, for the values of thermal diffusivity that corresponds to the layout in Table 3. Note that the y-axis in the third row is expanded.

Table 3. The value of the thermal diffusivities of each subplots.

			Left column	Central Column	Right column
Upper row	α_s	$\left[\frac{m^2}{s}\right]$	$1{,}14 * 10^{-6}$	$1.27 * 10^{-6}$	$1.40 * 10^{-6}$
	α_c		$3.78 * 10^{-7}$	$3.78 * 10^{-7}$	$3.78 * 10^{-7}$
Middle row	α_s		$1{,}14 * 10^{-6}$	$1.27 * 10^{-6}$	$1.40 * 10^{-6}$
	α_c		$4.20 * 10^{-7}$	$4.20 * 10^{-7}$	$4.20 * 10^{-7}$
Lower row	α_s		$1{,}14 * 10^{-6}$	$1.27 * 10^{-6}$	$1.40 * 10^{-6}$
	α_c		$4.62 * 10^{-7}$	$4.62 * 10^{-7}$	$4.62 * 10^{-7}$

The result in lower right sub-plot is out of visible range. Despite different heat-carrying fluid, the behaviour of the results is similar.

4.3. Results from the TRT in Koprki, Poland

Next analysis presents the temperature influence of grout and soil thermal diffusivities on the accuracy of matching to TRT tests. The following figure shows the change in the differences between TRT and HENS inlet and outlet temperatures. The best matching result is shown in the centre subplot in Fig 4.

TRT test was carried on nearby the Euros Energy headquarters.

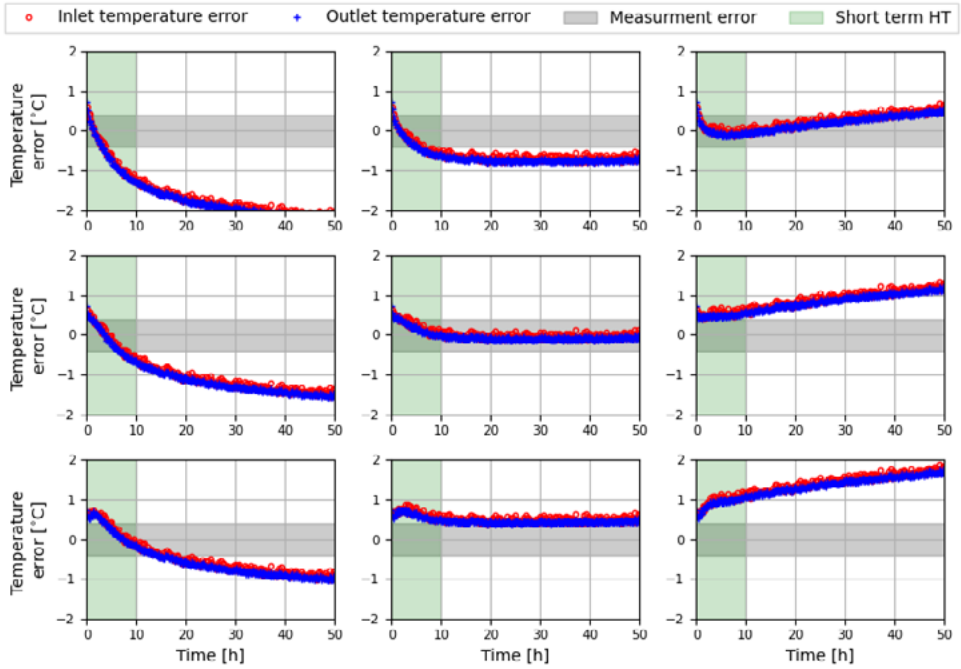

Fig. 4. Sensitivity analysis for the thermal response test in Koprki, nearby Warsaw. Each plot presents a temperature error plotted for the first 50 hours of TRT test, for the values of thermal diffusivity that corresponds to the layout in Table 4.

Table 4. The values of the thermal diffusivities of each subplots.

			Left column	Central Column	Right column
Upper row	α_s	$\left[\frac{m^2}{s}\right]$	$1.09 * 10^{-6}$	$1.21 * 10^{-6}$	$1.33 * 10^{-6}$
	α_c		$3.30 * 10^{-7}$	$3.30 * 10^{-7}$	$3.30 * 10^{-7}$
Middle row	α_s		$1.09 * 10^{-6}$	$1.21 * 10^{-6}$	$1.33 * 10^{-6}$
	α_c		$3.67 * 10^{-7}$	$3.67 * 10^{-7}$	$3.67 * 10^{-7}$
Lower row	α_s		$1.09 * 10^{-6}$	$1.21 * 10^{-6}$	$1.33 * 10^{-6}$
	α_c		$4.04 * 10^{-7}$	$4.04 * 10^{-7}$	$4.04 * 10^{-7}$

The results lead to the conclusion that soil thermal diffusivity determines the long term accuracy of temperature (the smaller the diffusivity value is the less heat is conducted through soil region and fluid temperature raise). Grout thermal diffusivity value specifies the rate of heat transfer in the short-term period.

5. Results – day/night cycles

Two four-weeks-long simulations present the simulated operation of the heat pump using different cycle schemes. Both tests are based on Koprki TRT parameters. The first one presents borehole heat load inversion every 12 hours. The second one shows a more complicated week-long cycle, during which there are 60 hours of heat delivery, 60 hours of heat extraction and 48 hours of idle.

5.1. Day cycle (12/12)

The 28 days of operation using 12/12 cycle plot presents high comparability of the results. Heat is delivered and extracted from a single BHE, with rate of 5 kW. During one cycle 60 KWh of energy is stored and restored out of the ground. There are no visible heat loss. An oscillating inlet temperature reaches 13.2 °C at peaks and

drops down to -9.2 °C. The lower plot visualizes the temporal values of coefficient of performance (COP). During the loading stage, when cold is stored in the BHE, the COP values drop from initial 8 to 5. The COP of cooling stage is divided into two components – the free-cooling part and regular cooling with heat pump. Free-cooling takes place when inlet temperature is smaller than 12 °C. The total cooling energy achieved by reusing cold stored in BHE reaches up to 43 kWh daily. The free-cooling COP is estimated by dividing total cooling energy by the electrical energy estimated to be used by fan coils and circulating pumps.

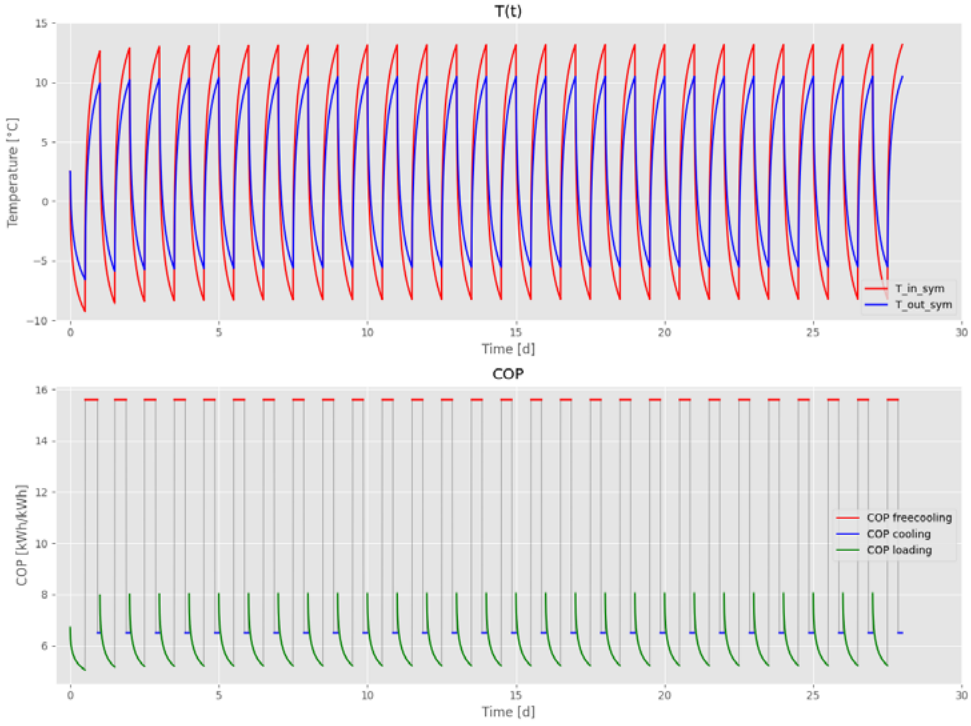

Fig. 5. Month simulation of the day/night cycle of loading and unloading the ground cold storage designed as a source of cooling of Euros Energy headquarter in Koprki.

5.2. Week cycle (12/9)

The second one shows a week-long cycle, during which there are 60 hours of heat delivery, 60 hours of heat extraction and 48 hours of idle. The details of cycle is specified in Table 5.

Table 5. Loading and unloading scheme. Notation: +Q states heat delivery; -Q states heat extraction; 0 states idle

	00^{00}-7^{00}	7^{00}-8^{00}	8^{00}-20^{00}	20^{00}-22^{00}	22^{00}-23^{59}
MON	+Q	0	-Q	0	+Q
TUE	+Q	0	-Q	0	+Q
WED	+Q	0	-Q	0	+Q
THU	+Q	0	-Q	0	+Q
FRI	+Q	0	-Q	0	
	00^{00}-7^{00}		7^{00}-19^{00}	19^{00}-23^{59}	
SAT	0		0	+Q	
SUN	+Q		0	+Q	

The week long cycle results plot presents that temperatures plots remain almost the same in case of comparing them week by week. The simulations starts on Friday at 20:00. During the weekdays inlet temperature at picks increases due to unbalanced heat energy supplied and received out of the BHE. The 12/9 cycle represents the

workload of a heat pump systems in an office building. The energy that is stored during nights and weekend can be retrieved during working hours at work days. Koprki's example presents 300 kWh of energy converted in BHE throughout one week. The COP of loading varies from 5.5 to 7.6. The free-cooling phase COP reaches 20.2, while conventional cooling phase coefficient of performance equals to 6.5.

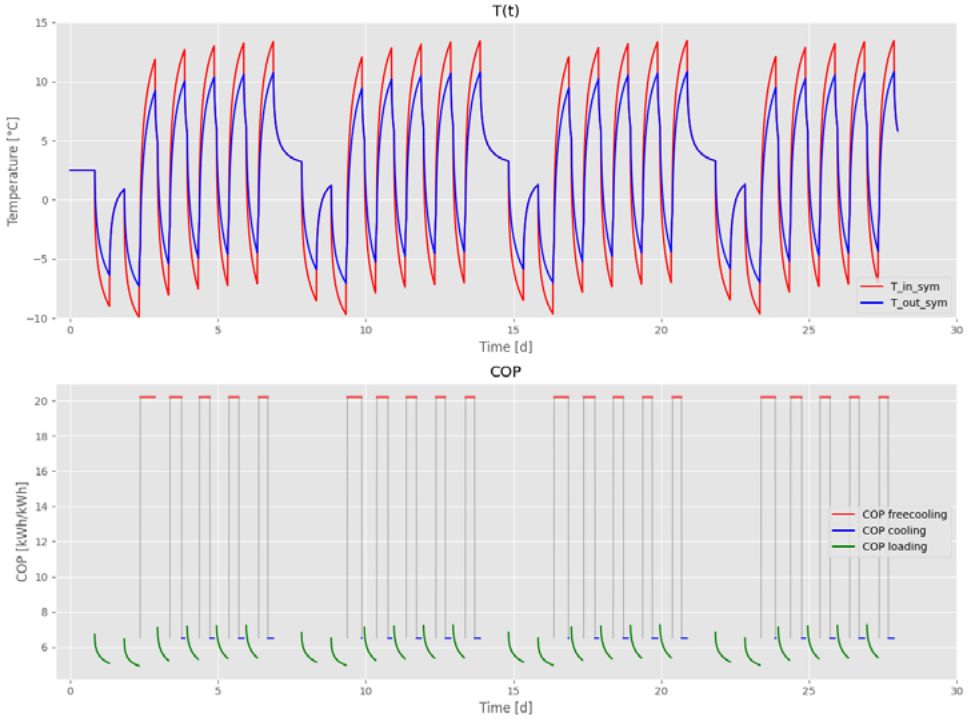

Fig. 6. Month simulation of the day/night cycle of loading and unloading the ground cold storage with weekends included.

6. Conclusions

The HENS model allows to solve complex heat conduction problem with relatively high accuracy. It is a great pre-processing tool to quickly evaluate the range of ground and soil thermophysical parameters. The correctness with three different TRT test proves that HENS can be highly applicable in research on heat pumps systems. Using HENS opens the possibility of investigation of long-term storage of heat or cold with defined workloads, including short-term cold storing with rapid loading/unloading. Moreover, a custom heat load may be specified. It allows to optimise cooling system for commercial of office buildings with specified energy tariff. Short-term heat storing takes place when the conditions are beneficial i.e. low energy tariff. Energy may be reused later to air condition buildings with free-cooling mode.

Nomenclature

r	Radius (m)	t	Time (s)
α	Thermal diffusivity (m^2/s)	Subscripts	
Q	Heat load (W)	b	Borehole
T	Temperature (K)	f	Fluid
q	Borehole heat load (W/m)	ff	Far-field
z	Depth (m)	g	Grout
k	Thermal conductivity (W/m/K)	s	Soil

Abstract

The Austrian building sector accounts for 16 percent of national CO_2 emissions. This makes it a key sector to decarbonize if long-term environmental targets are to be met. Relevant measures focus on the thermal-refurbishment of existing buildings and the phaseout of fossil-based technologies. The task specified by the Austrian government, involves replacing 600.000 oil heaters currently in use against renewable alternatives by 2035. This is the point of departure of this study. We investigate key barriers and solutions for the switch from fossil-based systems to c*omfort & climate boxes* (CCBs) in the Austrian 1-2 family housing segment. CCBs are integrated systems encompassing a heat pump, storage and integrated control. The study applies a two-step approach: First, 11 problem-centered stakeholder interviews are conducted and evaluated using quantitative content analysis. Next, a stakeholder survey is conducted to assess the subjective relevance of barriers identified in the interviews. Results yield 45 barriers clustered into 6 categories. We identify discrepancies in the relevance-perceptions between stakeholder groups, especially between researchers and key market actors. We advise realigning research agendas along market actors' perceptions, as these actors possess closeup insights about the market environment for CCBs.

Keywords: Heat pumps; innovation system; integrated storage; market barriers

1. Introduction

In line with the long-term goals of the European Parliament and Council, Austria has pledged to reach carbon-neutrality by 2050. These goals are to be met in part by national "effort-sharing": measures targeted at by increasing energy efficiency, the share of renewables in sectors not included in the European Emissions Trading Scheme (ETS). In 2017, the building sector accounted for over 16 % of total Austrian CO_2 emissions (excluding ETS sectors). Nearly a third of total energy consumption is used for space-heating, of which 17.6 % is provided using oil-based heaters and 28.2 % using natural gas [1]. Alternatives to these systems exist and are diffusing into the market at an accelerating pace, stimulated by falling technology prices and technical improvements, stronger environmental awareness and conducive policy shifts.

While the efficiency of heat pumps, thermal and electoral storage devices and solar PV systems is constantly improving, integrated systems that combine all or several of these individual technologies, are less common in Austria. Their integration, however, could valuably contribute to sectoral decarbonization. Integrated systems consisting of heat pumps and storage are an important technological option to accelerate the use of renewable energy for heating and cooling, in many countries worldwide. By combining heat pumps and storage, several issues may be tackled, such as: balancing and controlling electricity grid loads; capturing a larg(er) share of renewable (local/regional) input (i.e. solar thermal, solar PV); optimizing economics, CO_2-emissions, fuel use throughout time; providing optimal security of supply to buildings.

Commercial development of this type of solution is progressing very slowly in most countries, even in those who have relatively mature heat pump market. Therefore, the combined Annex HPT Annex 55/ECES Annex 34 (international collaboration project) was initiated in 2019 as a collaboration between two TCPs (Technology Collaboration Programmes) by IEA and the Mission Innovation initiative. This annex will aim at accelerating market diffusion of combined heat pump / storage packages including integrated control, a so called "Comfort and Climate Box", or "CCB". The work within the Annex is focused on systems that will be close to commercial realization, have a high quality and be adopted to their local market.

Aligned with the Annex goal, the aim of this study is to identify the factors hindering the diffusion of CCBs into the Austrian 1-2 family housing segment and to derive solutions for overcoming them. Findings may provide useful insights for industry strategy as well as targeted policy making on both a national and international level that could accelerate CCB diffusion.

The rest of this paper is structured as follows. Section 2 presents the technical CCB definition used. Section 3 introduces the conceptual framework used, as well as the key actors of the CCB system. Next, Section 4 explains the methodological design of the study. Section 5 presents research findings. Following a brief discussion in Section 6, we finish with conclusive remarks in Section 7.

2. CCB Definition

Contrary to the broader definition of CCBs used in the international IEA HPT Annex 55/ECES Annex 34 project, the data collection process of the present study mandates a more precise definition, as presented in Fig. 1.

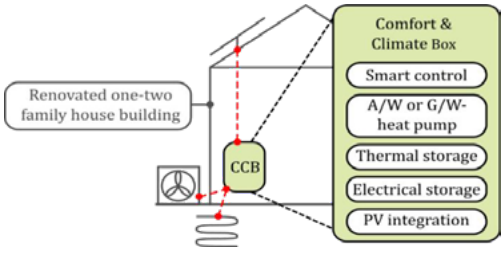

Fig. 1 Definition of the CCB for the present study

While heat pumps with integrated thermal storage are well-established in the Austrian market, their smart integration with PV systems and electrical storage is rather unknown. Ground- and air-source heat pumps with up to 10 kW heating power report rising yearly installation figures in Austria of +14.5% and +11.6 %, respectively [2]. Therefore, both systems are of great interest for this study. In line with the international annex definition, electrical and thermal storage as well as smart controls are included. Additionally, we include a PV system, as the increased installation of PV is a crucial measure specified by the Austrian government to reach climate goals [2]. Moreover, the combined use of PV and heat-pumps is associated with a higher proportion of own-consumption and lower electricity bills.

3. Technological innovation systems

The technological innovation system (TIS) provides a useful conceptual framework for our investigation of CCB diffusion in the Austrian 1-2 family housing segment. The central idea underlying TIS research is that technological innovation results from complex exchange of information and technologies between system actors [3]–[6]. Suurs et al. [3] describe a TIS in terms of its four principal components: its actors, institutions, technologies and their interrelations (networks). System *actors* include firms and non-firm organizations (such as interest groups, industry representatives, research organizations and authorities). *Institutions* refer to formal institutions (such as technical norms, laws and guidelines) as well as informal institutions (such as beliefs, habits and routines). Institutions play a pivotal part in the development of innovations, as they regulate actors' actions and the interactions between them, following Hekkert et al. [7]. The system *technology* refers to technical knowledge and skills, as well as technoeconomic factors such as costs and technical risks. Suurs et al. [3] stress that these technological factors are crucial for understanding feedback mechanisms between institutional and technological change.

The TIS framework focuses on a specific technology (or product) and is commonly applied to investigate what conditions foster or hinder the development of emergent technologies [7]. This makes the TIS framework ideal for the analysis of CCBs diffusion in the Austrian 1-2 family housing segment. Based on the expert knowledge about the research field within the research team – composed of applied researchers in the energy and buildings innovation nexus in Austria – a mapping of the system actors of the CCB TIS in Austria was conducted. The mapping is presented in Fig. *2* below. This mapping provided a useful basis for data collection and sampling decisions for the remainder of the research project.

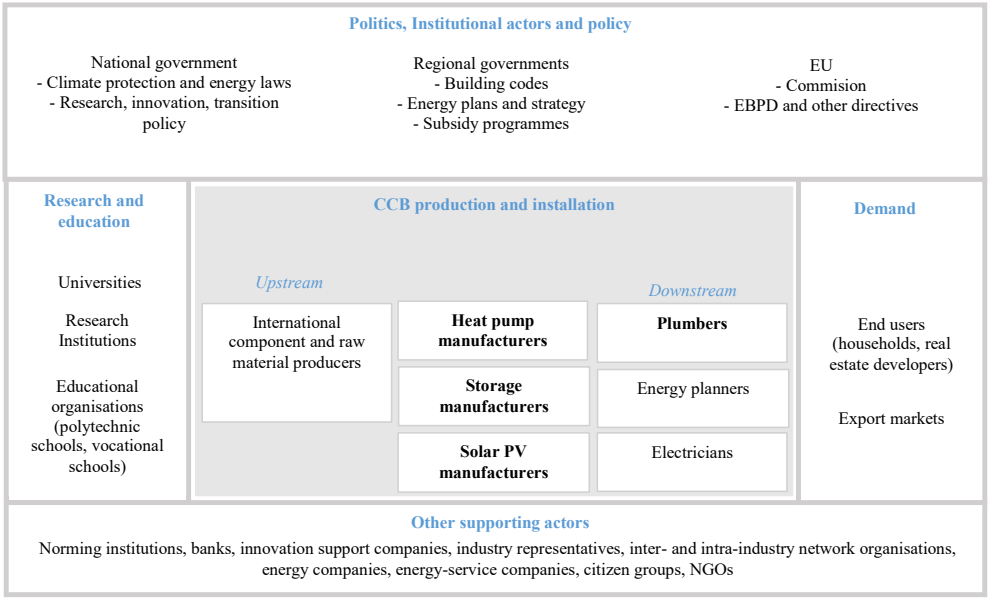

Fig. 2: Mapping of CCB innovation system actors - layout according to Hekkert et al. (2011) *[4]*. Key actors in bold.

A fruitful TIS does not develop overnight, but rather is formed with time during a complex build-up process [7]. A growing body of innovation system research has studied this buildup process by analyzing system functions (=key actions). This provided the starting point for the construction of our expert interview guidelines and provided support for our coding strategy in the data analysis section.

4. Methodology

This study adopts a mixed-method research (MMR) approach – an approach that combines at least one element of qualitative research with one element of quantitative research with the aim of increasing the depth of the investigation [8]. The benefits of mixed-methods research are increasingly recognized by the social science community, with authors such as Jungmann et al. (2015) [9] advocating for its wider application in multidisciplinary research domains such as that of innovation studies. The investigation is thus divided into two stages, as described in the following.

4.1. Expert interviews

In a first stage, 11 semi-structured expert interviews are conducted with key actors within the CCB TIS to identify potential barriers to CCB diffusion in Austrian 1-2 family housing segment. Expert interviews are an effective interviewing method commonly used in exploratory research to collect data about a specific field of interest. Following Meuser and Nagel (2004) [10], expert knowledge can be characterized as "specific knowledge in a particular field of action". While there is much ongoing debate about what constitutes an "expert", we adopt the broad definition of Bogner (2002) [11], where an expert is any actor who, due to his or

her current and past professional experiences, is in possession of a (institutionalized) competence to provide information on a specific topic.

Interviewees were selected using a theoretical sampling strategy [12] and snowballing (interviewees suggest further interview candidates). The aim was to include key actors relevant for the production and market diffusion of CCBs in Austria. The researcher teams' experience-based knowledge on the development and diffusion of other energy-innovations in the Austrian building sector, aided them in identifying these actors. The interview-sample thus included: 3 energy and building innovation researchers, 4 heat pump and storage technology producers, 1 plumber, 1 regional official responsible for regional energy-planning and 2 real estate developers. Focus was placed on regional diversification and on professional experience within the 1-2 family housing segment. Insights from a brief review on energy-innovation and TIS research provided the basis for the construction of the interview guidelines. Each interview was started with a brief introduction into the research project and technical overview of CCBs by the interviewer. The recorded interviews were transcribed, and a qualitative content analysis is conducted. In line with Mayring (2012) [13] the transcribed interviews were (1) openly coded, then (2) axially coded and finally (3) selectively coded to generate categories of barriers. The interviews and coding were conducted in German, then translated into English by the research team.

4.2. Survey

The target population for the survey were key industry actors involved in the development and diffusion of CCBs in Austria. Survey participants were provided with a concrete definition of a CCB prior to the survey (see section 2), then asked to rate the barriers collected during the expert interviews with respect to their relevance for the diffusion of CCBs in Austrian 1-2 family houses. In line with general opinion research, as reviewed by Marsden and Wright (2010) [14], a five-point Likert scale from 1 (irrelevant for CCB diffusion) to 5 (completely relevant for CCB diffusion) was selected for the survey. A pre-testing of the survey was conducted to ensure the questions and rating schemes were comprehensible by the target survey-participants.

The survey was initially disseminated to the participants of a workshop during the e-nova conference in November 2020 (https://www.fh-burgenland.at/news-termine/veranstaltungen/e-nova-2020/). The conference brings together researchers and interested professionals from the energy, buildings and environment domain across Austria, thus providing for a very valuable and informed survey participant sample (n=30). The survey was then further disseminated across the networks of the research team's institutional networks, yielding a total sample size of n=58.

Due to the limited sample size, we decided to limit the analysis to a descriptive statistical analysis. Given a sufficiently large and representative sample, a multivariate analysis will be presented in a follow-up paper.

5. Results

5.1. Expert interview findings

The expert interviews lasted between 30 and 50 minutes and were conducted between August and October 2020. All interview recordings were transcribed and deleted upon transcription. The anonymity of the interviewees was consistently safeguarded. The qualitative analysis yielded 45 barriers, clustered into 6 categories: Financial barriers (F), information barriers (I), regulatory and policy barriers (R), barriers related to subsidies (S), technical barriers (T) and stakeholder-specific resistance (W). See Table 1 below. Note that the table also includes the survey rating results (column *"Score A(R/M/P)"*, which will be discussed in section 5.2.

Table 1 Experts Interview results and score of the survey (A)ggregated value and (R)esearcher-, (M)anufacturer- and (P)lumber-specific. The 10 highest rated barriers are indicated with a bold style score.

Financial barriers		Score A (R/M/P)
CF1	Installation costs are too high for households	2.7 (2.5/2.7/2.7)
CF2	System costs are too high for households	2.9 (2.5/3.1/2.9)
CF3	The efficient use of CCBs requires extensive refurbishment efforts by households	3.3 (3.5/3.4/3.3)
CF4	Planning bureaus lack the financial incentive to plan CCBs	3.2 (3.4/3.5/2.9)
CF5	Energy consultancy costs are too high for households	2.3 (2.0/3.2/2.1)
CF6	Older households prefer systems with low upfront costs over systems with low operating costs	3.1 (3.4/3.0/3.1)
CF7	If the existing system is functional, households lack the financial incentive to switch to CCBs	3.6 (4.6/3.4/3.4)
Information barriers		
CI1	Better information on flammable refrigerants is required	3.5 (3.9/3.7/3.3)
CI2	**The general shortage of skilled workers reduces product and service quality in the construction market**	**4.0 (4.1/4.1/3.8)**
CI3	CCBs are generally unknown by plumbers	3.4 (3.4/3.9/3.0)
CI4	The comparison of combined products, like CCBs, with individual products, like heat pumps, is difficult	3.1 (3.8/3.7/2.0)
CI5	System labeling could help but is rarely used in practice	3.7 (3.6/3.8/3.8)
CI6	Information shortages among older households reduces propensity to switch to CCBs	3.7 (3.9/4.1/3.4)
CI7	There is no central CCB contact for households.	3.5 (4.0/3.7/2.9)
CI8	**There are diverging opinions on the usefulness of CCBs in un-renovated buildings**	**3.8 (3.9/3.9/3.4)**
Regulatory barriers		
CR1	Relevant technical international and national norms are unharmonized	3.2 (3.3/3.6/3.3)
CR2	**The regulation on maximal sound-emissions is unharmonized**	**3.8 (3.7/4.1/3.7)**
CR3	**Requirements for thermal refurbishment and withdrawal from fossil fuels are not strict enough**	**4.0 (4.1/3.9/4.2)**
CR4	The directive on refrigerants is outdated	3.1 (2.5/3.5/3.1)
CR5	There is no universal coefficient-of-efficiency for energy systems that considers storage-management	3.6 (3.9/3.6/3.6)
CR6	**National property law requires unanimous consent among the ownership community**	**4.2 (4.2/4.3/4.4)**
CR7	Uncertainty about future feed-in-tariffs reduce the incentive to switch to PV-coupled systems	3.3 (3.3/3.6/3.3)
Subsidy-related barriers		
CS1	**Subsidy schemes are not harmonized between federal states**	**3.9 (3.9/4.3/3.9)**
CS2	Subsidies for air-based heat pumps are insufficient	3.2 (3.1/3.9/2.9)
CS3	**Subsidies for ventilation systems are insufficient**	**3.7 (3.9/4.1/3.7)**
CS4	Subsidies for other CCB components (storage technologies, PV, etc.) are insufficient	3.5 (3.7/3.8/3.5)
CS5	Federal subsidies prioritize biomass-based systems	3.4 (3.3/4.4/2.8)
CS6	Subsidies for energy consultancy and supply of public energy consultancy services are insufficient	2.9 (3.1/3.5/2.6)
CS7	**The application process for relevant subsidies is complicated and lengthy**	**3.8 (4.2/4.4/3.4)**
Technical barriers		
CT1	Sound emissions are too high	3.3 (3.4/3.2/3.3)
CT2	There is limited space for indoor components	3.2 (3.2/4.1/2.5)
CT3	Without thermal refurbishment, system efficiency is limited	3.5 (3.7/3.7/3.8)
CT4	**If flammable refrigerants are used, this can cause difficulties for indoor installation**	**3.8 (3.7/4.1/3.5)**
CT5	CCBs are not flexible enough for their use in renovation cases (e.g. combinable with existing components)	3.1 (3.0/3.5/3.4)
CT6	If a ventilation system is included in the CCB, this can complicate the installation process	3.6 (3.6/4.4/3.3)
CT7	There is no universal communication protocol for energy systems	3.7 (3.8/4.3/3.2)
CT8	A CCB must be able to withstand power outages for extended time periods	2.3 (2.1/2.3/2.6)
Stakeholder-specific resistance		
CW1	The efficient use of CCBs requires behavioral adaptations by households	2.9 (2.6/3.6/2.8)
CW2	**Households prefer simple systems that require minimal adjustments to the building structure**	**4.0 (4.5/4.2/3.4)**
CW3	There is resistance against combined products by producers who do not produce these	3.2 (3.7/3.4/3.1)
CW4	There is resistance against combined products by plumbers, as the low required installation effort reduces their fees	2.7 (3.7/2.6/2.3)
CW5	There is resistance against combined products by housing companies, as they expect additional maintenance costs	3.1 (3.5/3.2/2.9)
CW6	Consultants and planers disregard CCBs, as they focus on systems that are eligible for subsidies	3.4 (3.2/3.7/3.5)
CW7	CCBs are only useful in passive-houses	1.9 (1.9/2.0/2.3)
CW8	Households that install complex energy systems tend to be demanding and require a lot of support	2.3 (2.1/2.9/2.4)

5.2. Survey findings

The close-ended survey was conducted using the online tool *Mentimeter* (https://www.mentimeter.com/) and was filled out by 58 individuals. The participants derived from different occupational groups from within the CCB TIS (as detailed in Section 3). Figure 1 shows the share of participants per occupational group. We find that 48 participants (83 %) were manufacturers (16 participants, 27 %), researchers (14 participants 24 %) or plumbers (18 participants, 31 %). We focus our analysis on the aggregate survey results and on occupational-group specific results of the aforementioned three groups only. The ten barriers with the highest mean rating across all occupational groups are indicated in bold in Table 1 above.

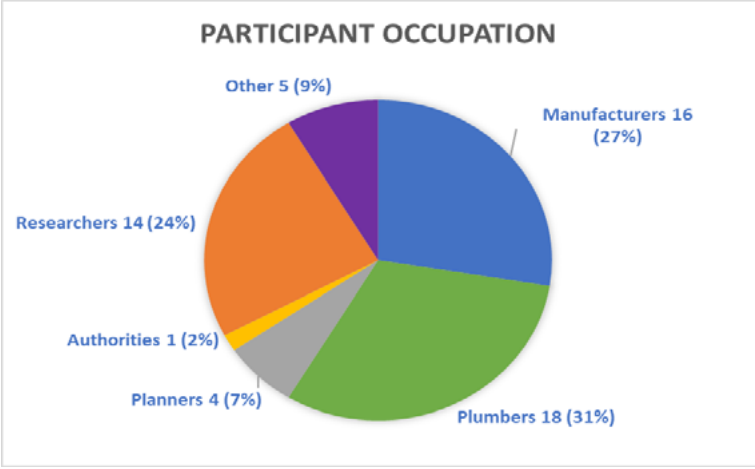

Fig. 3 Survey participants by occupational group

Notably, no financial barriers rank among the top 10 highest-rated barriers across occupational groups. In fact, the highest financial barrier (CF7) ranks 15th of 45. The top 10 highest-rated barriers are dominated by regulatory/policy-based barriers (CR6, CR3, CR2) and subsidy-based barriers (CS1, CS7, CS3).

The highest ranked barrier (CR6, score: 4.2) refers to the Austrian property laws (*Wohnungseigentumsgesetz* WEG2002). The law requires that any "unusual" changes to the building be unanimously agreed upon by the owner community. One abstention can block intentions to replace energy systems. This barrier is not relevant in a single-family house but becomes an issue in two- or multifamily houses. The second highest regulatory barrier for CCBs is CR3 (insufficiently strict requirements for thermal refurbishment and withdrawal from fossil fuels) with a score of 4.0. Without adequate regulatory pressure to reduce energy demand and emissions from buildings, demand growth for emerging renewable energy technologies like CCBs will be sluggish. The third regulatory barrier (CR2, score: 3.8) among the top 10 barriers, refers to unharmonized sound emission regulations across federal states in Austria. This requires and manufacturers to learn and monitor changes to different regulations when developing and installing CCBs all over Austria

Similarly, a lack of harmonization across subsidy-schemes between federal states (CS1, score 3.9) is rated a highly relevant barrier for CCB diffusion. Participants generally agree that complicated subsidy application processes and extensive waiting periods for subsidy-approval can hinder CCB diffusion (CS7, score 3.8). CS3 with a score of 3.7, refers to insufficient subsidies for ventilation systems. While not essential according to this study's CCB definition, several CCB currently on the market also include ventilation (see for example PKOM-4 from *Pichler Luft*). In several federal states, ventilation systems are not subsidized directly, but indirectly by means of subsidies for thermal refurbishments.

The fact that households prefer simple systems that require only minimal adjustments to the building structure (CW2, score 4.0) is rated as second highest overall CCB diffusion barrier. The installation of CCBs

can in fact involve extensive adjustments to the building structure – far more than just the replacement of one heating system for another. Therefore, solutions that can use as much as possible of the existing system should have advantages over others.

Two information/knowledge barriers are listed among the top 10 most relevant barriers: CI2 with a score of 4.0 addresses the general shortage of skilled workers in the CCB market. The need to plan and coordinate multiple CCB components require high-skilled work force. However, arguably many installation aspects could be simplified or standardized by manufacturers prior to installation. Diverging opinions on the usefulness of CCBs in unrenovated buildings (CI8, score 3.8) was also rated highly relevant.

Uncertainty among experts / consultants contribute to financial and technical uncertainty among decision-makers, thus reducing end-users' (household) willingness to invest and, similarly, plumbers' willingness to install CCBs. Finally, one technical barrier scores among the top 10 barriers. It refers to the difficulty of indoor installation of CCBs when flammable refrigerants are used (CT4, score 3.8). This is an issue for every new installed heat pump with a low GWP refrigerant and a high flammability. Some manufacturers solve this issue by placing all components that contain refrigerants in the outdoor unit. Others install additional safety measures to comply with the local guidelines and laws, or even reduce the amount of refrigerant in the system to fall below the minimum quantity for ignition.

The survey results disaggregated by occupational group yield interesting insights. Fig. 4 shows the barriers with mean researcher ratings greater than or equal to 4 (i.e. barriers rated "very relevant"). Researchers stress the relevance of household motivation: as long as the existing system is functional, there is little financial incentive to switch to new systems (CF7). With new oil-boilers living up to 20 years, this could mean that owners of homes newly outfitted with boilers within recent years, will lack the financial incentive to switch to new systems before the end of the 2030s. Researchers also stress the relevance of household preference for simple (non-invasive) system changes CW2, national property law unanimity clauses (CR6), complex and lengthy subsidy processes (CS7), lacking strictness of refurbishment strategy and regulations (CR3) and the lack of required skilled workers (CI2). Moreover, they stress that households in the 1-2 family housing segment have no central contact person for CCBS. In the multi-family residential building sector, this is the planer. Planning bureaus do not tend to operate in this 1-2 family segment. The current contact person for heating issues in this segment is the plumber. Plumbers are conventionally not trained to be able to perform complex technology-field overarching planning and coordinating.

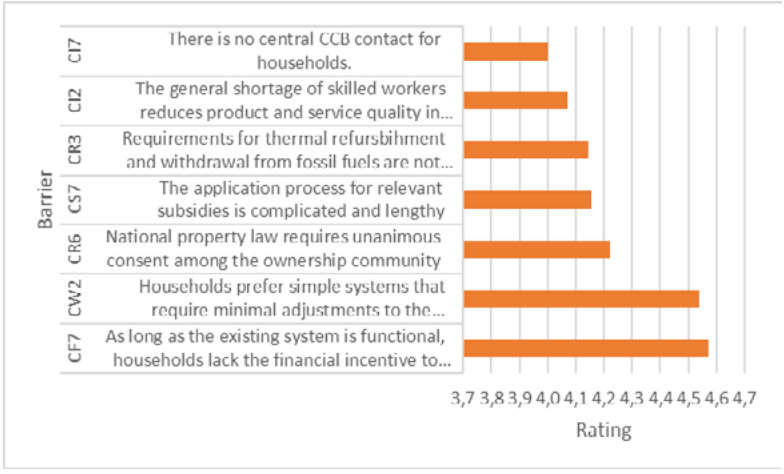

Fig. 4 Barriers rated 4 or higher by researchers

Thirteen barriers were rated greater than or equal to 4 in average by manufacturers, as seen in Fig. 5 We find a stronger perceived relevance of technical barriers and technology-oriented regulations among this occupational group. The surveyed manufacturers stress the relevance of CT6 (difficult retrofitting of CCBs with ventilation), CT7 (no standardized communication protocol), CT2 (limited space for indoor components)

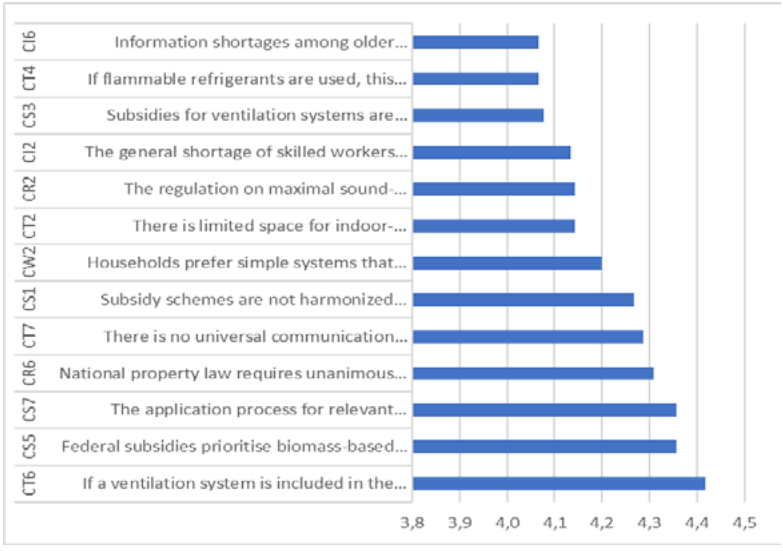

Fig. 5 Barriers rated 4 or higher by manufacturers

and CT4 (difficulty for indoor installation if flammable refrigerants are used). The focus on these technical/practical aspects by this group is unsurprising: They receive firsthand technical feedback from end-users and plumbers and can use this to improve product design, giving them a qualitative advantage over competitors.

Manufacturers consider the preferential treatment of biomass in federal subsidy schemes (CS5) a very relevant CCB barrier. Biomass is a strong competitor for heat pump-based systems in Austria, and very relevant for the 1-2 family house segment. Manufacturers also stress the generally complicated and lengthy subsidy application process (CS7) and their harmonization across federal states (CS1) that requires extensive bureaucratic efforts and reduces end-user incentives to apply for subsidies. They also stress the regulatory barriers CR6 (national property law, unanimity clause) and CR2 (unharmonized maximal sound emission regulation). Arguably, most of these regulatory and subsidy-based barriers refer to institutional phenomena that increase the *time* it takes to install CCBs. Thus, installation *speed* seems a crucial factor for CCB acceptance, according to manufacturers. Two information barriers are also rated highly: next to the issue of a general lack of skilled workers (CI2), manufacturers stress the limited access to relevant information among older generations. Of course, without awareness of innovative heating products and their benefits, households will not pursue them when engaging with their plumber.

Finally, two regulatory barriers were rated greater or equal to 4 by plumbers, as seen in Fig 6 below. CR6 (national property law unanimity clause) and CR3 (lacking strictness of refurbishment and withdrawal from fossil fuels). A closer look at the installers' survey results, yields a slightly larger variation in their rating behavior (standard deviation = 1.2 points), relative to researchers (= 1.12) and manufacturers (=1). This suggests a stronger heterogeneity of opinions among this occupational group and could explain its low count of highly relevant barriers. Exploring this further, however, exceeds the scope of this investigation.

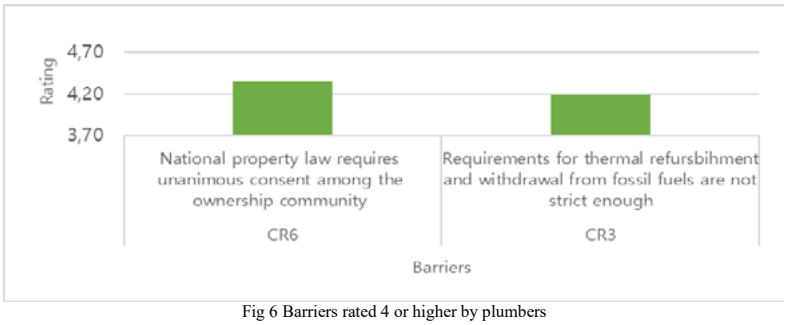

Fig 6 Barriers rated 4 or higher by plumbers

There are significant differences between the barrier-relevance perceptions of individual occupational groups. This is illustrated in the following figures (Fig. 7, Fig 8, Fig 9). The figures display those barriers with differences in ratings greater than 1 between two occupational groups.

Figure 7 displays those barriers for which the difference between the manufacturer rating and the researcher rating is greater 1. While researchers consider CW4 (resistance against combined products by plumbers, due to low installation effort, thus reduced revenues) a rather relevant CCB barrier (score: 3.7) manufacturers find it less of an issue (score 2.6). In fact, plumbers (score:2.3, cf. Fig 9 **오류! 참조 원본을 찾을 수 없습니다.**) consider it even less relevant. To understand this discrepancy, it would be interesting to further explore the channels through which CCBs reach end-users, and whether the installation of CCBs in fact reduce plumbers' revenues, thus disincentivizing their uptake into plumbers' service-portfolios. The knowledge gap between the researchers and the other two survey groups is worth uncovering, to better steer product development in the future. Next, we see manufacturers rating CS5 (biomass is prioritized in subsidies) higher than researchers. As manufacturers are directly involved in the market for heating technologies, while researchers are not, this result seems less surprising: heat-pump producers for example, directly compete with biomass-based heating technologies. Plumbers on the other hand, consider this less of a relevant barrier (score: 2.8). This might be an expression of end-users' non-monetary preferences, for example a preference for technical simplicity, or reliability. This raises the question of substitutability between renewable energy systems. Arguably, someone with a strong preference for heat-pumps, will not consider biomass-heating a reasonable substitute. In this case, a biomass-subsidy may then only affect his or her decision to invest in heat pumps weakly.

More of a surprise is the difference in CF7 (households lack financial incentive to switch to new systems if the old one is still functional), which was rated significantly higher by the researchers (4.6) than by the manufacturers (3.4). Plumbers (3.4) rate this barrier similarly to the manufacturers. They seem to believe, that households are not uninclined to switch away from a functioning system. As manufacturers and plumbers have more regular interaction with households, this insight could be of value to researchers developing systems that can compete against functioning systems, not just new systems. Finally, CF5 (high energy consultancy costs)

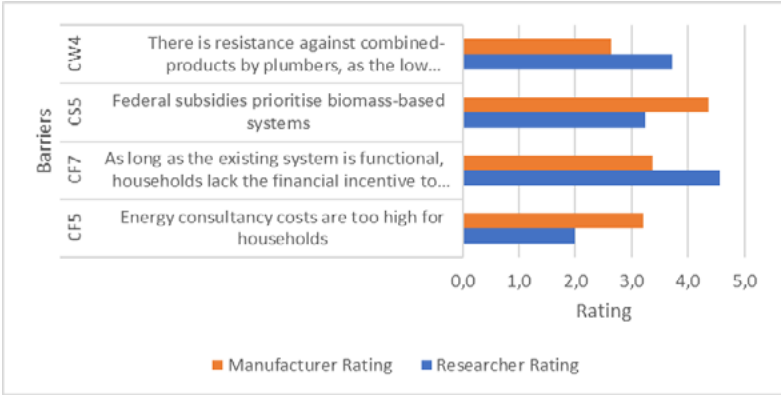

Fig. 7 Barriers with absolute difference in ratings greater than 1 – manufactures and researchers

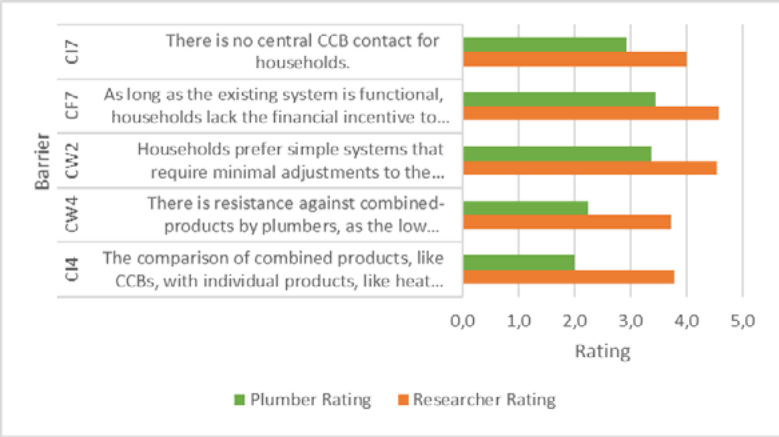

Fig 8 Barriers with absolute difference in ratings greater than 1 – plumbers and researchers

is rated rather irrelevant by researchers, while manufactures consider it relevant. Energy consultancy is a very heterogenous service and can range from a rudimentary consultancy provided (for free) by federal energy agents, to (costly) complex concept comparisons. These costs are often found lacking in technoeconomic studies of system alternatives.

Looking at Fig 8 we find that the largest rating differences between plumbers and researchers all refer to barriers perceived less relevant by plumbers. Like manufacturers, plumbers consider CW4 (plumber resistance against combined products) rather irrelevant for CCB diffusion, while researchers consider them very relevant. We also find that plumbers deem CI4 (difficulty of comparing combined systems) far less relevant than researchers (rating: 3.8) and manufacturers do (score 3.7., cf. Fig. 7 **오류! 참조 원본을 찾을 수 없습니다.**). One possible interpretation of this difference could be that the energy efficiency of the system is less important to plumbers than other points, such as reliability or simplicity of installation. Notably also, researchers seem to consider the fact that there is no central CCB contact for households (CI7) a more relevant barrier, while plumbers find it just relevant. Perhaps plumbers consider *themselves* the CCB contact for households. They may however be less informed about CCBs than researchers and might underestimate the extent to which CCB installation may differ from conventional heat pump installation processes.

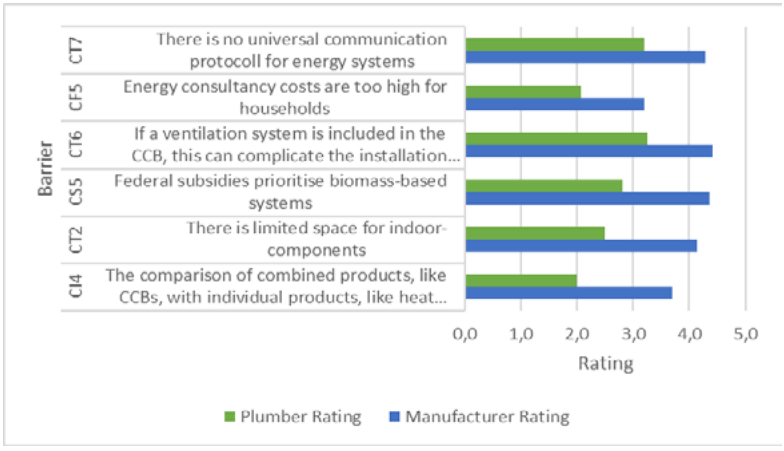

Fig 9 Barriers with absolute difference in ratings greater than 1 – plumbers and manufacturers

Similarly, as in Fig 8, we find that plumbers rate the relevance of six barriers lower than manufacturers. Differences largely concern technical barriers: CT7 (no universal communication protocol), CT6 (installation process if CCB it to contain a ventilation system) and CT2 (there is limited space for indoor components). Especially, the difference in CT2 ratings could be of great interest to manufacturers. Installers interact more

closely with the end-users, so this insight could be used by manufacturers to reconsider their product development strategy. The difference in CT7 could be explained by the fact that manufacturers tend to be specialized on specific components (e.g. heat pumps, or thermal storage technologies), thus integrating their component into a comfort climate box using components of other specialized producers will prove difficult given unharmonized protocols. This is an issue that installers may not feel as strongly, as they can simply go to those producers who provide complete CCBS (i.e. produce all components with harmonized protocols). The differences for CI4 (difficulty in comparing CCBs with individual products like heat pumps) and CS5 (biomass is prioritized by subsidies) were already discussed previously. Furthermore, the difference in rating of CI4 and CS5 could also stem from competition issues experienced by producers and felt less strongly by installers.

6. Discussion and Limitations

The selected methodology succeeded in generating interesting first insights into the dynamics of emerging energy-system in the Austrian 1-2 family building sector. Most importantly, it produced an extensive list of barriers blocking the diffusion of CCBs. Notably, we uncovered several potential knowledge gaps between occupational groups. Researchers could use these results to redirect their research to address practical barriers experienced by manufacturers and plumbers. Similarly, manufacturers and plumbers, two key actors in CCB diffusion, can use these findings to better align or synthesize product and service development to better reach the market.

However, the findings from the descriptive statistical analysis are limited. They do not allow for a deeper investigation of the *reasons* for rating-differences between occupational groups. Follow-up research should be conducted to further investigate these differences. Moreover, increasing the survey sample size to a representative size would allow for a more thorough multivariate analysis that could be of value to industry and research. Also including socioeconomic, geographic and company characteristics would prove interesting to understand differences in barrier-ratings. We also acknowledge the need to include the end-users into follow-up research and data collection. It would be interesting to discover whether supply-side perceptions of end-user energy-system adoption preferences are in line with actual household preferences.

Within the HPT Annex 55/ECES Annex 35, drivers and barriers for market diffusion for CCBs in all participating countries, from Europe, Asia and America, are investigated. The results from Austria will be compared to results from other countries, in order to map which barriers and drivers that are general for many countries and which are unique for Austria. As a next step, recommendations to important stakeholders/targets groups on both international and national level, to overcome the most important barriers, will be outlined, based upon the findings withing the Annex work.

7. Conclusion

CCBs are a promising, ecological alternative to fossil-based energy systems in the 1-2 family housing segment. Driving its development is the observation that demand for renewable energy technologies is obstructed by numerous barriers related to financial, technical, information-based, regulatory, subsidy-based factors and stakeholder-specific preference. This study contributes to the identification of these barriers and provides insights into their relevance from 3 key occupational groups involved in the development, innovation and diffusion of CCBs.

We find strong differences in the relevance-perception of barriers between researchers and the two key market actors for CCBs – manufacturers and plumbers. By aligning technology research with market actors' barrier perceptions, research can generate more problem-oriented solutions, thereby contributing to the acceleration of CCB diffusion in Austria. Diverging relevance-perceptions between the two key market actors, clearly presents a need for stronger industrial alignment. Manufacturers could benefit from adapting their product development strategies to the information supplied by plumbers about end-user preferences and technology-selection behavior. Household preference for simple systems requiring minimal adjustments to the building structure, call for CCBs that are largely integrable into the existing building and energy system. Moreover, as plumbers are (currently) the intermediary between manufacturers and the end-user, manufacturers could be advised to consider plumber needs and abilities in their product-development and marketing strategies. The current shortage of skilled labor, as well as the cross-technological nature of CCBs, call for the development of easy-to-install or standardized CCBs. Furthermore, small specialized components manufacturers (e.g. heat pump manufacturers, solar PV manufacturers), without the inhouse expertise or means

for producing all required components, could benefit from creating production consortia, to compete against large CCB producers.

As for policy and regulation, there is a unanimous call for the harmonization of building codes, subsidy schemes and norms. Moreover, calls for property law reforms and stricter obligations for thermal refurbishment are echoed by all surveyed system actors. Finally, policymakers are advised to focus on *actor-specific* barriers to develop truly effective measures.

Follow up research could yield more in-depth insights into CCB diffusion barriers as well as strategies for overcoming them, by extending the sample size and accounting for more system actors. Also, the inclusion of firm-level characteristics (e.g. firm size, segment-specific experience, networking behavior) could permit a more differentiated analysis of the results. We also advise to conduct a household-level investigation of heating-system preferences to augment this study's findings and generate fruitful insights for industry and research strategy.

8. Acknowledgements

The Austrian Research Promotion Agency (FFG) is gratefully acknowledged for funding this work under Grant No. 876733 and No. 871490. Furthermore, the authors would like to thank Christian Heschl (FH Burgenland), Andreas Heinz (TU Graz) and Fabian Ochs (Universität Innsbruck) from the Austrian IEA HPT Annex 55 team for discussions about CCB definitions and market barriers in the preparation phase of this study. Furthermore, we thank Christian Köfinger, Klemens Marx, Thomas Natiesta, Felix Hochwallner (all AIT) and Robert Kranner (FH Burgenland) for their help and support during the workshop at the e-nova conference

Performance simulation of CO_2 transcritical cooling system with mechanical subcooling cycle using low GWP refrigerants

Sun-Ik NA, Gu Hwang KANG, Min Soo KIM* *

Department of Mechanical and Aerospace Engineering, Seoul National University, Seoul 08826, Republic of Korea

Abstract

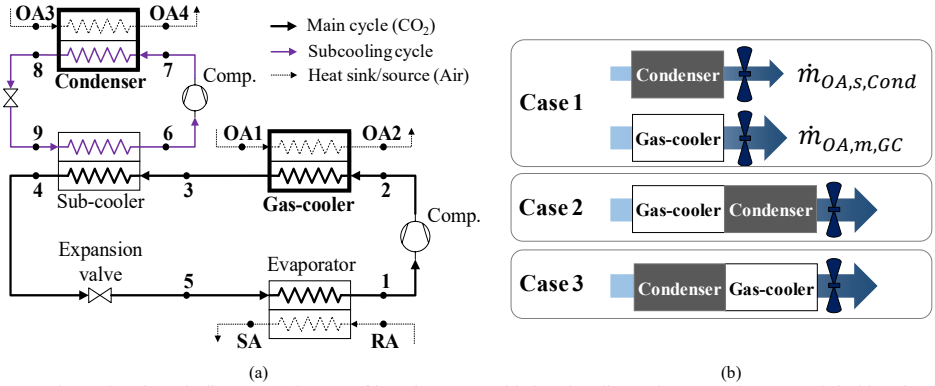
The conventional automobile cooling systems using CO_2 as a refrigerant are hard to achieve proper cooling performance at hot summer season. In order to enhance the of CO_2 cooling systems, a mechanical subcooling cycle is proposed for application to vehicles with limited installation space. To analyze performance of the system, numerical models were built to predict the COP by changing the design parameters and heat exchanger arrangement. In addition, the maximum COP is determined by using an optimal method. The results show that the COP improves when applying the subcooling cycle, and the maximum COP is obtained based on the thermodynamic states at the outlets of the gas cooler and the sub-cooler.

Keywords: Low GWP; Carbon dioxide (CO_2); Mobile air-conditioning systme(MAC); Heat pump; Mechanical subcooling cycle

1. Introduction

In order to restrain global warming, F-gases with GWPs greater than 150 are prohibited that use it for vehicles by the mobile air conditioning system (MACs) Directive of EU. Also, the Kigali amendment to the Montreal Protocol and F-gas regulation of EU are required to cut the usage of the high GWP refrigerants. With these tightened environmental regulations, the development of the refrigerant cooling system using low GWP refrigerants become increasingly important.

The carbon dioxide (CO_2) have been attracted because its GWP is just 1. Also, the CO_2 boosted attention since the German Association of the Automotive Industry (VDA) officially announced that suitable air-conditioning systems for a future vehicle would apply CO_2 as a refrigerant in 2007. Since then, Kim *et al.* [1] deal with the effects of the operating parameters on the cooling performance for an automotive air conditioning system. A refrigeration system using CO_2 as a refrigerant, which is cheap and easily available, is a good choice if its performance is comparable to that of other systems. In this sense, a dedicated mechanical subcooling system is introduced in this study in an attempt to improve the performance of the CO_2 cooling system. The dedicated mechanical subcooling cycle in the CO_2 cooling system is an additional vapor compression cycle which uses a small charge amount of the low-GWP refrigerant. Thornton *et al.* [2] explored the optimum value of the subcooling evaporator temperature by developing a numerical model for an ideal subcooling cycle in consideration of supermarket applications. Khan and Zubair [3] presented that the performance of a system is related to the refrigerant saturation temperature of the sub-cooler and is enhanced as compared to a simple CO_2 cooling cycle. Despite the dedicated subcooling cycle has been studied, there are relatively few studies on automobile applications with it.



In this paper, in order to obtain the maximum performance of the mobile air conditioning system (MACs), the numerical model is built, and performance analysis is conducted using an optimal method. Also, the influence of the low GWP refrigerants such as R-290, R-600a, R-1270, R-32, R-1234yf, and R-1234ze(E) on the subcooling cycle is investigated. In addition to the above points, this paper investigates the impact of the install configuration of heat exchangers on system efficiency.

2. System configuration and modeling

2.1. System configuration

The refrigeration system with mechanical subcooling consists of two as shown in Fig. 1(a). Each cycle uses a compressor, expansion valve, and heat exchangers. These two cycles are coupled with each other *via* a sub-cooler. The main cycle, as indicated by the bold line in Fig. 1(a), cools down the automotive cabin through heat exchange at the evaporator using CO_2. Meanwhile, the other cycle, named as the subcooling cycle, operates for the purpose of decreasing the quality of the CO_2 entering the evaporator of the main cycle by absorbing the heat at the sub-cooler.

(a) (b)

Fig. 1. The schematic diagram; (a) the CO_2 refrigeration system with the subcooling cycle. Two cycles are coupled with each other *via* a sub-cooler. (b) The layout cases according to the configuration of heat exchangers

For the refrigeration system using mechanical subcooling, it is necessary to install an additional condenser as compared to the conventional simple CO_2 cycle. This requirement is not a severe problem for a stationary system; however, for a vehicle, it should be considered that limited space is available for heat exchange with ambient air. Thus, the simulation cases were divided according to the heat exchanger configuration, as shown in Fig. 1(b). Case 1 is the case with two heat exchangers, the gas cooler of the main cycle and the condenser of the subcooling cycle, and they are located parallel with their faces to the outside of the vehicle, and the fans are operated separately. Meanwhile, in cases 2 and 3, the two heat exchangers are installed in a serial configuration, both cases have only one fan, and the air mass flow rate is the same through the two heat exchangers. Case 2 is that the gas cooler is located in front of the condenser of the subcooling cycle. Case 3 is that the gas cooler and the condenser are counterchanged compared with case 2.

2.2. System configuration

The energy balance equations for compressors and heat exchangers such as the gas cooler, sub-cooler, evaporator of the main cycle, and the condenser of the subcooling cycle are given in the following Eqs. (1)-(6):

$$\dot{W}_{m,Comp} = \dot{m}_{CO_2}(h_2 - h_1) = \dot{m}_{CO_2}(h_{2i} - h_1)\eta_{m,Comp} \quad (1)$$

$$\dot{W}_{s,Comp} = \dot{m}_s(h_7 - h_6) = \dot{m}_s(h_{7i} - h_6)\eta_{s,Comp} \quad (2)$$

$$\dot{Q}_{m,Evap} = \dot{m}_{CO_2}(h_1 - h_5) = \dot{m}_{RA}(h_{RA} - h_{SA}) \quad (3)$$

$$\dot{Q}_{m,GC} = \dot{m}_{CO_2}(h_2 - h_3) = \dot{m}_{OA,m,GC}(h_{OA2} - h_{OA1}) \quad (4)$$

$$\dot{Q}_{s,Cond} = \dot{m}_s(h_7 - h_8) = \dot{m}_{OA,s,Cond}(h_{OA4} - h_{OA3}) \quad (5)$$

$$\dot{Q}_{SC} = \dot{m}_{CO_2}(h_3 - h_4) = \dot{m}_s(h_6 - h_9) \quad (6)$$

$$COP_{c,AC} \equiv \frac{\dot{Q}_{m,Evap}}{\dot{W}_{m,Comp} + \dot{W}_{s,Comp}} \quad (7)$$

If the compressor performance is calculated by using a constant isentropic efficiency in Eqs. (1) and (2), the results might be different from actual situations because it considers only the inlet and outlet states of the compression process. The polytropic efficiency is known as it has the advantage of allowing real property effects to be included in a natural way because the polytropic efficiency calculates and integrates the work for

each differential step of the compression process. The polytropic efficiency can be translated analytically into an isentropic efficiency for a specific pressure ratio [4], as shown in Eq. (8).

$$\eta = \frac{W_{12,i}}{W_{12}} = \frac{\left(\frac{P_2}{P_1}\right)^{\left(\frac{k-1}{k}\right)}-1}{\left(\frac{P_2}{P_1}\right)^{\frac{1}{\eta_{PC}}\left(\frac{k-1}{k}\right)}-1} \quad (8)$$

The *UA* method is used in the model to obtain the results regarding the effect of varying the size of each heat exchanger. Because the *UA* values can represent the sizes of the heat exchangers [5-7].

All of the heat exchangers within the cycle were modeled to have countercurrent flow and were sliced into many segments so as to calculate the thermal properties of the fluid flowing inside. The *UA* values of a heat exchanger were calculated by summing the *UA* values of a segment as shown in the following Eqs. (9)-(12):

$$\sum_{k=0}^{n} UA_k = \sum_{k=0}^{n} \frac{\dot{Q}_k}{LMTD_k} \quad (9)$$

$$LMTD_k = \frac{\Delta T_k - \Delta T_{k+1}}{\ln(\Delta T_k / \Delta T_{k+1})} \quad (10)$$

$$\Delta T_k = T_{H,k} - T_{C,k} \quad (11)$$

$$\Delta T_{k+1} = T_{H,k+1} - T_{C,k+1} \quad (12)$$

In order to obtain the maximum COP, the generalized pattern search method, which is a direct search algorithm, was used in this paper. The direct search is a suitable method for solving non-linear optimization problems because it is not required any information about the gradient of the objective function. The simulation was performed through several iterations until the variables were converged within the error bound.

The simulation model was developed using the MATLAB program, and the thermal properties were loaded from the REFPROP database [8]. The operating condition and constraints were set up for calculating a reference result. In order to compare the calculation results under various conditions, the cooling load of the evaporator in the main cycle was kept at 5 kW. The equivalent thermal conductance of the gas cooler ($UA_{m,GC}$) and the evaporator ($UA_{m,Evap}$) were designed 500 W/K in the main cycle. In the subcooling cycle, the equivalent thermal conductance of the condenser ($UA_{s,Cond}$) and the sub-cooler (UA_{SC}) were sat as 100 W/K.

3. Performance analysis

3.1. Optimal operating conditions

According to the literature [9, 10], the cooling performance is depended on the thermal state of the CO_2 at the gas cooler outlet, i.e., state 3 in Fig. 1(a). To find the optimum operation condition, new variables are introduced as following Eqs. (13, 14).

$$\Delta T_{3-4} \equiv T_3 - T_4 \quad (13)$$

$$\Delta T_{3-OA1} \equiv T_3 - T_{OA1} \quad (14)$$

The CO_2 temperature difference between the inlet and outlet of the sub-cooler is defined as shown in Eq. (13). It is proportional relation with the heat capacity of the sub-cooler. And the temperature difference between the CO_2 and air at the gas cooler outlet (ΔT_{3-OA1}) is defined as Eq. (14). The CO_2 pressure of the gas cooler is mainly affected by ΔT_{3-OA1} and the equivalent thermal conductance of the gas cooler ($UA_{m,GC}$). To explore the influence of ΔT_{3-4} and ΔT_{3-OA1}, the simulation was conducted under the same condition except the values of ΔT_{3-4} and ΔT_{3-OA1}. As a result, the COP changed in a concave downward shape according to two variables of ΔT_{3-OA1} and ΔT_{3-4}, which means that the maximum point exists according to not only the temperature and pressure of the gas cooler outlet, but also the decreased temperature by the subcooling cycle.

3.2. Refrigerant for the subcooling cycle

To investigate the effect by the refrigerant type of the subcooling cycle, the model covers the refrigerants with not only natural refrigerants but also R-1234yf, R-1234ze(E), R-152a, and R-32 which are regarded as promising refrigerants. Fig. 2 displays the results of the simulation according to the ratio of the refrigerant flow rate (ϕ) which is defined as ratio of the subcooling cycle refrigerant mass flow rate ($\dot{m}_s$) to the CO_2 mass flow

rate in the main cycle($\dot{m}_m$), i.e., $\phi \equiv \dot{m}_s/\dot{m}_m$. The result reveals the reveal that the type of refrigerant in the subcooling does not show a significant difference. Even though the cases of R-600, R-601a, and R-610 were obtained higher efficiency, these refrigerants would be not recommended because the evaporating pressures are lower than an atmosphere. Even if there are minute leakage, air (non-condensation gas) and moisture can enter the system. Then injected non-condensation gas drops the cooling capacity and moisture cause corrosive and harmful to system components [11].

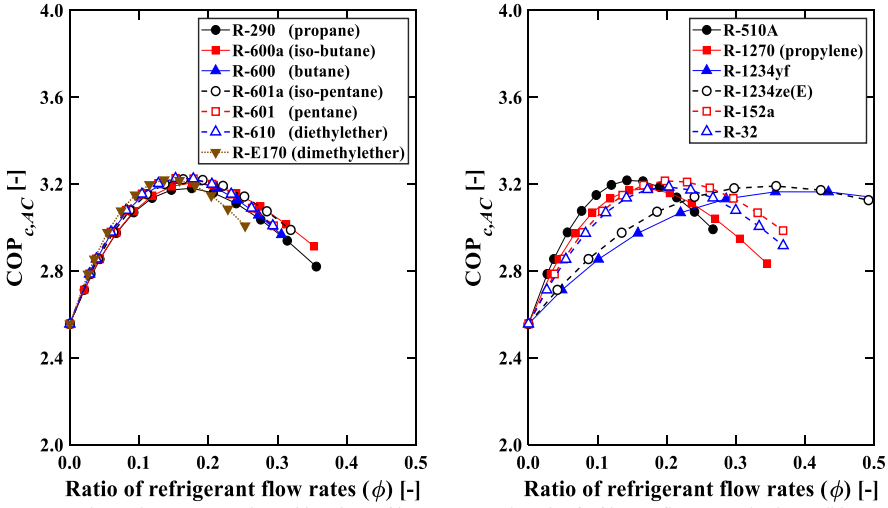

Fig. 2. The COP comparison with various refrigerants versus the ratio of refrigerant flow rate under the conditions. ($UA_{m,GC}$ = 500 kW/K, $UA_{s,Cond}$ = 100 kW/K, ΔT_{3-OA1} = 3°C)

While the optimum ratios of the refrigerant flow rate (ϕ_{opt}) of the hydrocarbon and R-32 were calculated similar values, the ϕ_{opt} of the R-1234yf and R-1234ze(E) were about twice. This result is obtained because the specific latent heat of vaporization of R-1234yf and R-1234ze(E) is roughly half with hydrocarbons'. In other words, the R-1234yf and R-1234ze(E) require a higher mass flow rate than hydrocarbons and R-32 to obtain the maximum COP.

3.3. Performance variation according to the heat exchanger configuration

In order to investigate the performance of the refrigeration system, the analysis was conducted by changing the configuration of heat exchangers. This analysis would be particularly necessary for automotive applications where the installation space for the mobile air conditioning system (MACs) is limited.

In case 1, the parallel configuration with two fans are applied with different capacities or operated at different revolution speeds. The air temperature of the gas cooler of the main and the condenser of the subcooling cycle is 35°C in both cases, i.e., $T_{OA1} = T_{OA3}$ =35°C. The air mass flow rate of the gas cooler in the main cycle, $\dot{m}_{OA,m,GC}$, is determined to reach the air temperature from 35 to 50°C in the gas cooler. Meanwhile, the air mass flow rate of the condenser in the subcooling cycle, $\dot{m}_{OA,s,Cond}$, is relatively calculated by the relative ratio of the air mass flow rate, as shown below in Eq. (15).

$$\psi \equiv \dot{m}_{OA,s,Cond}/\dot{m}_{OA,m,GC} \quad (15)$$

As a result, the COP was lower when it was placed in series than when it was placed in parallel. In case 2, the discharged air from the gas cooler is blowing into the subcooling cycle in order to form a higher condensation temperature than case 1, thereby increasing the pressure ratio of the subcooling cycle compressor and lowering the COP. In case 3, the air from the condenser of the subcooling cycle flows into the gas cooler of the main cycle. The increased air temperature of the gas cooler inlet leads to the raised pressure of the gas cooler and the reduced efficiency of the system. The results of case 3, in which the condenser of the subcooling cycle is arranged first, are not better than those of case 2. The first reason is that the performance is more sensitive to the pressure ratio of the main cycle due to the fact that the CO_2 refrigerant mass flow rate is greater

than the subcooling cycle refrigerant mass flow rate. Another reason is the thermodynamic property of the CO_2, as the thermodynamic state of the CO_2 gas cooler outlet exists above the CO_2 critical point. Near the critical point, the thermodynamic properties change drastically. For this reason, not even a slight difference from the optimum condition will affect the COP more sensitively.

The COP is improved when the air mass flow rate is high, but the power consumption of the fan should be considered for calculating the efficiency of the system. For this purpose, the system COP was newly defined as shown in Eq. (15) by adding the fan power consumption in the denominator.

$$COP_{c,sys} \equiv \frac{\dot{Q}_{m,Evap}}{\dot{W}_{m,Comp}+\dot{W}_{s,Comp}+\dot{W}_{Fan}} \tag{16}$$

The power consumption of a fan is strongly dependent on its specification and characteristics. Nevertheless, based on the fan laws [12], the power consumption of a fan is proportional to the cube of rotational speed when the density of the air and the diameters of the fans are constant, as shown in Eqs. (17)-(19):

$$\frac{\dot{W}_{Fan,\beta}}{\dot{W}_{Fan,\alpha}} = \left(\frac{D_{Fan,\beta}}{D_{Fan,\alpha}}\right)^5 \left(\frac{N_{Fan,\beta}}{N_{Fan,\alpha}}\right)^3 \left(\frac{\rho_{Fan,\beta}}{\rho_{Fan,\alpha}}\right) \tag{17}$$

$$\frac{\dot{V}_{Fan,\beta}}{\dot{V}_{Fan,\alpha}} = \left(\frac{D_{Fan,\beta}}{D_{Fan,\alpha}}\right)^3 \left(\frac{N_{Fan,\beta}}{N_{Fan,\alpha}}\right) \tag{18}$$

$$\frac{\dot{W}_{Fan,\beta}}{\dot{W}_{Fan,\alpha}} \cong \left(\frac{N_{Fan,\beta}}{N_{Fan,\alpha}}\right)^3 = \left(\frac{\dot{V}_{Fan,\beta}}{\dot{V}_{Fan,\alpha}}\right)^3 \cong \left(\frac{\dot{m}_{Fan,\beta}}{\dot{m}_{Fan,\alpha}}\right)^3 \tag{19}$$

In order to consider the fan power, a specific commercial radiator cooling fan was applied in the numerical model. It can blow about 0.89 kg/s by consuming 120 W at the 2,250 RPM. After considering the power consumption of fans, the system COPs are at their maximum points at a certain total air mass flow rate, as shown in Fig. 3. This result shows that fan power should be a design parameter of focus in the design of a MAC.

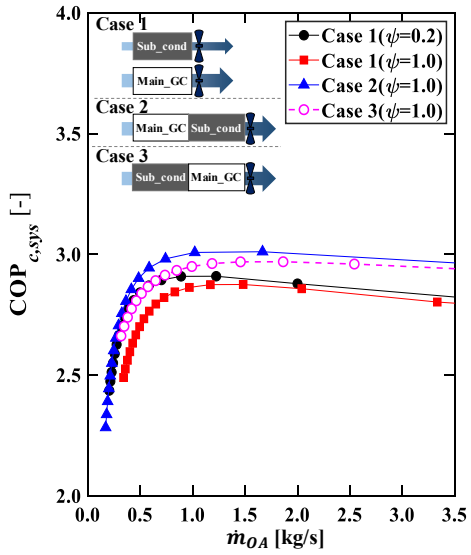

Fig. 3. The system performance ($COP_{c,sys}$) variation including the fan power consumption according to the total air mass flow rate. In contrast with $COP_{c,AC}$ which is calculated in Fig. 11, the $COP_{c,sys}$ is additionally considered energy consumption by the fan when obtaining the system efficiency. ($\dot{m}_{OA,m,GC}$).

4. Conclusions

This paper was conducted the thermodynamic analysis to investigate the performance of the CO_2 refrigeration system with the mechanical subcooling cycle using Low GWP refrigerants for a vehicle. The simulation was also conducted varied on the arrangement of the heat exchangers.

The results of this study show that the performance of CO_2 cooling system will be about 25% enhanced by using the subcooling cycle with the optimum operating condition. In order to obtain the optimum result, parameters such as mass flows of refrigerant, CO_2 temperatures and pressures at the gas cooler outlet and the sub-cooler outlet were variated. When the refrigerant mass flow rate in the subcooling cycle is optimum, the refrigerant type does not have a substantial effect on the performance. However, the systems using R-1234yf and R-1234ze(E) require a higher mass flow rate than hydrocarbons and R-32 to have the maximum COP. Because the specific latent heat of vaporization of R-1234yf and R-1234ze(E) is roughly half with hydrocarbons'.

Meanwhile, in order to implement the proposed mechanical subcooling system, heat exchangers would be additionally installed. If installation space is limited in a vehicle, design parameters and configuration should be considered about heat exchangers and fans. For this reason, performances were calculated according to heat exchanger arrangements. When two heat exchangers are installed serially, the gas cooler of the main cycle should be set to face outside in front of the condenser of the subcooling cycle in order to obtain higher COP. In addition, this study suggests that the power consumption of fans should be considered in the design of the mobile air conditioner system.

A study on the performance of heat pump by mixing ratio of isobutane/propane mixed refrigerants

Gu Hwang KANG, Sun-Ik NA, Min Soo KIM* *

Department of Mechanical Engineering, Seoul National University, Seoul 08826, Republic of Korea

Abstract

Natural refrigerants have global warming potential (GWP) and ozone depletion potential (ODP), but typical natural refrigerants have low COP, too. On the contrary, hydrocarbon refrigerants have high performance. In this study, using the characteristics of mixed refrigerants that can maintain a constant temperature difference during phase change, performance of the cycle according to the change in mixing ratio of isobutane and propane was calculated and measured. At outdoor temperature of 35℃ and indoor temperature 27℃, COP of the cycle was maximized at isobutane ratio is near 0.8.

Keywords: natural refrigerant; mixed refrigerant; isobutane; propane; COP

1. Introduction

As environmental problems such as global warming and the destruction of the ozone layer have emerged around the world, regulations on existing CFCs, HCFCs, and even HFCs refrigerants are being tightened. Therefore, research on heat pumps using natural refrigerants with low GWP and ODP is actively underway. There are many kinds of natural refrigerants, such as hydrocarbon, carbon dioxide, and water. Especially, isobutane shows low compressor work because of low compression ratio, and propane has a high cooling capacity. There are many studies on mixed refrigerant using isobutane and propane.

Nawaz *et al.* [1] studied water heaters using a mixed refrigerant of isobutane and propane, and Wu *et al.* [2] studied absorption heating cycles using natural refrigerants and low-GWP refrigerants mixtures. He *et al.* [3] calculated COP and cooling capacity of propane and isobutane mixed refrigerant with varying mixing ratios. Simulation was performed after fixing the cooling capacity, and the condensation temperature was 54.4℃, and the evaporation temperature was -23.3℃. Jung *et al.* [4] also conducted a study on the performance coefficient and the cooling capacity per unit volume due to changes in the mixing ratio of propane and isobutane. It fixed the cooling capacity at 130 W, fixed the secondary fluid inlet temperature is -15℃, and outlet temperature at -21℃. Chen *et al.* [5] conducted experimental studies on isobutane and propane mixed refrigerants, in which case only results were found when the propane ratio was 0.30 to 0.55 without conducting for the overall mixing ratio.

In this study, the performance of the heat pump according to the mixing ratio of the hydrocarbon refrigerant, isobutane and propane mixture is analyzed through a simulation and experimental study.

2. Simulation result

2.1. Characteristics of mixed refrigerant

In the case of a single refrigerant, the temperature remains constant when fluid phase is changed, and there is a pinch point where the heat exchange rate decreases. Therefore, the heat exchange with secondary fluid is not uniform. However, in the case of mixed refrigerant, temperature gradients exist even when phase change occurs, which has the advantage of maintaining heat exchange with secondary fluid.

2.2. Simulation condition

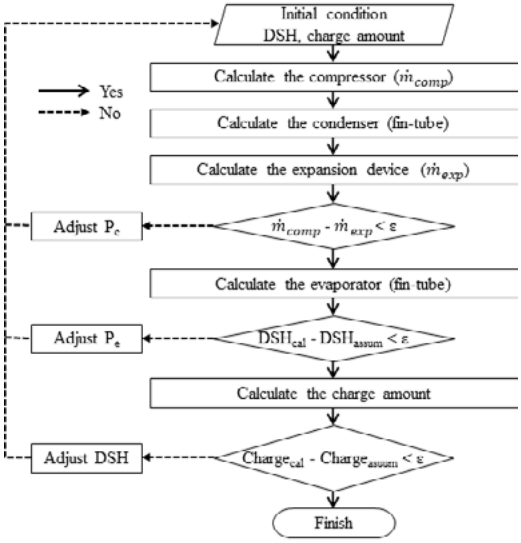

Fig. 1. Flow chart of simulation

The flow chart used of simulation is shows in Fig. 1. To maintain accuracy in the comparison between cycles, the degree of superheat was fixed at 5 K, and calculations were performed with the condenser pressure and evaporator pressure as variables to ensure the convergence of the cycles.

COP of cycles is calculated by equation (1) through compressor work and cooling capacity.

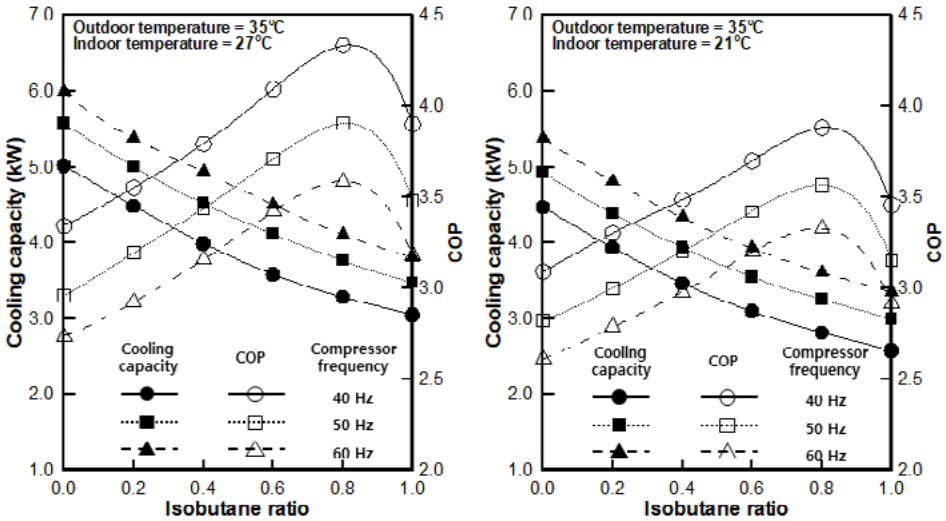
$$COP = \frac{Cooling\ capacity}{Compressor\ work} \tag{1}$$

In this simulation, reciprocating compressor model was used. Isentropic efficiency depends on pressure ratio, degree of superheat, etc., and isobutane and also have different isentropic efficiency in previous papers [6]. The enthalpy of compressor outlet can be calculated by equation (2)

$$h_{comp,out} = \frac{h_{comp,out,is} - h_{comp,in}}{\eta_{is}} + h_{comp,in} \tag{2}$$

The discharge mass flow rate of compressor, and compressor work are as shown in equation (3) and equation (4), respectively.

$$\dot{m}_{comp} = V_s \rho_{comp,in} Hz \left(1 - V_c \left(\frac{\rho_{comp,out}}{\rho_{comp,in}} - 1\right)\right) \tag{3}$$



$$W_{comp} = \dot{m}_{comp}\left(h_{comp,out} - h_{comp,in}\right) \tag{4}$$

In this paper, simulation analysis of mixed refrigerants has been performed, and a corresponding heat transfer coefficient calculation expression is required. For mixed refrigerants, the heat transfer coefficient of condenser was calculated by referring model of Shah [7], and heat transfer coefficient of evaporator was calculated by referring model of Choi [8]. Heat transfer coefficient of Shah and Chis are represented in equation (5) and equation (6)

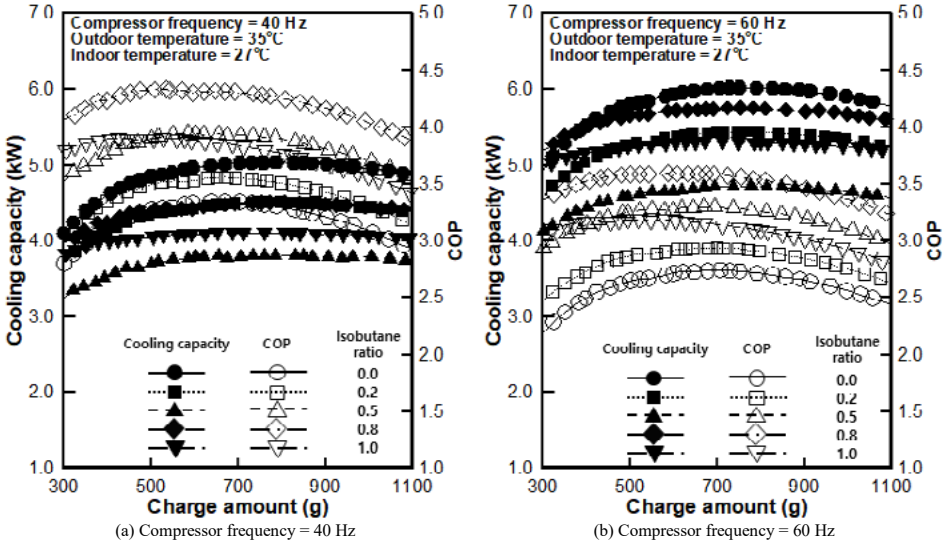
$$h_{tp,cond} = 0.023Re_{lo}^{0.8}Pr^{0.4}\left[(1-x)^{0.8} + \frac{3.8x^{0.76}(1-x)^{0.04}}{Pr_{cd}^{0.38}}\right]\frac{\lambda}{D} \tag{5}$$

$$h_{tp,eva} = E\left(0.023Re^{0.8}Pr^{0.4}\frac{\lambda}{D}\right) + SF_m\left(207\frac{k_l}{bd}\left(\frac{qbd}{k_l T_s}\right)^{0.674}\left(\frac{\rho_v}{\rho}\right)^{0.581}Pr^{0.533}\right) \tag{6}$$

Cycle calculation was performed using the above equations.

(a) 35℃/27℃ (b) 35℃/21℃

Fig. 2. Cooling capacity and optimal COP according to isobutane ratio

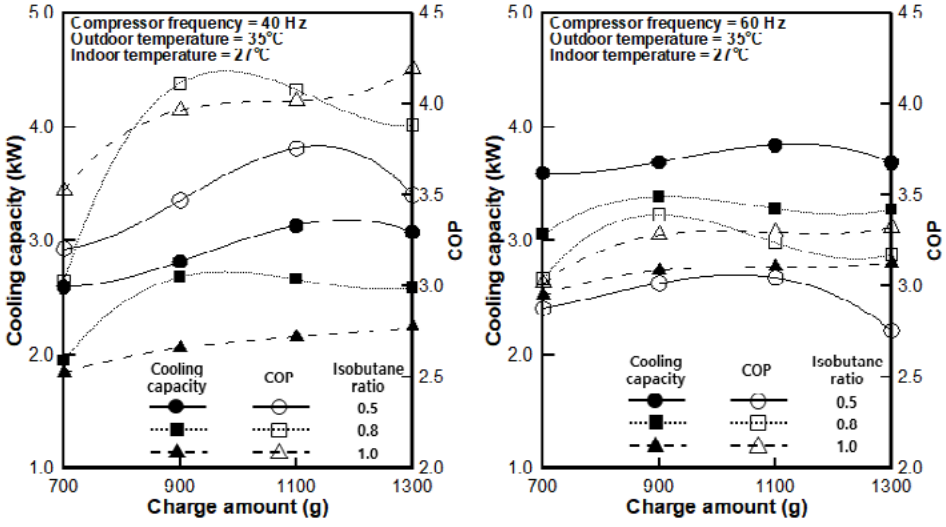


2.3. Simulation results

Simulation was performed on indoor temperature of 27℃, 21℃ under outdoor temperature of 35℃. The compressor frequency sets in the simulation are 50 Hz, 60 Hz, and 70 Hz. Fig. 2 is the cooling capacity and optimal COP according to the change of isobutane ratio at outdoor temperature is 35℃. Indoor temperature of (a) and (b) are 27℃ and 21℃, respectively. Isobutane ratio in x-axis is calculated by equation (7)

$$Isobutane\ ratio = \frac{m_{isobutane}}{m_{isobutane}+m_{propane}} \tag{7}$$

As isobutane ratio increases, cooling capacity decreases. This phenomenon due to the properties of isobutane and propane refrigerants. Propane refrigerant has better thermal properties that isobutane. However, isobutane has low compression ratio, so this leads low compressor work. Therefore, optimal COP exists between decreasing compressor work and increasing cooling capacity. Accordingly, as isobutane ratio increases, COP increases and decreases. The optimal isobutane ratio under all simulation compressor frequency and temperature conditions is approximately 0.8.



Calculation of the optimal amount of refrigerant according to the isobutane ratio was also carried out. The results can be seen in Fig. 3

(a) Compressor frequency = 40 Hz (b) Compressor frequency = 60 Hz

Fig. 3. Cooling capacity and COP according to refrigerant charge amount

Since isobutane and propane have different specific volume and the optimal refrigerant charge is present according to their respective isobutane ratio, calculation of the optimal refrigerant charge for each isobutane ratio is required to know the exact effect on the mixing ratio. As can be seen in Fig. 3, it can be seen that the optimum cooling capacity and the optimal refrigerant charge amount representing the optimal COP differ depending on the change in the isobutane ratio. This will be verified through further experiments.

(a) Compressor frequency = 40 Hz (b) Compressor frequency = 60 Hz

Fig. 4. Cooling capacity and COP according to the isobutane ratio and refrigerant charge amount

3. Experiment result

Based on the simulation results, experiments were conducted on the isobutane ratios of 0.5, 0.8, and 1.0, not on the overall mixing ratio. Furthermore, the simulation results showed that the optimal charge amount varies as the isobutane ratio changes, so the experiment was performed by varying the refrigerant volume. Outdoor temperature condition is 35℃, and indoor temperature condition is 27℃.

Fig. 4 shows experiment results. As the results of the simulations, the experiments also showed optimal COP near the isobutane ratio is 0.8. The cooling capacity also decreased as the isobutane ratio increased. In addition, experiment have identified the temperature distribution within the heat exchanger, shown in Fig. 8. As a result of the simulation, for single isobutane and propane refrigerants, the temperature remains constant before the superheated region, and the temperature glide occurs as the mixing takes place. The results of experiment have verified that the simulation results are close to reality.

4. Conclusions

In this study, a research was conducted on heat pump using mixed hydrocarbon refrigerants with very low GWP and zero ODP in preparation for continuously strengthened refrigerant regulations.

Simulation and experimental studies were conducted by mixing propane refrigerants with large cooling capacities and isobutane refrigerant with low compressor work. Simulation studies have shown that optimal COP near the isobutane ratio of 0.8 under various temperature conditions, and the temperature distribution inside the heat exchanger has also been calculated.

Simulation results were verified through experiment using a double-pipe heat exchanger, which allowed the optimal isobutane ratio of mixed refrigerants to be derived.

Abstract

A membrane mass exchanger where water vapor is exchanged in a vacuum membrane dehumidification (VMD) system utilizes the vapor pressure difference between the permeate side and the feed side. However, differently from a typical moisture selective membrane, this membrane is located under pressure difference to accelerate the separation. Thus, a new approach to validate performance of the water vapor selective membrane is required. In order to quantitatively measure the effect of this phenomenon on the moisture permeability, an experimental system was setup to measure water vapor selectivity and permeance under the presence of absolute pressure difference before and after the membrane. So far, it is known that the performance of membrane is only a function of partial pressure of vapor. However, from the experiment, it is observed that selectivity and permeance are also changeable by absolute pressure difference due to the physical deformation caused by absolute pressure difference across the membrane.

Keywords: Permeance, Selectivity, Dense membrane, Dehumidification ;

1. Introduction

The energy consumption for air conditioning is constantly increasing. And dehumidification loads account for a large part of the cooling load. Therefore, many systems are currently being developed to replace the vapor compression cycle, and membrane heat pumps have been selected as one of the most feasible system [2].

As a key component of membrane heat pumps, studies have continued to improve membrane performance. Membrane dehumidification models for performance analysis are considered ideal models operated only by the vapor pressure difference, which is different from the actual phenomenon. This difference is expected to be attributed to the influence of absolute pressure on the selectivity of the membrane separation. Bui et al. [3] study shows that the COP of the membrane heat pump changes depending on the selectivity of the membrane applied to the system. Therefore, the exact COP value of the designed model can only be calculated by pre-checking the selectivity and permeability of the membrane to be used according to the operating pressure in the system configuration. However, the membrane characteristic values mentioned in various existing papers are often the result of no specified experimental conditions, or only simple diffusion model, which is different from the actual system's conditions. So, in this work, we construct conditions similar to real-systems and then experimentally calculate selectivity and permeability.

2. Background

2.1. Dense membrane

The major purpose of membrane-based vacuum dehumidification is to separate water vapor from the air without vapor-liquid phase change. Thus the type of membrane is gas-gas separation type one. Gas separation

* Corresponding author. Tel.: +82-2-820-5973 ; fax: +2-82-3280-5867.
E-mail address: minsungk@cau.ac.kr.

membrane can selectively separate substance and can separate mixture using chemical potential difference between membrane sides. It can be made using various materials such as metal, ceramic and liquid, and mainly uses polymers that are easy to form. It can be largely divided into porous and dense membrane, of which no physical porosity exists that allows a substance to pass through a membrane.

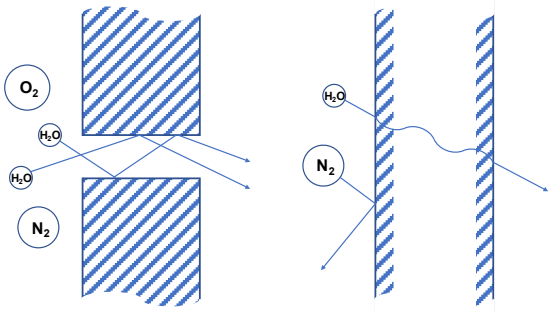

Fig. 1. Water vapor permeation in porous/dense membrane

In the case of dense membrane for water vapor separation, hydrophilic materials are usually bonded to hydrophobic polymer-based materials to form ion-nano channel in which water vapor molecules can move. Therefore, the solution-diffusion model can explain the movement of the substances, and steam vapor difference on both sides of the membrane acts as a driving force.

If you look at the previous analytical research data, it is often assumed that the selectivity is infinite using a dense membrane. However, in actual condition, the dense membrane also has a large but finite value. In this case, the design and operation of the system will be different, and not only steam but also air will pass through, so a method of periodically vacuuming should be devised.

2.2. Test method for water vapor permeability

The cup method measures the change in cup weight in an environment where water or desiccant filled cup is kept constant temperature and humidity [12]. If water is contained, the relative humidity inside the cup is assumed to be 100% and the amount of evaporated water is calculated. If desiccant is used, the water vapor mass is calculated through the vapor absorbed as 0% relative humidity. Although it is the most commonly used method, it has the disadvantage of creating a boundary layer according to the concentration of substance before and after the membrane. Accordingly, the measurement varies greatly depending on the distance from the water and desiccant to the membrane, so error analysis is essential. There are also disadvantages of not being able to add various experimental variables such as pressure changes.

To overcome these disadvantages, devices have been suggested that not only measure simply by gravimetric but also reflect various experimental conditions such as spring stiffness. A typical example is constant–volume variable–pressure method that permeates water vapor from feed side to the permeate side [13]. Depending on the amount of water vapor permeated in the device, the pressure on the permeate side changes, which allows the permeability to be calculated. However, in the case of gases mixed with other gases and water vapor, only the permeation of water vapor can be measured.

Therefore, this work uses experimental methods that combine different experimental methods.

3. Experiment

3.1. Experimental setup

As explained above, the experimental device was built based on the cup method and constant–volume variable–pressure method among the measurements described earlier. In the constant–volume variable–pressure method, the permeated water vapor is the cause of pressure rise, allowing the measurement of the permeability to be made through pressure change and time flow, but not the permeability of the additional substances. Considering this, the desiccant of cup method is applied to ensure that all permeated water vapor is absorbed into the absorbent, and the increase in pressure is the result of nitrogen. This allows for the calculation of permeability for both substances.

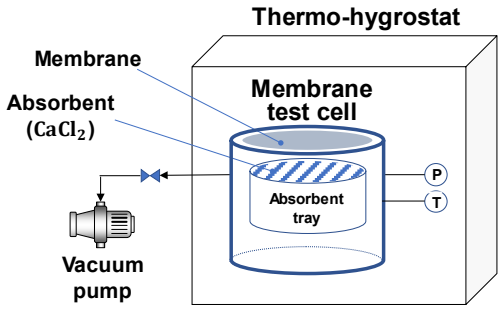

Fig. 2. Schematic diagram of test setup

The above figure represents the whole experimental device. The test cell has two tabs for the sensor, one for decompression or pressurization. In the experiment, the gas must pass through the membrane to enter the test cell, and the O-ring was installed in double to prevent leakage to the side of the membrane. The test cell was used in the experiment after checking its confidentiality through a pressure test in advance. In addition, a tray containing calcium chloride, was built in the test cell to keep the relative humidity at 0% and to measure the weight of the transmitted water vapor. During the experimental procedure, absolute pressure difference was generated before and after the membrane by vacuum pump or nitrogen tank, and the test cell was inserted into the thermo-hygrostat so that the experiment could be carried out at a constant temperature and humidity.

3.2. Membrane sample

The membrane used in this study was produced by dispersing silica particles, which are hydrophilic inorganic nanoparticles, to polyurethane, a hydrophobic material, and then joining them to polyamide supports. Membrane produced in this way is not over-spoiled by moisture, so its durability is complemented so that frequent replacement is not required.

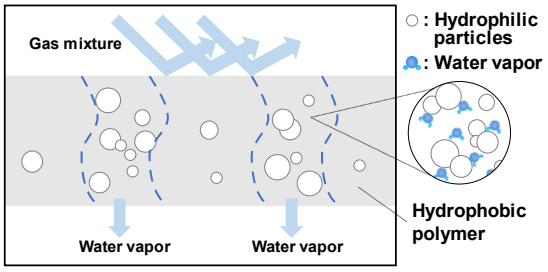

Fig. 3. Characteristic diagram of membrane sample used in experiment

The figure above shows the cross section of the membrane sample used. When hydrophilic particles are placed in the membrane as shown without being concentrated or too dispersed, ion-nano channels are created. In this case, water vapor inside the membrane moves in a molecular state by repeatedly adsorption and desorption to the hydrophilic particle surface.

3.3. Test condition and test

The experimental conditions were created close to the environment in which the actual system could be applied, considering the problems described earlier. It is arranged in the table below. The experiment was conducted in two main ways. The first is to compare two cells with nitrogen permeation set in opposite directions to see if nitrogen permeation affects water vapor permeability in a dense membrane. In addition, the experiment was conducted with the existing cup method, comparing the variation in the permeability with the occurrence of absolute pressure difference. Second, we measured the permeance and selectivity changes by changing humidity. The data from the measurements allow us to predict indicators in different humidity conditions with extrapolation.

Table 1. Experimental conditions for test setup

Variables	Value
Absorbent tray mass	70g - 100g
Distance from membrane to absorbent	5mm
Relative humidity	30% – 70%
Temperature	30℃
Test unit pressure (abs)	40kPa, 160kPa

3.4. Membrane performance unit

First, weight change of the absorbent tray, the area of the membrane through which the substance can be permeated in the cell, and the measurement time can be used to obtain the mass flux of water vapor.

$$J_{H_2O} = \frac{\Delta m_{CaCl_2}}{A_m \Delta t} \tag{1}$$

Since the above value does not consider the volume of the gas, the molar mass of H_2O is distributed to convert the mass of water vapor into mole. Since driving force of water vapor movement is vapor pressure difference, we separated steam pressure out of the mass flux to calculate the permeance. Since the steam pressure inside the cell is zero, the steam pressure difference can be calculated through the humidity of the chamber. In addition, multiplying the constants to fit the units allows the expression to be arranged as follows.

$$P_{H_2O} = \frac{\Delta m_{CaCl_2}}{M_{H_2O} p_v A_m \Delta t} \times \frac{10^{10}}{3.35} \tag{2}$$

The unit of GPU value obtained by the above formula is mol/m^2·s·Pa. The volume inside the cell is constant but the pressure continues to change, so the mass of permeated nitrogen can be calculated through the ideal gas equation. The slight change in volume due to compression of the O-ring, deformation of the membrane was ignored and the volume and pressure changes in the cell were calculated by the ideal gas equation. The mass flux of nitrogen obtained through this process is as follows.

$$J_{N_2} = \frac{\Delta m_{N_2}}{A_m \Delta t} = \frac{\Delta pV / R_{N_2} T}{A_m \Delta t} \tag{3}$$

R_{N_2} is the ideal gas constant of nitrogen. As with water vapor permeability calculations, the mass of nitrogen is divided into the molar mass of nitrogen. And in this experiment, the driving force of nitrogen is the absolute pressure difference excluding water vapor pressure, so the formula was calculated by dividing the formula by $(p_{atm} - p_v) - p$.

$$P_{N_2} = \frac{\Delta pV / R_{N_2} T}{M_{N_2}[(p_{atm} - p_v) - p] A_m \Delta t} \times \frac{10^{10}}{3.35} \tag{4}$$

The unit is mol/m^2·s·Pa, such as the water vapor permeance value. The selectivity of membrane is calculated by the permeance of water vapor and nitrogen calculated from the above equations.

$$\alpha = P_{H_2O} / P_{N_2} \tag{5}$$

Calculated from the data measured at intervals of five minutes using the above expression, the sum of the values and the values calculated at the beginning and end of the experiment were consistent with the error range. Therefore, it can be said that the assumptions included during the composition process of the expression are reasonable.

Table 3. Real-time measurement data of the representative Test A and test B

	Test 1		Test 2	
Time [hr]	p(abs) [kPa]	Absorbent mass [g]	p(abs) [kPa]	Absorbent mass [g]
0	42.22	77.31	41.98	79.92
12	58.78	-	57.36	-
24	69.02	-	67.68	-
36	76.76	-	75.19	-
48	82.48	80.60	80.97	83.21

4. Result and discussion

4.1. Measurement data

The experimental data were recorded using the LabVIEW program. For the weight of the absorbent tray, the cells were dismantled before and after the experiment and measured using the scale. The above table shows the representative case data that have been repeated under certain measurement conditions. After 48 hours of experimentation, both cells increased by about 40 kPa to measure the amount of nitrogen passed, and it can be confirmed that the weight of the absorbent tray has increased due to the permeation of water vapor.

Figure 4 shows the change in pressure within the cell over the measurement period. Since it was assumed that all the water vapor passed into the cell is absorbed by the absorbent, the cause of the increased pressure is the result of the permeation of nitrogen. The slope of the graph decreases over time, which can be interpreted as a weaker driving force as the absolute pressure difference decreases. Therefore, it was confirmed that the drive forces of nitrogen and air can work even in a dense membrane and that consideration is required.

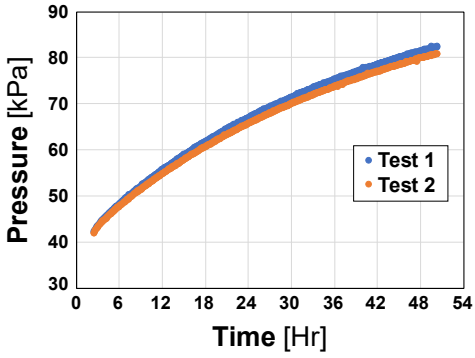

Fig. 4. Pressure variation in test cell

4.2. Calculation result

4.2.1. Effect of absolute pressure difference

This section presents the experimental results for checking the effects of absolute pressure difference in a water vapor permeability of dense membrane. At the start of the experiment, the absolute pressure difference before and after the membrane formed by pressurization or decompression is the same as 60 kPa, but both nitrogen and water vapor are brought into the cell for Test A, and Test B allows nitrogen to penetrate outward. The data measured under the same 50% relative humidity conditions are listed.

As nitrogen permeates, it can be confirmed that the cell pressure in Test A increases, and the pressure in Test B decreases. The above measurements were presented by converting them into performance factors. The data measured by the cup method are also listed for comparison. The relative humidity was measured at 70% for the cup method measurement.

The selectivity was not indicated for Test B because it was the ratio of the substance permeated in the same direction, nor was the test cup measurement recorded because it was not possible to measure the permeance of nitrogen. When looking at the data, we can see that the permeability of the water vapor was measured the highest at Test A with the same direction of permeation of nitrogen and water vapor. Depending on the direction in which nitrogen is permeated in the test cell, and partly confirmed that the presence of absolute pressure difference affects the permeability of water vapor.

Table 4. Real-time measurement data of the Test A and Test B which has opposite directions of nitrogen permeation

	Test A		Test B	
Time [hr]	p(abs) [kPa]	Absorbent mass [g]	p(abs) [kPa]	Absorbent mass [g]
0	42.25	89.19	162.46	75.78
12	58.24	-	153.40	-
24	68.95	-	144.95	-
36	76.58	-	138.03	-
48	82.43	92.38	132.22	77.76

Table 5. Membrane performance factor values of Test A, Test B and cup method

Performance factor	Test A	Test B	CUP
Permeance (H_2O) [GPU]	3.56×103	2.08×103	1.68×103
Permeance (N_2) [GPU]	4.40	2.52	-
Selectivity [-]	808.29	-	-

Among the membrane-based vacuum dehumidification systems introduced in the introduction, in the case of the W-MVD system, the membrane is mounted before and after the vacuum compressor, and each condition creates the direction of the pressure difference, such as Test A and Test B. The experimental results show different indicator values even for the same membrane sample and should be used to take this part into account during the analysis process.

4.2.2. Membrane performance according to relative humidity

This section describes the changes in permeability measured by varying relative humidity. The relative humidity was changed from 30% to 70% according to the conditions set earlier, and the error value due to membrane damage was removed during the experiment. After converting the measurements into performance factor, it was expressed as an average. Calculations showed that the permeance of both H_2O and N_2 increased as the relative humidity increased, but the permeance increase of H_2O was greater, so was the value of selectivity.

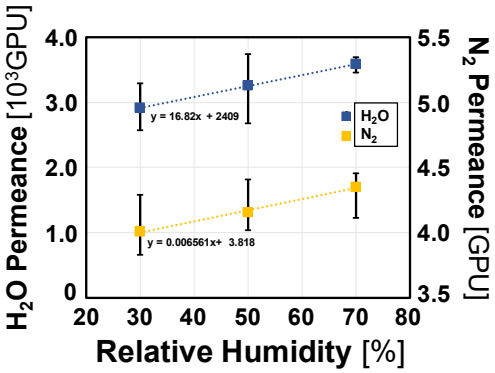

Fig. 5. Permeance variation of H_2O and N_2 according to relative humidity

The result of the calculation shows the data on the graph. The water vapor permeance formula used in this study is linearly proportional to changes in water vapor pressure, and data presented as actual averages can also be found to be close to linearity. The permeance of nitrogen also appears to be increasing like water vapor, which is interpreted as the effect of absolute pressure difference in the calculation formula has decreased as the water vapor pressure rises. Because both performance indicators exhibit linearity, the permeance of nitrogen and water vapor with changes in humidity was predicted through extrapolation. The trend line was calculated through the MATLAB curve fitting tool and the results were shown on the graph. Using this expression, the permeance and selectivity values for relative humidity of 0% were calculated, as shown in Table 1. The permeance value of H_2O is calculated as 2409 GPU and the permeance value of N_2 is 3.818 GPU and has a selectivity value of approximately 630.96. The following sections compare with data from existing studies.

4.3. Membrane performance factors comparison

The results of this experiment and analysis, and the conditions of the experiment were summarized in Table 6. Units were unified for comparison with the data previously investigated. Since permeance is an indicator calculated without considering membrane thickness, the measured membrane thickness average of 75 μm was multiplied by the result and converted to permeability.

Except for the test cases of the reverse direction and the cup method where selectivity data were unavailable, the remaining five results were placed on the Fig. 2 to compare with the data in the previous paper. From the results, water vapor permeability was high without considering experimental conditions. However, as the

selectivity is relatively low, additional device is required to prevent pressure rise of the compressor due to permeated N_2 if the corresponding membrane is used in the system configuration.

Table 6. Membrane factors data and condition in this paper

Test method	RH [%]	H_2O permeability [Barrer]	N_2 permeability [Barrer]	Selectivity [-]
Cup method	70	11390.51	-	-
Reverse permeation of N_2	50	15608.44	18.93	-
Test result	30	21821.67	30.08	725.56
	50	24425.44	31.16	783.81
	70	26868.04	32.04	838.47
Extrapolation	0	18067.5	28.64	630.96
	100	30682.5	33.56	914.37

5. Conclusion

In this study, experiments were conducted through simple experimental device to check the effect of absolute pressure difference on the performance of a dense membrane with water selective properties. There are several methods for measuring permeability and selectivity, but each threshold exists. Thus, in order to improve the shortcomings, a new experimental device was formed that fused the cup method with the constant-volume variable-pressure method.

The results of the cup method and reverse pressure gradient experiments show that there is an effect of absolute pressure difference on the movement of water vapor in a dense membrane, and it is concluded that consideration is necessary accordingly.

Nomenclature

A_m	area of membrane [m^2]	p_s	water saturation pressure [kPa]
b	width of masked edge [m]	p_v	water vapor pressure [kPa]
d	distance of absorbent from membrane [m]	Δp	pressure difference [kPa]
D	diffusion coefficient [-]	P_{H_2O}	water vapor permeance [mol/m^2sPa]
J_{H_2O}	mass flux of H_2O [g/m^2s]	P_{N_2}	nitrogen permeance [mol/m^2sPa]
J_{N_2}	mass flux of N_2 [g/m^2s]	R_{H_2O}	ideal gas constant of H_2O [kJ/kgK]
Δm_{CaCl_2}	mass variation of $CaCl_2$ [g]	R_{N_2}	ideal gas constant of N_2 [kJ/kgK]
Δm_{N_2}	mass variation of N_2 [g]	Δt	time variation [s]
M_{H_2O}	molar mass of H_2O [g/mol]	T	temperature [°C]
M_{N_2}	molar mass of N_2 [g/mol]	V	volume of cell [m^3]
p	pressure of test cell [kPa]	α	selectivity [-]
p_{atm}	atmospheric pressure [kPa]	δ	specimen thickness [m]

Introduction: IIR and low-GWP refrigerants

I. Environmental challenges and refrigerants

I. Required actions

Conclusion: Refrigerants and national strategies

Introduction: Who is the IIR?

Founded in 1908

Intergovernmental science and technology-based organisation

Dissemination and promotion of knowledge on all refrigeration technologies and uses

Key Domains Include…

- Food quality and safety from farm to consumer
- Comfort in homes and commercial buildings
- Health products and services
- Low-temperature technology and liquefied gas technology
- Energy efficiency
- Use of non-ozone depleting and low global warming refrigerants in a safe manner

- Databases
- Publications
- Conferences
- Working groups
- International, regional and national projects

….

a lot of information on refrigerants

I. Environmental challenges and refrigerants (1/2)

- The stratospheric ozone layer
  Montreal protocol
  Phase out of HCFCs

- Climate change
  - Refrigerating systems alone:
    - Energy 63% of the global warming impact of the systems
    - Refrigerants 37%
    - Total: 7.8% of global greenhouse gases emissions (IIR IN); increasing impact because of increasing refrigeration needs
  - Others: materials
  - Other issues: insulation, passive buildings…..

I. Environmental challenges and refrigerants (2/2)

- TFA
- Safety
- The Kigali amendment of the Montreal Protocol:
  Different schedules depending on the countries
  →Risks (traffic…), but same direction for all
- The Paris agreement
  International objectives but National Determined Contributions (NDCs) to be revised in 2021

II. Required actions (1/2)

- Research and development

  Few very new refrigerants possible (NIST study)

  → Low-GWP refrigerants will therefore continue to be used: natural refrigerants (ammonia, CO_2, hydrocarbons, water, air) + HFOs and mixtures

  → + Relatively low-GWP refrigerants (R32)

  + Intermediate refrigerants

  + Not-in-kind refrigeration systems (adsorption/absorption, solid-state technologies…)

  In any case, because of increasing constraints, many technological developments are underway and must continue.

II. Required actions (2/2)

- Immediate actions are however necessary:
  - Old equipment → Reduce leakages (containment, certification …)
    Intermediate refrigerants
  - New equipment → Existing low-GWP refrigerants (IIR INs…)
- Safety issues
  New international standards on flammability must be implemented in building codes, practice (IIR WG)
- Training on low-GWP refrigerants due to safety issues + energy efficiency issues and maintenance (Real Alternatives for Life…)
- Coordination between policies: renewable energies (solar refrigeration…), energy efficiency (Labelling, Ecodesign…)

Conclusion

- Growing refrigeration needs: air conditioning, cold chain for food and health products (vaccines…), heat pumps
  Refrigeration can be a tool for mitigating and adaptating to global warming
- International awareness: in 2019, United Nations declarations.
  Partnership with UNEP, ISA…
- Until now, actions were essentially focused on refrigerants. The energy issue is now at the top of the agenda: moving to a low-GWP refrigerant without a better energy efficiency, a new design… is not enough.
- The new challenges: including the refrigeration issue in the new NDCs to be presented in Glasgow.

  + helping developing countries to move.
